(Communicated by Camil Muscalu)

Abstract. We prove Strichartz estimates found after adding regularity in the spherical coordinates for Schrödinger-like equations. The obtained estimates are sharp up to endpoints. The proof relies on estimates involving spherical averages, which were obtained in [5]. We discuss sharpness making use of a modified Knapp-type example.

1. Introduction. Since we consider homogeneous estimates, we shall confine ourselves to homogeneous equations:

\[
\begin{cases}
i \partial_t u(t,x) + \varphi(D) u(t,x) = 0, & (t, x) \in \mathbb{R} \times \mathbb{R}^n, \\
u(0, \cdot) = u_0.
\end{cases}
\]

In the following we will deal with Schrödinger-like equations for most of the time, that is the dispersion relation \( \varphi \in C^\infty((0, \infty), \mathbb{R}) \) is given by

\[
\varphi(\rho) = \rho^a, \quad a > 1.
\]

Strichartz estimates capture the dispersive properties of solutions to linear dispersive equations and classical homogeneous estimates for (1) in the case of (2) state as follows

\[
\|u\|_{L^q_t L^p_x(\mathbb{R}^n)} \lesssim a, n, p, q \|u_0\|_{\dot{H}^s},
\]

where the derivatives are determined by scaling

\[
s = n \left( \frac{1}{2} - \frac{1}{p} \right) - \frac{a}{q}.
\]

Keel and Tao proved the sharp range of homogeneous estimates in [8], which is given by

\[
\frac{1}{q} \leq n \left( \frac{1}{2} - \frac{1}{p} \right), \quad q, p \geq 2, \quad p \neq \infty.
\]

Making use of the bilinear interpolation argument worked out in [8], Cho, Ozawa and Xia showed homogeneous estimates for more general dispersion relations in [3, Theorem 2, p. 1123].

Sharpness of (5) is seen considering a Knapp-type example, that is a maximally anisotropic propagating wave. This example was already considered by Strichartz...
in his seminal paper [10, Lemma 3., p. 707], in which he linked special cases of
estimates of the kind (3) to Fourier restriction estimates through duality. We review
a modified example in Proposition 1.2.

This raised the question, whether one can extend the classical range of inte-
grability coefficients, which was found in [8] and [3] if one penalizes anisotropic
propagation by considering angular regularity of the initial data. More precisely,
for equations (1) in the case of (2) we want to consider estimates of the kind:

\[
\|u\|_{L^q_t L^p_x} \lesssim_{a,n,p,q,\alpha} \|u_0\|_{\dot{H}^{s,\alpha}_x}, \tag{6}
\]

where the Sobolev spaces \(\dot{H}^{s,\alpha}_{x} = D^{-s} \Lambda^{-\alpha} L^2(\mathbb{R}^n)\) with angular regularity \(\alpha\) are
defined making use of the inhomogeneous Laplace-Beltrami operator
\(\Lambda_{\omega} = (1 - \Delta_{\omega})^{1/2}\), when \(\Delta_{\omega} = \sum_{1 \leq i < j \leq n} \Omega_{ij}^2, \ \Omega_{ij} = x_i \partial_j - x_j \partial_i\).

Estimate (6) was discussed by Fang and Wang in [4] and Jiang et al. in [7], where
the estimates were also linked to further generalizations of Strichartz estimates for
instance via radial weights. The special case of spherically symmetric initial data
was considered by Guo and Wang in [6].

The following result due to Cho and Lee strengthened the previous ones:

**Theorem 1.1** ([2, Theorem 1.2., p. 994]). Let \(n \geq 2\) and suppose that \((q,p)\) satisfies

\[
\frac{n}{2} \left(\frac{1}{2} - \frac{1}{p}\right) < \frac{1}{q} \leq \frac{2n - 1}{2} \left(\frac{1}{2} - \frac{1}{p}\right), \ q,p \geq 2, \tag{7}
\]

\((n,q,p) \neq (2,2,\infty)\) and \((q,p) \neq (2,(4n - 2)/(2n - 3))\).

Then we find the estimate (6) to hold for the solution \(u\) to (1) with \(s\) from (4)
provided that \(\alpha > ((2n - 1)/(2n - 2))(2/q + n/p - n/2)\).

Sharpness of the \((q,p)\)-range (also for more general dispersion relations) up to
endpoints was also seen in [2, Section 4.1., pp. 1005f].

Probing the angular regularity with a Knapp-type example we find also for the
more general dispersion relations that an angular regularity \(\alpha = \frac{2}{q} + \frac{n}{p} - \frac{n}{2}\)
is necessary:

**Proposition 1.2.** Suppose that \(n \geq 2\) and \((q,p)\) satisfies (7). Then we find that
\(\alpha \geq \frac{2}{q} + \frac{n}{p} - \frac{n}{2}\) is necessary for estimate (6) to hold.

Making use of a result due to Guo from [5] we prove the following result establish-
ing estimates of the kind (6) for Schrödinger-like equations with sharp angular
regularity up to endpoints:

**Theorem 1.3.** Let \(q,p \geq 2\), suppose that we are in the case of (2) and

\[
\frac{n}{2} \left(\frac{1}{2} - \frac{1}{p}\right) < \frac{1}{q} \leq \frac{2n - 1}{2} \left(\frac{1}{2} - \frac{1}{p}\right) \ \text{for} \ n = 2,
\]

\[
\frac{n}{2} \left(\frac{1}{2} - \frac{1}{p}\right) < \frac{1}{q} \leq \frac{2n - 1}{2} \left(\frac{1}{2} - \frac{1}{p}\right), \ (q,p) \neq \left(\frac{2}{4n - 2}, \frac{2n - 3}{2n - 3}\right) \ \text{for} \ n > 2.
\]

Then, for \(n = 2\) or \(n > 2\) and \(q = 2\), we find the estimate (6) to hold for \(\alpha > \frac{2}{q} + \frac{n}{p} - \frac{n}{2}\) and for \(n > 2\) we find the estimate (6) to hold for \(\alpha = \frac{2}{q} + \frac{n}{p} - \frac{n}{2}\),
whenever \(q \neq 2\).
2. Proof of Proposition 1.2 and Theorem 1.3. First, we show the necessary angular regularity:

Proof of Proposition 1.2. To simplify the concrete computation let us consider the special case of Schrödinger’s equation, that is \( \varphi(\rho) = \rho^2 \) in (1). Later on, we shall see that the example allows broader application.

As initial datum we consider a small rectangular block in frequency space

\[
\hat{u}_0(\xi) = \chi_{(1-\varepsilon,1+\varepsilon)}(\xi_1)\chi_{(-\varepsilon,\varepsilon)}(\xi_2) \cdots \chi_{(-\varepsilon,\varepsilon)}(\xi_n). \tag{8}
\]

For the solution to (1) we obtain

\[
u(t,x) = C_n \int_{-\varepsilon}^{1+\varepsilon} e^{ix_1 \xi_1 t} d\xi_1 \int_{-\varepsilon}^{\varepsilon} e^{i(x_2 - t) \xi_2} d\xi_2 \cdots \int_{-\varepsilon}^{\varepsilon} e^{i(x_n - t) \xi_n} d\xi_n.
\]

We perform a change of variables \( \tilde{\xi}_1 = \xi_1 - 1 \) and the first integral becomes

\[
\int_{-\varepsilon}^{\varepsilon} d\tilde{\xi}_1 e^{ix_1 (1+\tilde{\xi}_1 - it)} = e^{ix_1 e^{-it}} \int_{-\varepsilon}^{\varepsilon} d\tilde{\xi}_1 e^{i(x_1 - 2t) \tilde{\xi}_1} e^{-it \tilde{\xi}_1^2}.
\]

Observe that the phase nearly vanishes in the domain of integration, if \( |x_1 - 2t| \ll 1/\varepsilon, |x_i| \ll 1/\varepsilon (i \neq 2, \ldots, n) \), \( |t| \ll 1/\varepsilon^2 \) and therefore we have

\[
|u(t,x)| \gtrsim \varepsilon^n \text{ for } |x_1 - 2t| \ll 1/\varepsilon, |x_i| \ll 1/\varepsilon (i = 2, \ldots, n), |t| \ll 1/\varepsilon^2 \tag{9}
\]

and we obtain the estimate

\[\|u\|_{L^p_t L^q_x} \gtrsim \varepsilon^{n-p-q/2}.
\]

Observe that smoothing out the sharp transitions does not change the behaviour found above. For the following part, we consider the sharp borders to be mollified on a scale of \( \varepsilon/10 \). The mollified variations will be denoted by \( \tilde{\chi} \). We denote the non-negative derivative of the transition region centered at the origin by \( \psi_\varepsilon(x) \), which is symmetric and satisfies \( \psi_\varepsilon(0) \sim 1 \), \( \text{supp}(\psi_\varepsilon) \subseteq (-\varepsilon/10, \varepsilon/10) \), \( \int \psi_\varepsilon = 1 \); the family \( \{\psi_\varepsilon\} \) is in fact an approximate identity.

To estimate the Sobolev norm of the initial data with incorporated angular regularity, we note that we can equivalently consider the Fourier transform of the initial data and that the norm of the radial part of the initial datum is estimated by \( \|\hat{u}_0^{rad}\|_{L^2} \sim \varepsilon^{n-1/2} \) because the radial part is roughly supported in \( r = (1-\varepsilon,1+\varepsilon) \) with a norm of order \( \varepsilon^{n-1} \), which comes from intersecting the approximate block with spheres, when the intersection is approximately a square of sidelength \( \varepsilon \) due to \( \varepsilon \) very small. We still have to compute \( \|(-\Delta_\omega)^{1/2}\hat{u}_0\|_{L^2}^2 = \sum_{1 \leq i<j \leq n} \|\Omega_{ij}\hat{u}_0\|_{L^2}^2 \).

Let us take a look at the concrete pair \( i = 1, j = 2 \), the other cases can be handled similarly. For this computation we will not keep track of the variables which remain untouched by the concrete vector field.

\[
\Omega_{12} \tilde{\chi}_{(1-\varepsilon,1+\varepsilon)}(x_1) \tilde{\chi}_{(-\varepsilon,\varepsilon)}(x_2)
\]

\[
= x_1 \chi_{(1-\varepsilon,1+\varepsilon)}(x_1) (\psi_\varepsilon(x_2 + \varepsilon) - \psi_\varepsilon(x_2 - \varepsilon))
\]

\[
- \left( \psi_\varepsilon(x_1 - (1 + \varepsilon)) - \psi_\varepsilon(x_1 - (1 + \varepsilon)) \right) x_2 \tilde{\chi}_{(-\varepsilon,\varepsilon)}(x_2)
\]

Taking the square we find three terms: For the first one, we have

\[
x_1^2 \tilde{\chi}_{(1-\varepsilon,1+\varepsilon)}(x_1) \left( \psi_\varepsilon^2(x_2 + \varepsilon) + \psi_\varepsilon^2(x_2 - \varepsilon) \right).
\]

Observe that this is the term of leading order after integration, which gives a quantity \( \sim \varepsilon^{n-2} \). The other contributions are of order \( \sim \varepsilon^{n-1} \).

---

1This region is determined by the uncertainty principle \( (\Delta x)(\Delta p) \gtrsim 1 \) and by the group velocity \( \varphi'(1) \), where \( \varphi \) denotes the dispersion relation.
Likewise we find that the contribution from the other vector fields of the kind \( \Omega_{1j} \) is also of order \( \sim \varepsilon^{-1} \), contributions from vector fields of the kind \( \Omega_{ij} \), \( 1 \neq i < j \) are of higher order. We find the asymptotic
\[
\varepsilon^{n-n/p-2/q} \lesssim \varepsilon^{n/2-1}
\]
to hold for any \((q,p)\) radially admissible as \( \varepsilon \to 0 \). But, we find that after adding angular regularity of \( \alpha < 1 \) we obtain \( \|u_0\|_{H^{\alpha,o}} \lesssim \varepsilon^{n/2-\alpha} \) by means of interpolation and we find as a necessary condition
\[
\varepsilon^{n-n/p-2/q} \lesssim \varepsilon^{n/2-\alpha},
\]
which gives as \( \varepsilon \to 0 \) that \( \alpha \geq \frac{n}{p} + \frac{2}{q} - \frac{n}{2} \).

Closely linked to estimates of the kind (6) are estimates involving spherical averages, that is we consider the following norms:
\[
\|u\|_{L^q_t L^p_r \omega} = \left( \int_{\mathbb{R}} dt \left( \int_0^\infty dr r^{n-1} \left( \int_{S^{n-1}} d\omega |u(t,r,\omega)|^2 \right)^{p/2} \right)^{q/p} \right)^{1/q}
\]
The link is established through Sobolev embedding on the sphere
\[
\|f\|_{L^q_\omega} \lesssim_{n,q,\alpha} \|\Lambda^\alpha_\omega f\|_{L^q_\omega} \quad (q < \infty, \frac{1}{q} \geq \frac{1}{2} - \frac{\alpha}{n-1})
\]
and for Schrödinger-like equations Guo showed that those estimates hold in essentially the same range as the estimates found after requiring additional angular regularity:

**Theorem 2.1** ([5, Theorem 1.1, p. 1670]). Let \( a > 1, q, p \geq 2 \) and suppose that
\[
\frac{n}{2} \left( \frac{1}{2} - \frac{1}{p} \right) < \frac{1}{q} \leq \frac{2n-1}{2} \left( \frac{1}{2} - \frac{1}{p} \right) \quad \text{for } n = 2,
\]
\[
\frac{n}{2} \left( \frac{1}{2} - \frac{1}{p} \right) < \frac{1}{q} \leq \frac{2n-1}{2} \left( \frac{1}{2} - \frac{1}{p} \right), \quad (q,p) \neq \left( \frac{2}{2}, \frac{4n-2}{2n-3} \right) \quad \text{for } n > 2.
\]
Then we find the estimate
\[
\left\| P_N e^{itD^a} u_0 \right\|_{L^q_t L^p_r \omega} \lesssim_{a,n,p,q} N^n \|u_0\|_{L^2}
\]
to hold for any \( N \in 2^\mathbb{Z} \) with \( s = \frac{n}{2} - \frac{n}{p} - \frac{a}{q} \).

Theorem 1.3 is a consequence:

**Proof of Theorem 1.3.** For \((q,p)\) admissible for Theorem 2.1 we find provided that \( \alpha = (n-1) \left( \frac{1}{2} - \frac{1}{p} \right) \)
\[
\|P_N u\|_{L^q_t L^p_r} \lesssim_{n,p} \|\Lambda^\alpha N P_N u\|_{L^q_t L^p_r} \lesssim_{a,n,p} N^n \|\Lambda^\alpha P_N u_0\|_{L^2}
\]
Taking \( p \) to the sharp line, we find for \( q > 2 \)
\[
\alpha = (n-1) \left( \frac{1}{2} - \frac{1}{p} \right) = \frac{2}{q} + \frac{n}{p} - \frac{n}{2}.
\]
For \( q = 2 \) we only find
\[
\alpha > \frac{2}{q} + \frac{n}{p} - \frac{n}{2} \quad \text{as } p \to \frac{4n-2}{2n-3}.
\]
The frequency localization is removed employing Littlewood-Paley theory and the proof is concluded interpolating with the estimates on the classical sharp line. \( \square \)
3. **Remarks.** The special case of the wave equation, which corresponds to \( a = 1 \) in (1), had been treated in [2, 9] and the results holding the analogs of the estimates we discussed above are sharp up to endpoints. In [1, Corollary 1.5., p. 803] the endpoint angular regularity was obtained for \( q \geq p \).

From the weakened dispersion the classical estimates, which were already found in [8], are only valid in the range

\[
\frac{1}{q} \leq \frac{n-1}{2} \left( \frac{1}{2} - \frac{1}{p} \right), \quad q, p \geq 2, \quad p \neq \infty,
\]

whereat the estimates found after taking spherical averages or adding angular regularity are valid in the range

\[
\frac{n-1}{2} \left( \frac{1}{2} - \frac{1}{p} \right) < \frac{1}{q} < (n-1) \left( \frac{1}{2} - \frac{1}{p} \right), \quad q, p \geq 2, \quad p \neq \infty.
\]

Sharpness is again found employing Knapp-type examples (cf. [9, pp. 190, 195]). In [9] was also considered additional angular regularity.

Furthermore, we note that Proposition 1.2 also provides a Knapp-type example for far more general dispersion relations than those associated to Schrödinger-like equations, for which Cho and Lee proved estimates of the kind (6) in the same range as in Theorem 1.1 provided that \( \alpha > \frac{5n-1}{5n-5} \left( \frac{n}{q} + \frac{p}{n} - \frac{n}{2} \right) \) (cf. [2, Theorem 1.1., p. 993]).

The example given in Proposition 1.2 leads us to conjecture that even for more general dispersion relations the sharp angular regularity is \( \alpha = \frac{n}{q} + \frac{p}{n} - \frac{n}{2} \).
