Abstract

We study double-spin asymmetries in Drell-Yan processes in which one initial hadron is transversely polarized and another one is longitudinally polarized. The complete part of the hadronic tensor relevant to asymmetries is derived. This part consists of twist-2 and twist-3 parton distributions and is gauge invariant. We construct some observables which can be used to extract these parton distributions from experimental measurements.

1. INTRODUCTION

Predictions about high energy scattering of hadrons of large momentum transfers can be made with QCD factorizations. At the leading power of the inverse of large momentum transfers, cross sections can be predicted with collinear twist-2 parton distributions convoluted with perturbative coefficient functions. These parton distributions contain information about inner structures of hadrons and are nonperturbative. Currently, the twist-2 parton distributions are well known and used to make predictions of various processes.

Beyond the leading power, the contributions to cross sections are factorized with twist-3 or higher twist parton distributions. Although they are power suppressed, but with the progress of the experiment it is now possible to measure them. An example is of single transverse-spin asymmetries, which have been observed in early experiments in\cite{1,2}. Such asymmetries are factorized with twist-3 parton distributions as pointed out in\cite{3,4}. The importance for studying and measuring twist-3 parton distributions is that they contain information about hadron’s inner structure more than twist-2 parton distributions.

In this work, we study with QCD collinear factorization double-spin asymmetries in Drell-Yan processes where one initial hadron is transversely polarized and another is longitudinally polarized. These double-spin asymmetries at the leading power can be factorized with collinear twist-3 parton distributions. Measurements of these asymmetries will help to learn twist-3 parton distributions. The double-spin asymmetries in Drell-Yan processes have been studied in\cite{5,6,7} at leading order of $\alpha_s$. At the order, the transverse momentum $q_\perp$ of the lepton pair is small, or approximately zero, and because of that there is no hard parton radiation. One may expect that the relevant part of the hadronic tensor is proportional to $\delta^2(q_\perp)$. This is true for the twist-2 part. However, at twist-3 the hadronic tensor contains not only a part with $\delta^2(q_\perp)$, but also a part with the derivative of $\delta^2(q_\perp)$, as shown in\cite{8,9}. Each part alone is not electromagnetic gauge invariant. Only the sum of the two parts is gauge invariant. In this work, we will derive the complete part of the hadronic tensor for the double-spin asymmetries. With our result more double-spin asymmetries can be predicted with twist-3 parton distributions.
At the next-to-leading order of $\alpha_s$, the transverse momentum can be large. The contribution from the next-to-leading order is the one-loop correction to the tree-level results of the proposed observables here. It is noted that the correction can contain collinear divergences. It is expected that such collinear divergences can be factorized into various parton distributions, as shown in an explicit calculation of one-loop correction to single transverse-spin asymmetries at twist-3 of Drell-Yan processes in [10].

Our work is organized as the following: In Sect.II we introduce our notations and definitions of collinear twist-3 parton distributions. Relations among these distributions are discussed. In Sect.III we derive the hadronic tensor for double-spin asymmetries, where we explain in detail how the contribution with the derivative of $\delta^2(q_\perp)$ arises. In Sect.IV we construct observables of double-spin asymmetries. Sect.V is our summary.

2. NOTATIONS AND PARTON DISTRIBUTIONS

We consider the Drell-Yan processes:

$$h_A(P_A, s_\perp) + h_B(P_B, \lambda_B) \to \gamma^*(q) + X \to \ell^-(k_1) + \ell^+(k_2) + X,$$

where $h_{A,B}$ is a spin-1/2 hadron. To study the process it is convenient to use the light-cone coordinate system, in which a vector $a^\mu$ is expressed as $a^\mu = (a^+, a^-, a_\perp) = ((a^0 + a^3)/\sqrt{2}, (a^0 - a^3)/\sqrt{2}, a^1, a^2)$ and $a_\perp^2 = (a^1)^2 + (a^2)^2$. In this system we introduce two light-cone vectors $l^\mu = (1, 0, 0, 0)$ and $n^\mu = (0, 1, 0, 0)$. With the two vectors one can define the metric $g_{\perp}^{\mu\nu}$ and the totally antisymmetric tensor $\epsilon_{\perp}^{\mu\nu}$ in the transverse space,

$$g_{\perp}^{\mu\nu} = g^{\mu\nu} - n^\mu l^\nu - n^\nu l^\mu, \quad \epsilon_{\perp}^{\mu\nu} = \epsilon^{\alpha\beta\mu\nu} l_\alpha n_\beta, \quad \epsilon_{\perp}^{12} = -\epsilon_{\perp}^{21} = 1.$$  

We take a frame in which the momenta of hadrons are given by

$$P_A^\mu \approx (P_A^+, 0, 0, 0), \quad P_B^\mu \approx (0, P_B^-, 0, 0).$$

We consider the case that $h_A$ is transversely polarized with the spin vector $s_A^\mu = (0, 0, s_A^\perp, s_A^3)$, and $h_B$ is longitudinally polarized with the helicity $\lambda = \pm 1$. The hadronic tensor $W^{\mu\nu}$ for the process is defined as

$$W^{\mu\nu} = \sum_X \int \frac{d^4x}{(2\pi)^4} e^{iq\cdot x} \langle h_A, h_B|\bar{\psi}(0)\gamma^\nu\psi(0)|X\rangle \langle X|\bar{\psi}(x)\gamma^\mu\psi(x)|h_B, h_A\rangle,$$

where $q$ is the momentum of the lepton pair. Its invariant mass is $q^2 = Q^2$.

The hadronic tensor contains all information about the strong interaction in the process. From the tensor one can obtain the differential cross section,

$$\frac{d\sigma}{dQ^2d\Omega} = \sum_q \frac{(4\pi\alpha e_q)^2}{64\pi^2 S Q^4} \int d^4q q^\mu q^\nu L_{\mu\nu} W^{\mu\nu},$$

where $\Omega$ is the solid angle of the lepton in a chosen frame. A commonly used one is the Collins-Soper frame. Note that $e_q$ is the charge fraction of the quark in unit of $e$. The sum is over flavors of quarks. Besides the differential cross section or angular distribution, one can introduce the so-called weighted cross section,

$$\frac{d\sigma(F)}{dQ^2d\Omega} = \sum_q \frac{(4\pi\alpha e_q)^2}{64\pi^2 S Q^4} \int d^4q q^\mu q^\nu L_{\mu\nu} W^{\mu\nu} F,$$
i.e., the event distribution is reweighted by a weight factor $F$, which can be dependent on lepton momenta and $q_\perp$. Taking $F = 1$, one obtains the standard differential cross section as given in Eq. (5). In this work we will consider weights which are proportional to $q_\perp$. It is noted that the transverse momentum $q_\perp$ is integrated in Eq. (6).

In the case that only one initial hadron is transversely polarized, the hadronic tensor relevant to these asymmetries can be factorized with twist-3 parton distributions. For the hadronic tensor can be factorized in QCD collinear factorization. At the leading power of the inverse of $Q$, the parton distributions with perturbative coefficient functions. At this order, the asymmetries appearing, in the case that only one initial hadron is transversely polarized, are zero. At the next-to-leading power, the discussed double-spin asymmetries and single transverse-spin asymmetries become nonzero. The part of the hadronic tensor relevant to these asymmetries can be factorized with twist-3 parton distributions. For our purpose, we discuss in the below the definitions and relations of relevant twist-3 parton distributions.

Since we work at the leading order of $\alpha_s$, the relevant parton distributions involve quark fields. From the quark density matrix, we can define twist-2 and twist-3 quark distributions of a hadron with the momenta $P^\mu \approx (P^+, 0, 0, 0)$ as follows:

$$
\int \frac{d\lambda}{2\pi} e^{-i\lambda x P^+} \langle h | (\bar{\psi}(y)\mathcal{L}_n(y))_\beta \left( \mathcal{L}_4^\dagger(0)\psi(0) \right)_\alpha | h \rangle = \frac{1}{2} \left[ q(x)\gamma^- + \lambda\Delta q(x)\gamma^- \right] + \frac{1}{2} \left[ e(x) + q_T(x)\gamma^- \cdot s_\perp + \frac{1}{2} \lambda h_L(x) i\sigma_\perp \gamma_5 \right] + \cdots, \quad (7)
$$

where $\alpha$ and $\beta$ are Dirac indices. Terms beyond twist-3 are denoted with \cdots. They are irrelevant here. Note that $\mathcal{L}_n(x)$ is the gauge link defined as

$$
\mathcal{L}_\alpha(x) = P \exp \left\{ -ig_s \int_{-\infty}^{0} d\lambda n \cdot G(\lambda n + x) \right\}. \quad (8)
$$

In Eq. (7) $\lambda$ is the helicity of the hadron. The transverse spin is given by the vector $s_\perp^\mu$. In the above, $q(x)$ or $\Delta q(x)$ is the unpolarized or longitudinally polarized quark distribution, respectively. Note that $h_1(x)$ is the transversity distribution. These distributions are of twist-2. The remaining three distributions are of twist-3.

Besides the twist-3 quark distributions given in the above, there are other twist-3 parton distributions, which can be defined by sandwiching the operator of the gluon field strength tensor, covariant derivative, or derivative in the quark density matrix in Eq. (7). We introduce three types of twist-3 matrix elements as in the following:

$$
\begin{align*}
\mathcal{M}_{F,\alpha\beta}^\mu(x_1, x_2) & = g_s \int \frac{d\lambda_1 d\lambda_2}{2\pi} e^{-i\lambda_1 x_1 P^+ - i\lambda_2 (x_2 - x_1) P^+} \langle h | \bar{\psi}_\beta(\lambda_1 n) G^\mu(\lambda_2 n) \psi_\alpha(0) | h \rangle, \\
\mathcal{M}_{D,\alpha\beta}^\mu(x_1, x_2) & = P^+ \int \frac{d\lambda_1 d\lambda_2}{2\pi} e^{-i\lambda_1 x_1 P^+ - i\lambda_2 (x_2 - x_1) P^+} \langle h | \bar{\psi}_\beta(\lambda_1 n) D^\mu_\perp(\lambda_2 n) \psi_\alpha(0) | h \rangle, \\
\mathcal{M}_\partial^{\alpha\beta}(x) & = \int \frac{d\lambda}{2\pi} e^{-i\lambda x P^+} \langle h | \bar{\psi}_\beta(\lambda n) \partial_\perp^{\alpha\beta}(0) | h \rangle, \quad (9)
\end{align*}
$$

where $D^\mu(x)$ is the covariant derivative $D^\mu(x) = \partial^\mu + ig_s G^\mu(x)$. In the above, we have suppressed gauge links built with that in Eq. (8) between operators. The three types of twist-3 matrix elements are not independent. One can derive the relation among them as follows:

$$
\mathcal{M}_{D}^\mu(x_1, x_2) = \frac{1}{x_2 - x_1 - i\epsilon} \mathcal{M}_{F}^\mu(x_1, x_2) + 2\pi \delta(x_1 - x_2) \lambda \mathcal{M}_\partial^{\alpha\beta}(x_1). \quad (10)
$$
This relation is for matrix elements defined with the past-pointing gauge link in Eq. (8). In the case of future-pointing gauge links the relation becomes slightly different. We will come back to the difference later.

The introduced twist-3 matrix elements are parametrized with twist-3 parton distributions. With respect to symmetries, the parametrization is

\[
\begin{align*}
\mathcal{M}^\mu_F(x_1, x_2) &= \frac{1}{2} \left[ T_F(x_1, x_2) s\gamma_5 + T_\Delta(x_1, x_2) i s\gamma_5 \right] \gamma^\mu + \frac{1}{4} \left[ \lambda T_\Delta(x_1, x_2) i \gamma_5 \gamma_5 + \tilde{T}_F(x_1, x_2) i \gamma_5 \right] \gamma^\mu, \\
\mathcal{M}^\mu_D(x_1, x_2) &= \frac{1}{2} \left[ D_F(x_1, x_2) s\gamma_5 + D_\Delta(x_1, x_2) i s\gamma_5 \right] \gamma^\mu + \frac{1}{4} \left[ \lambda D_\Delta(x_1, x_2) i \gamma_5 \gamma_5 + \tilde{D}_F(x_1, x_2) i \gamma_5 \right] \gamma^\mu, \\
\mathcal{M}^\mu_0(x) &= \frac{1}{2} \left[ -i \gamma_5 \gamma_5 - s\gamma_5 q_0(x) - i \gamma_5 s\gamma_5 q_0(x) \right] + \frac{1}{4} \left[ -i \lambda \gamma_5 \gamma_5 \gamma_5 h_0(x) + \gamma_5 \gamma_5 \gamma_5 e_0(x) \right],
\end{align*}
\]

where \( s\gamma \) is given by \( s\gamma = \epsilon_{\gamma \gamma} s_{\gamma \gamma} \). From Hermiticity and symmetries of parity and time reversal, one can find the properties of twist-3 parton distributions in \( M^\mu_D,F \).

\[
\begin{align*}
T_F(x_1, x_2) &= T_F(x_2, x_1), & T_\Delta(x_1, x_2) &= -T_\Delta(x_2, x_1), & \tilde{T}_F(x_1, x_2) &= \tilde{T}_F(x_2, x_1), \\
\tilde{T}_\Delta(x_1, x_2) &= -\tilde{T}_\Delta(x_2, x_1), & D_F(x_1, x_2) &= -D_F(x_2, x_1), & D_\Delta(x_1, x_2) &= D_\Delta(x_2, x_1), \\
\tilde{D}_F(x_1, x_2) &= -\tilde{D}_F(x_2, x_1), & \tilde{D}_\Delta(x_1, x_2) &= \tilde{D}_\Delta(x_2, x_1).
\end{align*}
\]

From the relation in Eq. (10), we have the following relations between twist-3 parton distributions relevant to our work:

\[
\begin{align*}
D_\Delta(x_1, x_2) &= \left( P \frac{1}{x_2 - x_1} \right) T_\Delta(x_1, x_2) - 2\pi \delta(x_1 - x_2) q_0(x_1), \\
D_F(x_1, x_2) &= \left( P \frac{1}{x_2 - x_1} \right) T_F(x_1, x_2), & T_F(x, x) &= +2q_0(x), \\
\tilde{D}_\Delta(x_1, x_2) &= \left( P \frac{1}{x_2 - x_1} \right) \tilde{T}_\Delta(x_1, x_2) - 2\pi \delta(x_2 - x_1) h_0(x_1), \\
\tilde{D}_F(x_1, x_2) &= \left( P \frac{1}{x_2 - x_1} \right) \tilde{T}_F(x_1, x_2), & \tilde{T}_F(x, x) &= 2e_0(x),
\end{align*}
\]

where \( P \) stands for the principal-value prescription. As mentioned, these relations are of parton distributions defined with the past-pointing gauge link for Drell-Yan processes. For semi-inclusive deeply inelastic scatterings (SIDIS), one should use future-pointing gauge links to define parton distributions. With parity and time reversal symmetries one can show that the twist-2 parton distributions defined with past-pointing gauge links are the same defined with future-pointing gauge links. However, this is not the case for twist-3 parton distributions, especially for those defined with \( M^\mu_0 \) because of the transverse derivative acting on gauge links. Taking \( q_0' \) as an example, with parity and time reversal symmetries one can show that \( q_0' \), with the future-pointing gauge link, is \( -q_0' \) defined with the past-pointing gauge link. Therefore, the second relation in the second line of the above equation is for Drell-Yan processes. For the corresponding relation in SIDIS, the \( + \) should be changed into \( - \), as noticed in [9]. It is noted that without parity and time reversal symmetries one already can show that there is a nonzero difference between the two parton distributions defined with different gauge links, and the difference is proportional to \( T_F(x, x) \).

From equation of motion some relations between twist-3 parton distributions defined with quark-gluon correlators and those defined with quark density matrix can be derived. There are
the following relations between twist-3 parton distributions relevant to our work:

\[
\frac{1}{2\pi} \int dx_1 \left( P \frac{1}{x_2 - x_1} \right) \left[ T_F(x_1, x_2) - T_\Delta(x_1, x_2) \right] = x_2 q_T(x_2) - q_\theta(x_2),
\]

\[
\frac{1}{2\pi} \int dx_1 \left( P \frac{1}{x_2 - x_1} \right) \tilde{T}_\Delta(x_1, x_2) = \tilde{h}_\theta(x_2) - \frac{1}{2} x_2 h_L(x_2).
\]  

(14)

The process we study is effectively annihilation of quark and antiquark into a virtual photon. The antiquark distributions can be obtained from definitions of quark distributions through a charge-conjugation transformation of the operators in the definitions. We obtain the following relations between antiquark and quark distributions at twist-2:

\[
\bar{q}(x) = -q(-x), \quad \Delta\bar{q}(x) = \Delta q(-x), \quad \bar{h}_1(x) = -h_1(-x),
\]  

(15)

and the relations at twist-3,

\[
\bar{e}(x) = e(-x), \quad \bar{h}_L(x) = -h_L(-x), \quad \bar{q}_T(x) = q_T(-x)
\]

\[
\bar{e}_\theta(x) = e_\theta(-x), \quad \bar{h}_\theta(x) = h_\theta(-x), \quad \bar{q}_\theta(x) = q_\theta(-x), \quad \bar{q}_\theta(x) = -q_\theta(-x).
\]  

(16)

In the above, antiquark distributions are in the left-hand side of each equation. In our notation all twist-2 parton distributions are dimensionless. All twist-3 parton distributions have the dimension one in mass.

\begin{figure}[h]

\includegraphics[width=\textwidth]{fig1.png}
\caption{Tree-level diagrams for $W^{\mu\nu}$ of Drell-Yan processes. The black dots represent the insertion of the electromagnetic current.}
\end{figure}

3. THE DOUBLE-SPIN DEPENDENT PART OF THE HADRONIC TENSOR AND DOUBLE-SPIN ASYMMETRIES

At the leading order of $\alpha_s$, the contributions to $W^{\mu\nu}$ are from diagrams given by Fig.1. In these diagrams the upper and lower bubble represent jetlike Green functions related to the longitudinally polarized hadron $h_B$ in the initial state, and transversely polarized $h_A$, respectively. The middle part in the diagrams consist of explicit Feynman diagrams of parton scattering. In this work we use the Feynman gauge. Since the jet functions are jetlike, there are power counting for momenta of partons from $h_A$ or $h_B$, respectively. For example, in Fig.1(a) the momenta $k_A$ and $k_B$ scale like

\[
k_A^\mu \sim Q(1, \lambda^2, \lambda, \lambda), \quad k_B^\mu \sim Q(\lambda^2, 1, \lambda, \lambda),
\]  

(17)
and momenta of gluons scale similarly. The gluon field vectors also scale like the pattern of their momentum as in Eq. (17) in the gauge we work.

In collinear factorization one needs to expand the contributions from Fig. 1 in power of $\lambda$. We first consider diagrams in Fig.1(a). The contribution can be written in the form

$$W^{\mu\nu}(P_A, P_B, q) \bigg|_{1a} = \int d^4 k_A d^4 k_B \Gamma_{ji}(P_A, k_A) H^{\mu\nu}_{ij,kl}(k_A, k_B, q) \Gamma_{kl}(P_B, k_B),$$

where $\Gamma_{AB}$ are quark density matrices represented by the lower and upper bubble, respectively. They are given by

$$\Gamma_{ji}(P_A, k_A) = \int \frac{d^4 \xi}{(2\pi)^4} e^{-i \xi \cdot k_A} \langle h_A(P_A) | [\bar{q}(\xi)]_i | q(0) \rangle_j | h_A(P_A) \rangle,$$

$$\Gamma_{ij}(P_B, k_B) = \int \frac{d^4 \xi}{(2\pi)^4} e^{-i \xi \cdot k_B} \langle h_B(P_B) | [\bar{q}(\xi)]_i | q(0) \rangle_j | h_B(P_B) \rangle,$$

where $ij$ stand for Dirac and color indices. Note that $H^{\mu\nu}_{ij,kl}(k_A, k_B, q)$ is the middle part of Fig.1(a) which is given by

$$H^{\mu\nu}_{ij,kl}(k_A, k_B, q) = \delta^4(k_A + k_B - q) \left[ \gamma^\mu \right]_{lj} \left[ \gamma^\nu \right]_{ik}.$$

To find the contributions, we expand $H$ in $\lambda$,

$$H^{\mu\nu}_{ij,kl}(k_A, k_B, q) = \delta^4(\hat{k}_A + \hat{k}_B - q) \left[ \gamma^\mu \right]_{lj} \left[ \gamma^\nu \right]_{ik} - (k_A + k_B)_j^\mu \frac{\partial \delta^4(\hat{k}_A + \hat{k}_B - q)}{\partial q_i^\mu} \left[ \gamma^\mu \right]_{lj} \left[ \gamma^\nu \right]_{ik} + \mathcal{O}(\lambda^2),$$

with

$$\hat{k}_A = (k_A^+, 0, 0, 0), \quad \hat{k}_B = (0, k_B^-, 0, 0).$$

The terms of $\mathcal{O}(\lambda^2)$ will give contributions beyond twist-3 and can safely be neglected. With the expansion $W^{\mu\nu}$ from Fig.1(a) becomes:

$$W^{\mu\nu}(P_A, P_B, q) \bigg|_{1a} = \int dk_A^+ dk_B^- \left[ \gamma^\mu \right]_{lj} \left[ \gamma^\nu \right]_{ik} \int \frac{d^4 \xi}{(2\pi)^4} e^{-i \xi \cdot k_A} \int \frac{d^4 \xi}{(2\pi)^4} e^{-i \xi \cdot k_B} \left\{ \delta^4(\hat{k}_A + \hat{k}_B - q) \langle h_A(P_A) | [\bar{q}(\xi - n)]_i | q(0) \rangle_j | h_A(P_A) \rangle \langle h_B(P_B) | [\bar{q}(\xi + l)]_k | q(0) \rangle_l | h_B(P_B) \rangle \
+ i \frac{\partial \delta^4(\hat{k}_A + \hat{k}_B - q)}{\partial q_i^\mu} \left[ h_A(P_A) | [\partial_{\perp \rho} \bar{q}(\xi - n)]_i | q(0) \rangle_j | h_A(P_A) \rangle \langle h_B(P_B) | [\bar{q}(\xi + l)]_k | q(0) \rangle_l | h_B(P_B) \rangle + h_A(P_A) | [\bar{q}(\xi - n)]_i | q(0) \rangle_j | h_A(P_A) \rangle \langle h_B(P_B) | [\partial_{\perp \rho} q(\xi + l)]_k | q(0) \rangle_l | h_B(P_B) \rangle \right] \right\} + \cdots,$$
where $\lambda$ is the helicity of $h_B$ and $s_{\perp}^i$ is the transverse spin vector of $h_A$. $q^+$, and $q^-$ are given by

$$q^+ = xP_A^+, \quad q^- = yP_B^-.$$  \hspace{1cm} (25)

Here, and in the below, we always use the notation that parton distributions with the variable $x$ or $y$ are of $h_A$ or of $h_B$, respectively. It is noted that the above results are not exactly only from Fig.1(a) because of that the parton distributions contain gauge links. To find the contributions of gauge links, we need to consider diagrams of one gluon exchange as Fig.1(b) and Fig.1(c) and diagrams with exchanges of more gluons. We will call the gluons with the polarization index $-$ or $+$ as $G^-$ or $G^+$ gluons, respectively.

With the power counting discussed around Eq.(17), one easily finds that the leading contributions from the exchange of any number of $G^-$ gluons with the upper bubble or $G^+$ gluons with the lower bubble are at the same leading power of $\lambda$ as that of Fig.1(a). The summation of these contributions can be done with Ward identity in a standard way. The summation gives the contributions of gauge links in the parton distributions.

Figures 1(b) and 1(c) give the so-called three-parton contributions, where the exchanged gluon can be transversely polarized. In Fig.1(b) the twist-3 contribution involves twist-2 quark distribution and twist-3 parton distributions of $h_B$. The calculation is straightforward. It is found that the contribution from the transversely polarized gluon and $G^-$ gluon can be summed into the form which involves the field strength tensor operator $G^{-\mu}$. We obtain the contribution of Fig.1(b) and its complex conjugates as follows:

$$W_{1b+c.c.}^{\mu\nu} = \frac{\lambda_B}{2\pi N_c} \delta^2(q_L) \frac{1}{xP_A \cdot P_B} (P_B^{\mu} s_{\perp}^y + P_B^{\nu} s_{\perp}^x) h_1(x) \int \frac{dy_1}{y - y_1} T_\Delta(-y, -y_1).$$  \hspace{1cm} (26)

Similarly, we obtain the contribution from Fig.1(c) and its complex conjugates as follows:

$$W_{1c+c.c.}^{\mu\nu} = -\frac{\lambda_B}{2\pi N_c} \delta^2(q_L) \frac{1}{yP_A \cdot P_B} (P_A^{\mu} s_{\perp}^y + P_A^{\nu} s_{\perp}^x) \Delta \bar{q}(y) \int \frac{d\bar{x}_1}{\bar{x} - \bar{x}_1} (T_\Delta(x_1, x) - T_F(x_1, x)).$$  \hspace{1cm} (27)

Again, these contributions, in fact, contain contributions of diagrams with exchanges of more than one $G^+$ or $G^-$ gluon. These contributions can be summed into the form of gauge links in parton distributions as discussed after Eq.(25). It is interesting to note that the involved integrals of twist-3 parton distributions in the above can be expressed with two-parton distributions by using the relation in Eq.(14) and the relations between quark and antiquark distributions in Eqs. (15) and (16).

The results in Eqs. (24), (26), and (27) are the contributions for the partonic process, in which an initial quark or antiquark comes from $h_A$ or $h_B$, respectively. The complete hadronic tensor is the sum of the contributions in Eqs. (24), (26), and (27) and the contributions from the charge-conjugated partonic process. The sum is

$$W^{\mu\nu} = \frac{\delta^2(q_L)}{N_c P_A \cdot P_B} \left\{ \left( P_B^{\mu} s_{\perp}^y + P_B^{\nu} s_{\perp}^x \right) \left[ - q_T(x) \Delta \bar{q}(y) + \frac{1}{x} h_1(x)(\bar{h}_\partial(y) - \frac{1}{2} y \bar{h}_L(y)) \right] + \left( P_A^{\mu} s_{\perp}^y + P_A^{\nu} s_{\perp}^x \right) \left[ - \frac{1}{y} (q_\partial(x) - x q_T(x)) \Delta \bar{q}(y) + \frac{1}{2} h_1(x) \bar{h}_L(y) \right] \right\} + \frac{\partial \delta^2(q_L)}{\partial \bar{q}} \frac{\lambda}{N_c} \left\{ \left( g_{\perp}^{\mu x} s_{\perp}^y + g_{\perp}^{\nu y} s_{\perp}^x - g_{\perp}^{\mu y} s_{\perp}^x \right) \frac{1}{2} h_1(x)(\bar{h}_\partial(y) - \frac{1}{2} y \bar{h}_L(y)) \right\} + (q \leftrightarrow \bar{q}).$$  \hspace{1cm} (28)

where the notation $(q \leftrightarrow \bar{q})$ stands for the contribution of the charge-conjugated partonic process. It is obtained by replacing the combination $a(x)b(y)$ of parton distributions with $\bar{a}(x)b(y)$, where $a(x)$ or
$\bar{b}(y)$ is a parton distribution of $h_A$ or $h_B$, respectively. This result contains $\delta^2(q_\perp)$ and its derivative. Therefore, one should take the result as a distribution of $q_\perp$. The $U_{em}(1)$ gauge invariance should be then understood as

$$\int d^2q_\perp \delta \mathcal{F}(q_\perp) q_{\mu}W^{\mu\nu} = \int d^2q_\perp \mathcal{F}(q_\perp) q_{\mu}W^{\mu\nu} = 0,$$

where $\mathcal{F}(q_\perp)$ is a test function. Our result satisfies this equation and hence is gauge invariant. Because the hadronic tensor at the order of $\alpha_s$ is a distribution of $q_\perp$, in predictions of relevant physical observables, $q_\perp$ is integrated over. With this in mind, the introduced weight observable in Eq.(6) with $\mathcal{F} = 1$ will be determined by the part with $\delta^2(q_\perp)$ in $W^{\mu\nu}$, the observables with $\mathcal{F}$ proportional to $q_\perp$ will be determined by the part with the derivative of $\delta^2(q_\perp)$ in $W^{\mu\nu}$.

Before ending this section, it is worth discussing the physical meaning of terms with the derivative of $\delta^2(q_\perp)$ in the hadronic tensor. At the considered order $\alpha_s^0$, the quark and the antiquark, which annihilate into the virtual photon, are partons directly from initial hadrons. They have only intrinsic nonzero but small transverse momenta at order of $\Lambda_{QCD}$. The angular distribution can be derived by introducing four covariant vectors as coordinate vectors as

$$\frac{d\sigma}{dQ^2 d\Omega} = \lambda |s_\perp| \sum_q \frac{(4\pi\alpha)^2 e_q^2}{64\pi^2 N_c Q^3} \int dx dy \delta(x y S - Q^2) \left[ x W_1 - y W_2 \right] \sin(2\theta) \cos(\Delta\phi_{s\ell}),$$

where $\Delta\phi_{s\ell}$ is the difference $\phi - \phi_s$. Note that $W_{1,2}$ is given by the first line and second line of $W^{\mu\nu}$ in Eq.(23),

$$W_1 = -q_T(x) \Delta \bar{q}(y) + \frac{1}{x} h_1(x) \left[ \bar{h}_1(y) - \frac{1}{2} y \bar{h}_L(y) \right] + (q \leftrightarrow \bar{q}),$$

$$W_2 = -\frac{1}{y} \Delta \bar{q}(y) \left[ q_0(x) - x q_T(x) \right] + \frac{1}{2} \bar{h}_L(y) h_1(x) + (q \leftrightarrow \bar{q}).$$

4. PHYSICAL OBSERVABLES

In this section we consider experimental observables related to the polarizations of initial hadrons. We consider the angular distribution of the final lepton in the Collins-Soper frame[18]. In this frame the momentum $k_1$ of the lepton is

$$k_1^\mu = \frac{Q}{2} (1, \sin \theta \cos \phi, \sin \theta \sin \phi, \cos \theta),$$

where $\theta$ is the polar angle between the lepton momentum and $Z$ axis, which bisects the angle between directions of the two initial hadrons. Note that $\phi$ is the azimuthal angle between $k_\perp$ and $q_\perp$. It is noted that the transverse spin vector in the laboratory frame given in Sect.II is not exactly the same in the Collins-Soper frame. In the considered case of small $q_\perp$, the difference is at order of $q_\perp^2$, which can be safely ignored. We denote the azimuthal angle between $s_\perp$ and $q_\perp$ as $\phi_s$.

The angular distribution can be derived by introducing four covariant vectors as coordinate vectors as discussed in [19]. With our hadronic tensor, the contribution proportional to $\lambda |s_\perp|$ is obtained as follows:
This result is in agreement with that in [6]. The differential cross section given in Eq.(31) is determined by the nonderivative part of $W^{\mu\nu}$. To see the effect of the derivative part, one has to consider the weighted differential cross section introduced in Eq.(6). It is noted that in [6] the result of the hadronic tensor with collinear parton distributions is given where $q_\perp$ is integrated over. After the integration, only the nonderivative part remains, and the derivative part gives no contribution to the result. Therefore, with the result in [6] one cannot make predictions of weighted differential cross sections with weights involving $q_\perp$. We introduce two weights,

$$ F_1 = \frac{1}{Q} q_\perp \cdot s_\perp, \quad F_2 = \frac{1}{Q} q_\perp \cdot \bar{s}_\perp. $$

(33)

The corresponding weighted differential cross sections are:

$$ \frac{d\sigma(F_1)}{dQ^2 d\Omega} = -\lambda|s_\perp|^2 \sum_q \frac{(4\pi\alpha)^2 e_q^2}{64\pi^2 N_c Q^3} \int dx dy \delta(xyS - Q^2) \left[ D_1 (1 + \cos^2 \theta) - D_2 \sin^2 \theta \cos(2\Delta \phi_{st}) \right], $$

$$ \frac{d\sigma(F_2)}{dQ^2 d\Omega} = -\lambda|s_\perp|^2 \sum_q \frac{(4\pi\alpha)^2 e_q^2}{64\pi^2 N_c Q^3} \int dx dy \delta(xyS - Q^2) \left[ D_2 \sin^2 \theta \sin(2\Delta \phi_{st}) \right], $$

(34)

where $D_{1,2}$ are given by the derivative part of $W^{\mu\nu}$,

$$ D_1 = -\Delta \bar{q}(y)q\phi(x) - \Delta q(y)\bar{q}\phi(x), \quad D_2 = \frac{1}{2}(\bar{h}_\phi(y)h_1(x) + h_\phi(y)\bar{h}_1(x)). $$

(35)

From these spin-dependent differential cross sections, one can define various double-spin asymmetries by taking their differences between those with $\lambda = \pm 1$. It is interesting to note that only the differential cross section weighted with $F_1$ can be measured if the azimuthal angle or the solid angle is integrated. In this case we have only one observable remaining nonzero,

$$ \frac{d\sigma(F_1)}{dQ^2} = -\lambda|s_\perp|^2 \sum_q \frac{(4\pi\alpha)^2 e_q^2}{12\pi N_c Q^3} \int dx dy \delta(xyS - Q^2) D_1. $$

(36)

With this result, a simple asymmetry can be defined as

$$ A(F_1)_{LT} = \frac{\frac{d\sigma(F_1)}{dQ^2}(\lambda = 1, s_\perp) - \frac{d\sigma(F_1)}{dQ^2}(\lambda = -1, s_\perp)}{\frac{d\sigma(F_1)}{dQ^2}(\lambda = 1, s_\perp) + \frac{d\sigma(F_1)}{dQ^2}(\lambda = -1, s_\perp)} = \frac{1}{Q}|s_\perp|^2 \sum_q e_q^2 (\bar{q}\phi(x)\Delta q(y) + q\phi(x)\Delta \bar{q}(y))}{\sum_q e_q^2 (q(x)\bar{q}(y) + \bar{q}(x)q(y))}. $$

(37)

where $\sigma_0$ is the unpolarized cross section at the leading power. In the above $y$ is fixed as $Q^2/xS$. Similar asymmetries in angular distributions can also be constructed with the results here.

5. SUMMARY

We have made an analysis for double-spin asymmetries in Drell-Yan processes. The asymmetries arise at twist-3 level. The complete part of the hadronic tensor relevant to these asymmetries is derived. This twist-3 part contains not only a contribution of $\delta^2(q_\perp)$ as twist-2 parts do, but also a contribution proportional to the derivative of the $\delta$ function. Only the sum of the two contributions as a distribution of $q_\perp$ is gauge invariant. Based on our results, observables are constructed to identify the spin effects. From these observables one can build double-spin asymmetries, which can be used for extracting twist-3 parton distributions.
