The microphthalmia-associated transcription factor (Mitf) gene and its role in regulating eye function

Andrea García-Llorca1,2, Snaefridur Gudmundsdottir Aspelund3, Margret Helga Ogmundsdottir4, Eiríkur Steingrimsson4 & Thor Eysteinsson1,2*

Mutations in the microphthalmia-associated transcription factor (Mitf) gene can cause retinal pigment epithelium (RPE) and retinal dysfunction and degeneration. We examined retinal and RPE structure and function in 3 month old mice homo- or heterozygous or compound heterozygous for different Mitf mutations (Mitf<sup>+/vga9</sup>, Mitf<sup>+/enu22/339b</sup>, Mitf<sup>+/enu22/339b</sup>, Mitf<sup>+/-</sup> and Mitf<sup>+/-</sup>/Mitf<sup>+</sup>) which all have normal eye size with apparently normal eye pigmentation. Here we show that their vision and retinal structures are differentially affected. Hypopigmentation was evident in all the mutants while bright-field fundus images showed yellow spots with non-pigmented areas in the Mitf<sup>+/vga9</sup> mice. Mitf<sup>+/</sup> and Mitf<sup>+/vga9</sup>/Mitf<sup>+</sup> mice showed large non-pigmented areas. Fluorescent angiography (FA) of all mutants except Mitf<sup>+/vga9</sup> mice showed hyperfluorescent areas, whereas FA from both Mitf<sup>+/-</sup>/Mitf<sup>+</sup> and Mitf<sup>+/vga9</sup>/Mitf<sup>+</sup> mice showed reduced capillary network as well as hyperfluorescent areas. Electroretinogram (ERG) recordings show that Mitf<sup>+/vga9</sup> and Mitf<sup>+/enu22/339b</sup>/Mitf<sup>+</sup> mice are severely impaired functionally whereas the scotopic and photopic ERG responses of Mitf<sup>+/vga9</sup> and Mitf<sup>+/enu22/339b</sup>/Mitf<sup>+</sup> mice were not significantly different from wild type mice. Histological sections demonstrated that the outer retinal layers were absent from the Mitf<sup>+/vga9</sup> mice. Our results show that Mitf mutations affect eye function, even in the heterozygous condition and that the alleles studied can be arranged in an allelic series in this respect.

One of the major causes of visual impairment and blindness in humans are retinal degenerations. These are either due to inheritance of mutations in genes known to cause defects in the retina or the retinal pigment epithelium (RPE)1–5. Animal models with either inherited or induced degeneration are of proven value to understand the molecular basis of such degenerations and to assess the functional state of degenerating retina5–9. Many of the mutations known to cause retinal degeneration can be traced to retinal structural proteins and to proteins involved in phototransduction9. Other mutations causing retinal degenerations are related to dysfunctional proteins expressed in retinal neurons, the photoreceptors9,10, or RPE cells4,6,11. The most common mutations leading to retinal degenerations have been found in genes expressed in photoreceptors, while known mutations in genes specifically expressed in the RPE are fewer11. Hence, mouse models of retinal degenerations involving mutations in genes expressed specifically in the RPE are of interest, since they can shed light on the role that RPE dysfunction by itself play in such degenerations1. Mutations in RPE-specific genes known to cause retinal degenerations in humans include RPE65 (which is also expressed in red/green cones in humans12), LRAT, and MERTK; mouse models are available for investigating all of them6,11,13,14.

Several transcription factors have an important role in determining the eye phenotype. The most studied of these transcription factors, are the homeodomain transcription factors Crx15 and Otx216–20, the retina-specific basic motif-leucine zipper (bZIP) transcription factor NRL21,22, and the microphthalmia-associated transcription factor family Mitf-Tf23,15,18,23. Mutations in these transcription factors can lead to retinal degeneration. Nrl controls the expression of rod genes24, and at least 20 of these target genes are associated with human retinal dystrophies; the Nrl-KO mouse has no rods and no expression of rod-specific genes25. The MITF protein is a member of the MYC supergene family of basic-helix-loop-helix-leucine-zipper (bHLHZip) transcription factors

and is known to regulate the expression of cell specific target genes by binding DNA as a homodimer or as heterodimer with related proteins. The MITF transcription factor is composed of a basic DNA binding domain, and helix-loop-helix and zipper regions, both important for dimerization. The expression of these transcription factors in the eye differs, with the CRX and NRL genes expressed in photoreceptors, whereas different isoforms of MITF are expressed preferentially or exclusively at birth in the retinal pigment epithelium (RPE). OTX2 is expressed in both the RPE, bipolar cells and photoreceptors, although a limited number of mutant alleles have been examined. Mutations in other genes expressed solely in the RPE, such as LRAT and MERTK, have been identified in patients with early-onset retinal degeneration, and mutations in the gene can lead to severe retinal degenerations affecting both rods and cones. However, available mouse models of retinal degeneration or dysfunction caused by known mutations in RPE-specific genes are relatively few, compared to those caused by mutations in photoreceptor genes.

In mice, there are over 30 distinct alleles in the Mitf gene that have different phenotypic effects, and these can be arranged in allelic series according to their phenotypic severity, from normal to microphthalmia, osteopetrosis, early onset of deafness, a failure of secondary bone resorption and loss of pigmentation. In humans, MITF mutations have been found in patients with the pigmentaion and deafness disorders Waardenburg (OMIM # 193510) and Tietz (OMIM # 103500), syndromes and recently, they have been associated with microphthalmia and osteopetrosis. Mutations of these genes have the same effect. Interestingly, the RPE65 gene is expressed in both mouse and human RPE and subpopulations of cone photoreceptors, and mutations in the gene can lead to severe retinal degenerations affecting both rods and cones. However, available mouse models of retinal degeneration or dysfunction caused by known mutations in RPE-specific genes are relatively few, compared to those caused by mutations in photoreceptor genes.

In mice, there are over 30 distinct alleles in the Mitf gene that have different phenotypic effects, and these can be arranged in allelic series according to their phenotypic severity, from normal to microphthalmic animals with osteopetrosis. Common to all the Mitf mouse mutations are defective neural-crest-derived melanocytes, resulting in a reduction or lack of pigmentation in the coat, inner ear and eye. Mitf mutant mice may have defects in some or all of the various tissues listed above, for instance, reduced eye size or microphthalmia, early onset of deafness, a failure of secondary bone resorption and loss of pigmentation. In humans, MITF mutations have been found in patients with the pigmentaion and deafness disorders Waardenburg (OMIM # 193510) and Tietz (OMIM # 103500), syndromes and recently, they have been associated with microphthalmia and osteopetrosis. Mutations affect both kinds of pigment cells in the eye, the neural-crest derived melanocytes and the neuroepithelial-derived RPE cells. Mitf promotes RPE differentiation, regulates the proliferation of the RPE during development and consequently their retinal function. There is evidence that the Mitf-Tfe family of transcription factors regulate the expression of vascular endothelial growth factor (VEGF) in the RPE and thus may affect retinal vascular function.

The purpose of this study was to examine the eye phenotype in mice with four different mutations in the Mitf gene that have mild or intermediate effects on eye development in heterozygous, homozygous or in compound heterozygous conditions. Our primary focus is on the structure and function of the retina and the RPE in mice with different mutations in a gene that is expressed in the RPE.

Results

Mice used in the study. The Mitf mutations studied here have all been described previously and are listed in Table 1. Heterozygotes carrying Mitf+/− were used and Mitf−/−/− mutants have normal eye size: although the former has normal coat pigmentation, the latter have grey dilute coat colour (Fig. 1; Table 1). Mice homozygous for the Mitf−/−/− mutation have a black coat with a white belly and unpigmented spots over the rest of the body, and dark ruby eyes of normal size. The Mitf−/−/−/− mice have a white coat whereas eye size is normal (Fig. 1). These particular mutations, in heterozygous, homozygous or compound heterozygous conditions, were selected for study as they all have apparently normal eye development. After application of the mydriatic tropicamide, the irises of all mutants fully dilate, except the Mitf−/−/−/− mice, which show an iris that is less pigmented than that of wild type mice, and which dilates only partially with tropicamide, possibly due to hypoplasia (Fig. 1).

Varying hypopigmentation in Mitf mutant eyes. Representative bright field and fluorescent fundus images obtained with a rodent fundus camera from the eyes of wild type (n = 6) and mutant mice are shown in Fig. 2. As demonstrated by the bright field images (Fig. 2, upper panel) the optic disc areas were of normal size in all mutants, further indicating that the eyes of these mutant mice develop to a normal size in all cases. All the mutant mice show some hypopigmentation in their fundi, varying in degree. The fundi of the Mitf−/−/−/− mice (n = 6) show discrete yellow lesions, with only minor hypopigmentation overall, but discreet pigment motting scattered throughout the entire fundus. The bright field fundus images from Mitf−/−/−/− mice (n = 6) reveal large unpigmented lesions in both eyes, usually in the superior half of the fundus, with irregular borders. The fundi of the Mitf−/−/−/− mice (n = 6) also show hypopigmentation and comparable large non-pigmented

| Allele          | Symbol   | Heterozygote                                                                 | Homozygote                                                                 | Lesion                                |
|-----------------|----------|------------------------------------------------------------------------------|---------------------------------------------------------------------------|---------------------------------------|
| microphthalmia  | Mitf+/−  | Iris pigment less than in wild type; spots on belly, head and tail            | White coat, eyes small and red; deficiency of mast cells, spinal ganglia, adrenal medulla and dermis smaller than normal; incisors fail to erupt, osteopetrosis; inner ear defects | 3-bp deletion in basic domain         |
| white           | Mitf−/−/− | Coat color lighter than dilute (a/d); eyes dark ruby; spots on feet, tail and belly; inner ear defects | White coat; eyes small and slightly pigmented; spinal ganglia, adrenal medulla and dermis smaller than normal; inner ear defects; reduced fertility | I211N                                 |
| emu-22(398)    | Mitf+/−/− | Normal                                                                        | Black with white belly and spots over the rest of the body.               | QQ6STOP                               |
| VGA-9          | Mitf+/−/− | Normal                                                                        | White coat, eyes red and small; inner ear defects                          | transgene insertion and 882-bp deletion |
areas, although more extensive, but no pigment mottling. The fundus images of the MitfMi-Wh/+
mouse (n = 6) showed more widespread lack of pigmentation and larger apparent RPE lesions, without any pigment mottling.

The fluorescent angiography (FA) images from wild type (n = 6) and MitfMi-vga9/+ mice (n = 6) showed normal retinal vasculature with no hyperfluorescent signals, and extensive capillaries emanating from the major vessels (Fig. 2, lower panel). The FA of the MitfMi-enu22(398)/MitfMi-enu22(398) and MitfMi-Wh/+ animals, possibly corresponding to the non-pigmented areas in the bright field images.

Mitf has an impact on visual function. ERG recordings were obtained from wild type and mutant mice. Dark-adapted ERG responses evoked by the 1.87 log cd sec/m² stimulus are presented in Fig. 3a–c. Two of the Mitf mutant mice, MitfMi-Wh/+ and MitfMi-Wh/MitfMi showed no detectable dark-adapted ERG responses above baseline (Fig. 3a), suggesting that they have severely impaired retinal function. The dark-adapted ERG responses of these mice were all less than could be detected above baseline regardless of stimulus luminance (data not shown), while the other two mutant mice (MitfMi-vga9/+ and MitfMi-enu22(398)/MitfMi-enu22(398)) showed dark-adapted ERG a- and b-waves that were not significantly different in amplitude (Fig. 3d, f) or implicit time (Fig. 3e, g) from wild type at any of the levels of the stimulus luminance tested (P > 0.05). The mean amplitude of the dark-adapted a-wave of the ERG in response to the 1.87 log cd sec/m² stimulus was 189.1 ± 30.9 μV in wild type (n = 6), 183.4 ± 22.4 μV in
Mitfmi-Gga9+/ mice (n = 6), and 184.4 ± 27.8 µV in Mitfmi-enu22(398)/Mitfmi-enu22(398) mice (n = 6). The mean amplitude of the dark-adapted b-wave of the ERG in response to the same stimulus was 383.3 ± 26.0 µV in wild type mice, while it was 357.6 ± 11.5 µV in Mitfmi-Gga9+/ mice (n = 6) and 352.4 ± 35.6 µV in Mitfmi-enu22(398)/Mitfmi-enu22(398) mice (n = 6). The a- and b-wave implicit times were normal in those mutants that showed dark-adapted ERG responses at any of the levels of the stimulus luminance tested (P > 0.05). The mean of the a-wave implicit time in response to the 1.87 log cd sec/m² stimulus was 8.9 ± 0.8 µV in wild type, while it was 8.0 ± 1.1 µV in Mitfmi-Gga9+/ mice, and 7.9 ± 0.5 µV in Mitfmi-enu22(398)/Mitfmi-enu22(398) mice. The mean of the b-wave implicit time in response to the 1.87 log cd sec/m² stimulus in normal mice was 33.7 ± 2.0 µV, whereas it was 31.8 ± 2.6 µV in Mitfmi-Gga9+/ mice, and 27.1 ± 1.8 µV in Mitfmi-enu22(398)/Mitfmi-enu22(398) mice.

The dark-adapted oscillatory potentials, evoked by the 1.87 log cd sec/m² stimulus but isolated with a 100–500 Hz digital filter are presented in Fig. 4a–c. These wavelets riding on the dark-adapted b-wave, reflecting inner retinal activity, were not significantly different between Mitfmi-Gga9+/, Mitfmi-enu22(398)/Mitfmi-enu22(398) and wild type mice at any of the levels of the stimulus luminance tested (P > 0.05) (Fig. 4d). The mean amplitude of the dark-adapted OPs in response to the 1.87 log cd sec/m² stimulus was 43.4 ± 15.5 µV in normal mice, 39.0 ± 6.5 µV in Mitfmi-Gga9+ mice, and 44.1 ± 6.4 µV in Mitfmi-enu22(398)/Mitfmi-enu22(398) mice in response to the same stimulus.

Light-adapted ERG responses were recorded after 10 minutes of light adaptation with a steady white background light of 1.7 log cd/m², which was kept present during the recordings, while evoking ERG responses with light flashes of increasing intensity. Figure 5a–c shows examples of photopic ERG responses recorded from wild
Wild type mice was 206.9

Mitfmutant mice show retinal degeneration. In order to assess the structures of mutant retinas at 3 months of age we examined tissue sections stained with haematoxylin and eosin (H&E). In eyes from Mitf/Wh/+ (n = 6) and Mitf/enu22/398/Mitf/Wh/+ (n = 6) animals all the layers of the retina and RPE were found to be present (Fig. 6a). However, Mitf/enu22/398/Mitf/Wh/+ mutant mice (n = 6) compared to wild type mice (n = 6). However, Mitf/Wh/+ and Mitf/enu22/398/Mitf/Wh/+ mice showed clear evidence of retinal degeneration; we observed that photoreceptor outer segments (POS) and ONL were absent from animals of both genotypes (Fig. 6a), and the total retina...
and inner plexiform layer (IPL) were significantly thinner compared to wild type (P < 0.001). In addition, eyes from MitfMi-Wh/Mitfmi animals showed thinner inner nuclear layer (INL) than wild type mice (Fig. 6b). The eyes of the MitfMi-Wh/Mitfmi animals show no evidence of the RPE, Bruch’s membrane or choroidal melanocytes in histological sections, while a thin layer of RPE cells is present in sections of eyes from MitfMi-Wh/+ mice (Fig. 6a).

Discussion

The different mutations at the mouse Mitf locus have different effects on the phenotype, ranging from no visible effects to deaf animals lacking melanocytes with severe microphthalmia and osteopetrosis (reviewed in32). Here we study eye function and morphology in mice carrying alleles which result in mild effects on adult eye size and apparent external structures; all have normal eye size. Our analysis shows that Mitf is not only important for normal adult eye size and external structure but is also critical for normal retinal function at 3 months of age. We showed that although eye size is normal in these mutants, pigmentation of the fundus is altered in all the mutants. The alterations in the fundus vary from a widespread lack of pigmentation to various degrees of hypopigmentation to yellow spots with non-pigmented areas (Table 2). We found that despite some depigmentation of the RPE, two of the mutants, Mitfmi-vga9/+ and Mitfmi-enu22(398)/Mitfmi-enu22(398) not only have normal adult eye size and external structure but also have functioning retinas. The histology shown in Fig. 6a shows pigment in the RPE layer of these two mutants, although reduced, while choroidal melanocytes are near absent from Mitfmi-enu22(398)/Mitfmi-enu22(398) mice but present in Mitfmi-vga9/+ mice. The pigmentation observed by fundus photography is dependent on the presence of melanin in both RPE cells and choroidal melanocytes, both of which are affected by Mitf mutations. Hypopigmentation observed in the fundus of these mice is not necessarily an indication of RPE dysfunction or retinal degeneration. However, it is of course possible that despite lack of morphological changes, these mutations affect the expression of important downstream target genes affecting photoreceptor function or integrity at older ages. For example, homozygous Mitfmi-vga9 mice develop photoreceptor degeneration as they age due to effects on PEDF expression48. The other two mutants studied, MitfMi-Wh/+ and MitfMi-Wh/Mitfmi have clear histological defects in the RPE layer and a near absence of choroidal melanocytes, and show clear evidence of severe retinal degeneration at 3 months of age (summarized in Table 2). Thus it appears that Mitf mutant mice with intact RPE layers have normal retinal function and structure at 3 months of age, even though there is a severe reduction of choroidal melanocytes. We have yet to determine the exact time course of these retinal degenerations, which may be either progressive and rapid, or present at birth and thus directly due to the effects of Mitf during eye development.

The electoretinographic findings indicate that mice carrying the Mitfmi-vga9/+ and Mitfmi-enu22(398)/Mitfmi-enu22(398) mutations have normal dark-adapted and light-adapted ERG responses, while the other two, Mitf335-Wh/+ and Mitf335-Wh/Mitf335 mice, show no ERG responses to any stimuli under either condition (Table 2). The compound heterozygote
MitfMi-Wh/mutant carries two different alleles in the Mitf gene. The semidominant MitfMi-Wh mutation results in grey coat in heterozygotes and white coat in homozygotes; eye development is normal in the heterozygote whereas intermediate microphthalmia is seen in the homozygote (Table 1). In the homozygous condition, the Mitfmi mutation leads to white, microphthalmic mice which die at 3 weeks of age due to osteopetrosis; heterozygotes are normal apart from a small belly spot. The MitfMi-Wh/Mitfmi compound heterozygote is of particular interest since it shows interallelic complementation as its phenotype is more normal with respect to eye development than the phenotype of each homozygote alone. Interestingly, we observed that MitfMi-Wh/+ and MitfMi-Wh/Mitfmi mice have no ERG response and the retina is abnormal at 3 months of age. The normal development of a full size eye, as induced by the interallelic complementation, is clearly not sufficient to prevent severe and early degeneration. Our results show that the MitfMi-Wh/+ mutant is clearly semidominant with respect to eye function. Interestingly, these mice show a profound hearing dysfunction due to an absence of melanocytes from the post natal cochlea suggesting semidominant action also in the ear. The hearing abnormality present in these mice reinforces the notion of their similarity to individuals with Waardenburg and Tietz syndromes. Waardenburg syndrome, of which there are four subtypes with different penetrance of the clinical features, is a congenital, dominantly inherited pigmentation anomaly characterized by deafness, hypopigmentation of the skin, hair and eyes, with a midline white forelock of hair, and in some cases facial anomalies. Ocular symptoms

Figure 6. Histology and analysis of the retinal layers of eyes from wild type and Mitf mutant mice. Representative retinal sections of 3 months old mice are shown. (a) Central retina from wild type and mutant mice. (b) Analysis of the retinal layers. Total retinal thickness from GCL to POS, ONL, INL and IPL thicknesses were measured from the sections. Scale bar; 50 µm, Ch, choroid; RPE, retinal pigment epithelium; POS, photoreceptor outer segments; ONL, outer nuclear layer; INL, inner nuclear layer; IPL, inner plexiform layer; GCL, ganglion cell layer. One-way ANOVA followed by Bonferroni's post-hoc comparisons test (wild type set as control) was used. Data are presented as means ± SEM, n = 6, ***p < 0.001.
| Mutant mice | Fundus photography | Fluorescein angiography | Electroretinogram | Histology |
|------------|-------------------|------------------------|------------------|-----------|
| Mitf<sup>mi-vit</sup><sup>+</sup> | Yellow lesions and minor hypopigmentation | Normal vasculature | Normal | All retinal layers are present |
| Mitf<sup>mi</sup>-<sup>enu22,398</sup>/Mitf<sup>mi</sup>-<sup>enu22,398</sup> | Large white lesions | Hyperfluorescent areas but with capillaries present | Normal | All retinal layers are present |
| Mitf<sup>mi</sup>-<sup>Wt</sup>-<sup>A</sup> | Hypopigmentation and comparable large non-pigmented areas | Hyperfluorescent regions across the entire fundus, and a clear reduction in the capillary network | Not above baseline | RPE, POS and ONL are absent |
| Mitf<sup>mi</sup>-<sup>Wt</sup>/Mitf<sup>+</sup> | Widespread lack of pigmentation and larger RPE lesions | No fluorescence in their retinal vasculature | Not above baseline | RPE, POS and ONL are absent |

Table 2. Eye phenotype summary of the mutants. RPE, retinal pigment epithelium; POS, photoreceptor outer segments; ONL, outer nuclear layer.

include iridial heterochromia, hypopigmentation of the fundus<sup>36,50–52</sup>, and in rare cases unilateral macular degeneration have also been observed.<sup>35</sup> Tietz syndrome patients show more severe symptoms of the same kind, and they are invariably deaf while approximately 75% of Waardenburg syndrome patients are deaf or have a severe hearing loss<sup>38,39</sup>. This shows again, similarities in human and mouse phenotypes, although reports on visual function or electroretinography performed on Waardenburg or Tietz patients are scant or in most cases non-existent.

In previous electroretinographic studies of other mice with mutations in the Mitf gene, the results have varied. Some of the mutations, such as Mitf<sup>enu22,398-vit+mig</sup> and Mitf<sup>enu22,398-vit+sp</sup> mice, have normal ERGs, or in the case of Mitf<sup>mi</sup>-<sup>Wt</sup>-<sup>A</sup> mice, a reduction in all components of the response<sup>23</sup>. A slow, progressive loss of the ERG b-wave occurs in the homozygous Mitf<sup>enu22,398-vit+</sup> mice<sup>29,54</sup>. However, homozygous Mitf<sup>enu22,398-vit+</sup> mice show no ERG response at 3 months of age<sup>23</sup>, as found in two of the mutant mice in the present study. These results together suggest that even with changes in the pigmentation and morphology of the RPE caused by specific mutations in the Mitf gene, such as in Mitf<sup>enu22,398-vit+</sup> and Mitf<sup>enu22,398+</sup> mice, the photoreceptors and the inner layers of the neuroretina may survive and function normally.

Light microscopic analysis of histological sections of the eyes of the mutants revealed that the RPE layer in the Mitf<sup>enu22,398-vit+</sup> mice shows localized thinning of melanin-containing areas. This is probably due to the localized degeneration of choroidal melanocytes in these animals. An equivalent light microscopic analysis of the eyes of Mitf<sup>enu22,398-vit+</sup> mice shows a normal RPE layer and apparent choroidal melanocytes, although fundus images reveal fine pigment mottling as white spots across the fundus. The Mitf<sup>enu22,398-vit+</sup> and Mitf<sup>enu22,398-vit+</sup> mice showed a near complete absence of the melanin-containing areas of the RPE layer, and Mitf<sup>enu22,398-vit+</sup> mice showed a thin monolayer of RPE cells but absence of apparent choroidal melanocytes or a Brücke’s membrane. Retinal thickness analysis showed that the POS and ONL layers are absent from Mitf<sup>enu22,398-vit+</sup> and Mitf<sup>enu22,398-vit+</sup> mice; the IPL is thinner compared to wild type. In addition, the Mitf<sup>enu22,398-vit+</sup> mice showed thin INL compared to normal mice. In both cases, the major phenotypic effects can be attributed to the Mitf<sup>enu22,398+</sup> allele which clearly has severe effects on the eye. Despite substantial thinning of the melanin-containing areas of the RPE layer in Mitf<sup>enu22,398+</sup> mice, due to absence of choroidal melanocytes, and some hypopigmentation and pigment mottling in the fundi of Mitf<sup>enu22,398+</sup> mice, no significant differences were observed in the thickness of the ONL, INL and IPL in these mice as compared to wild type mice; the total retina is thinner in the Mitf<sup>enu22,398+</sup> mice than in either wild type or Mitf<sup>enu22,398+</sup> mice.

This study provides more evidence that a functional RPE is important for normal photoreceptor function. Thus, mutations in genes expressed in the RPE such as Mitf and Otx2, can have profound effects on retinal structure and function, as a consequence of alterations in the RPE<sup>17,18,35</sup>. RPE-specific ablation of Otx2 in the adult mouse retina leads to RPE dysfunction, which in turn leads to photoreceptor degeneration comparable to those that occur in Mitf<sup>enu22,398-vit+</sup> and Mitf<sup>enu22,398-vit+</sup> mice<sup>17,18,35</sup>. Mutations in the human OTX2 gene on chromosome 14q22.3, which codes for a transcription factor that shares 100% amino acid identity with its mouse ortholog (Otx2), cause pattern dystrophy of the RPE, and slow photoreceptor degeneration in patients<sup>19</sup>, similar to what occurs in mice with Otx2 ablation<sup>17,18</sup>. However, unlike Mitf, Otx2 is also expressed in the bipolar and photoreceptor cells of the retina, in addition to its role in regulating visual cycle function in the RPE<sup>17,20</sup>. Thus, it can be stated with certainty that retinal dysfunction or degeneration in Mitf mutant mice found here are due to mutations in a gene which in the eye is only expressed in the RPE<sup>35</sup>, while those seen in Otx2 mutant mice, and in patients with OTX2 mutations, are more complex.

The RPE plays a vital role in the visual cycle<sup>48</sup>. This process is a key element of the interactions between the RPE cells and photoreceptor outer segments. In the RPE, Mitf is known to regulate the expression of two visual cycle genes, Rhlp1 which encodes retinaldehyde binding protein-1 (RLBP1), and Rdh5, which encodes retinol dehydrogenase-5 (RDH5)<sup>35</sup>. Thus, Mitf controls expression of visual cycle genes and consequently the reconstitution of functional rhodopsin, although not the same processes of the visual cycle as Otx2 in the RPE. Wen et al<sup>35</sup> also found that postnatal injection of 9-cis-retinal can partially rescue the retina in homozygous Mitf<sup>enu22,398-vit+</sup> mutant mice with respect to gene expression, structure and function. This means that the lack of Mitf in the RPE may have such profound developmental effects that the adjacent retina might be permanently damaged<sup>35</sup>. It is likely that these processes of the visual cycle play a role in inducing the degeneration found in the eyes of Mitf<sup>enu22,398-vit+</sup> and Mitf<sup>enu22,398-vit+</sup> mice. We have shown here that mutations in a transcription factor expressed in the RPE, and not in the neuroretina, have profound effects on the appearance of the fundus of the eye, in particular its pigmentation, and can lead to changes in neuroretinal function, and to severe retinal degeneration in some cases. The study further demonstrates that the RPE is essential for vision, and that transcription factors whose expression in the eye is restricted to the RPE play a role that is critical for normal retinal structure and function.
Material and Methods

Animals. The following 3-month-old Mitf mutants were used in this study: C57BL/6J-Mitfenu22c, C57BL/6J-Mitfenu22c22380, C57BL/6J-Mitfenu22c22380/Mitfenu22c22380, C57BL/6J-Mitfenu22c22380/Mitfenu22c22380 and C57BL/6J-Mitfenu22c22380/Mitfenu22c22380 (Table 1). The mice were kept at the University of Iceland. All animal experiments were approved by The Icelandic Food and Veterinary Authority (MAST licence numbers 2017-04-03 and 2018-05-02) and were performed in accordance with the Association for Research in Vision and Ophthalmology Statement for the Use of Animals in Ophthalmic and Visual Research.

Fundus photography. Live fundus photographs were obtained from anaesthetized mice with a Micron IV rodent fundus imaging system (Phoenix Research Labs Inc., Pleasanton, CA). Prior to fundus examination the mouse was given an intraperitoneal injection of a mixture of 40 mg/kg Ketamine (Pfizer, Denmark) and 4 mg/kg Xylazine (Chanelle Pharmaceuticals, Ireland), and the anaesthesia was maintained as needed with half of that dose. Pupils were dilated with topical application of Mydriacyl (1% tropicamide) (Alcon Inc., U.S.A) eye-drops, and Alcaine (Alcon, Inc., U.S.A) drops were applied as a local corneal anaesthetic. A photograph of the front of the anterior chamber of the eye was then taken with the fundus camera to assess both eye size and pupil dilation. A 1% methylcellulose gel was applied to the cornea of both eyes and a mini contact lens (Ocuscience LLC, Henderson, NV) 2.5 mm in diameter placed on the cornea, to reduce the risk of cataract formation57. The contact lens from one eye was removed before fundus photography and 1% methylcellulose applied to the eye again. A bright field image of the anterior segment was first obtained, and then bright field images of the fundus with the optic nerve in the centre of the field. Fluorescent angiography fundus images were obtained after intra-peritoneal injection of fluorescein sodium salt (0.1%, 10 µl/kg).

Electroretinogram (ERG). Instrumentation. The electroretinogram (ERG) was recorded between two electrodes with a MacLab ML131 BioAmp amplifier. A coiled urethane coated stainless steel wire (0.2 mm in diameter) was used as the corneal ERG electrode58. One platinum wire was placed in the chin of the mouse for reference59 and another one in the outer ear, serving as ground. The signal was amplified 1000 times. The recording was fed into a computer through a PowerLab analogue/digital converter (ADInstruments Pty Ltd., NSW, Australia). Data acquisition and analysis was performed with the LabChart 7 Pro software package (ADInstruments Pty Ltd., NSW, Australia). Voltage responses were amplified 10,000 times and passed through a 50Hz notch filter and band pass filters set at 0.3–500 Hz. In the LabChart Pro software a 100–500 Hz digital band pass filter was set to isolate the oscillatory potentials (OPs) in a separate recording channel. The sampling rate of the recordings was set at 20 kHz. White light stimuli, with a duration of 10 µs to evoke the ERG, were generated with a Grass PS-33 photostimulator (Astro-Med/Grass Inc., West Warwick, RI, USA), and presented with a Ganzfeld strobe. The light stimuli used were of four different luminances: 0.67, 1.27, 1.57 and 1.87 log cd sec/m².

Recording procedure. Prior to each ERG experiment the mouse was given an intraperitoneal injection of 40 mg/kg Ketamine and 4 mg/kg Xylazine and then the anaesthesia was maintained with half of that dose. The electrode always contacted the cornea through a layer of 1% methylcellulose58. The pupil was dilated with topical application of Mydriacyl (1% tropicamide) (Alcon Inc., U.S.A) and Alcaine (Alcon, Inc., U.S.A) drops were used as a local corneal anesthetic. Saline solution drops were systematically applied to the eye as a tear supplement, in order to prevent dehydration and cataract formation, and to provide adequate electrical conduction for the corneal electrode. The mouse was placed on a heating pad with a rectal thermal sensor beneath it, both connected to a thermal regulator. The head of the mouse was positioned in a straight line with the body, by a short string threaded behind its upper front teeth, to maintain normal breathing. The mice were dark adapted for 30 minutes before recording the scotopic ERG responses. At least one minute elapsed before stimulus presentations in order to allow the photoreceptors to recover from any photopigment bleaching and to maintain the dark adaptation state between flashes59. Afterwards the mouse was light adapted with a steady background light of 1.7 log cd/m² for ten minutes. The ERG recording protocol was the same after light adaptation as the one following dark adaptation. At the end of the experiment the anaesthetized animal was sacrificed via cervical dislocation and then bled by femoralarterial sectioning.

ERG data analysis. The amplitudes of the ERG and its components are presented as means ± standard error of the mean, in microvolts (µV). The a-wave amplitude was measured from baseline to the lowest base of the cornea-negative deflection. The b-wave was either measured from baseline or lowest point of the a-wave (if present), to its peak. Implicit times of the a-, b-waves were measured from flash onset and until their apex60,61. Oscillatory potentials (OPs) were extracted with a band-pass filter (100–500 Hz). The peaks of the first four OPs were measured and summed to generate the total OP amplitude as previously described62. The amplitude of each OP was measured individually from the preceding trough to the peak of the OP considered, except for OP1 that was measured from the preceding baseline to its peak.

Histology and measurement of the retinal layers. Mice were euthanized by cervical dislocation. Eyes were enucleated and fixed in 4% paraformaldehyde over night at 4°C. Subsequently, the eyes were embedded in paraffin and sectioned at 5 µm onto glass slides. Retinal tissue sections were deparaffinised and then stained with hematoxylin and eosin (H&E). Microscopic examination was performed using an Olympus IX71 microscope (Tokyo, Japan). The distance from the retinal surface to the end of the photoreceptor outer segments was measured as the retinal thickness. The thicknesses of the ONL, INL and IPL in the central retina were measured by light microscopy at the point where the ratio of the distance from the optic disc to the point to the distance from
the optic disc to peripheral end of the retina was 0.263. The values recorded for each parameter for the nasal and temporal sides were averaged to obtain a single value for each eye. For consistency, only retinal sections with optic nerve stumps were used.

**Statistical analysis.** All data are presented as mean ± SEM. One-way ANOVA followed by Bonferroni's post-hoc comparisons test was performed in all statistical analyses. Values of P > 0.001 were considered statistically significant (indicated with ***). Statistical analysis and graphs were plotted using SigmaPlot 13 (Systat Software, San Jose, CA).

**Data availability** The datasets generated during and/or analysed during the current study are available from the corresponding author on reasonable request.
