Conference Paper

Automatic System to Control the Anisotropy of Lyocell Felted Webs

Nuno José Ramos Belino, Mário Figueiredo Nunes, and Paulo Torrão Fiadeiro
Universidade da Beira Interior

Abstract
The webs produced using a card as former system generally keep the fiber orientation. This effect is not very important for a great number of applications. But if an even pore distribution is necessary or the mechanical properties are to be uniform in all directions, then this system doesn’t work very well. Taking into account these considerations, a new technological solution has been specifically devised to control the fibre orientation during the drafting operation in pre-needled felts. A prototype is used as drafting unit with the rolls driven by stepper motors and controlled by computer. Two video cameras collect images of the surface of the web, before and after the drafting operation, and process them in a computer. The values of the images textural descriptors, are calculated and compared. It is intended an increase in entropy which means that the web become less ordered and this is the situation we are aiming for. A computer program will adjust automatically the speed and pressure of the drafting cylinders so as to achieve the best possible situation in terms of the isotropy of the final product and, consequently, MD:CD ratio close to 1.

Keywords: Anisotropy, Nonwoven felts, Image analysis, Textural descriptors, Estiragem

1. Introduction
Although presently there are available several different methods for web formation, the use of a card, as a web former unit, is very common, mainly because it is a technology very well-known and accepted by the textile industry. For technical applications, the only problem present when the card is the former system is that a certain fiber orientation always occurs, which is acceptable in many cases because normally a cross lapper is used to increase the thickness of the web and to adjust the mass per unit of area. Although the mechanical properties of a product based on such a system may be similar in both principal directions, it must be considered that each layer keeps its particular fiber direction. Yet, for many applications, it is necessary that the distribution of fibers be as isotropic as possible in order to permit an even pore distribution as well as equal mechanical properties in all directions, particularly, along the MD and CD axis hence, requiring an MD:CD ratio close to 1. When the web consolidating system to be used
is a needling process, a good solution consists in producing this needling operation in two steps: pre-needling and final needling [1, 2]. During the pre-needling operation tufts of fibers are transported from their horizontal position to a vertical situation. If a drafting operation is introduced between these two steps, the fibers of the horizontal structure may rotate around the fibers of the vertical structure and reorient themselves. The critical point of this method is the control of the drafting operation. If it is not enough extended, then the web will keep some fiber orientation in a particular direction. On the other hand, if the drafting operation has been carried out too far, then a new kind of orientation will arise with all the inconveniences of the first one [3, 4]

11. Characterization of web superficial properties with image analysis

Image analysis deals with images and can be summarized as a set of techniques that convert object images in numbers and prepares this data to be processed by computer methods. It is also known as digital image analysis [5]. Texture analysis is an essential concept of image analysis that deals with primitives or elements called texels, and this mean a contiguous set of pixels with some regional property or pattern. A texture feature is a numerical value, extracted from an object image, that gives us some information about the variation of grey levels distribution and variation on an image. From a statistical point of view, image textures are complicated pictorial patterns that can be defined by statistical models, in way to characterize these same patterns.

According to the consulted bibliography, we found a prevalence of texture discrimination by the co-occurrence matrixes method in multiple researches works in many fields. This technique gives us a high dimensional texture description and puts in evidence the space relations between the grey levels. Thus, as the grey levels are a function of the mass per unit area, we have a direct characterization of the material structure [6]. The probability of spatial grey level co-occurrence is a second order density probability, which can be defined by a matrix of relative frequencies \( f(i,j) \) with witch two neighbouring pixels separated by a distance \( d \) on \( \theta \) direction, occur on the image, one with grey level \( i \), and the grey level \( j \). Thus, for an image with \( N_G \) grey levels, the probability density functions can be written under the form of four squared matrices \( N_G \times N_G \) for the \( 0^\circ, 45^\circ, 90^\circ \) e \( 135^\circ \).

directions Haralick, Shanmungan and Dienstein [7] proposed 14 measures of textural features derived from the co-occurrence matrices, each one representing certain image
properties. However, the textural descriptors used in this work were a subset, defined by equation 1 and 2.

First order entropy

\[
H = - \sum_{i=0}^{G-1} p(i) \log_2[p(i)]
\]  

Second order entropy

\[
ENT = - \sum_{i=0}^{G-1} \sum_{j=0}^{G-1} P_{d,\theta}(i, j) \ln[P_{d,\theta}(i, j)]
\]

2. Materials and Methods

The experimental setup developed in this research work was comprised by the following elements:

1. A Cosmatex nonwoven laboratorial line composed by a feeding/opener, card, cross-lapper and pre-needling/needling apparatus;

2. An image analysis system composed by a Frame grabber DT3155 from Data Translation inc; 3 - 2 CCDs Cohu model 2652-2000; Lenz system from Cosmicar – pentax; Monochromatic video monitor model TM923B from JVC;

3. A specifically devised pre-needled drafting prototype, conceived with 4 drafting zones between 5 drafting sets of cylinders and equipped with two CCDs, one at the beginning of the process and another one at the end;

4. 1 PC for the drafting and pressure control and 1 PC for image acquisition and processing.

The pre-needled webs were produced using Lyocell fibres with 6,4 dtex and 60,5 mm. The needling density was kept constant and the webs mass per unit area were 170 g/m². The drafting operation was conducted with constant pressure on each pair of rolls (2.4bar) and constant and equal pre-drafting length for all drafting zones. The variable parameters were the drafting ratio which assumed the following values: 0%; 6,7%; 13,3%; 20%; 26,7%; 33,3%; 40% and the used drafting zone (C1; C2; C3; C4).
Figure 1: Illustration of the developed prototype (A) and control system (B).

The pre-needled web’s images were acquired at the entry (IN) and exit (OUT) of the drafting operation. Their textural descriptors were extracted using the spatial grey level dependence method and compared in a fully automated and real time process.

The observation of the evolution of the 1st order entropy when dependent of the increasing drafting ratio clearly shows that, for every drafting value considered and for all the drafting zones involved, the output entropy value is always higher than their comparative entry value. Additionally, our findings point that all the drafting zones analysed present a continued growth of the output entropy value until it reaches their maximum, which occurs in the drafting zone 4 and with a drafting ratio of 20%. When surpassing this value, with a continued increasing of the drafting ratio, all the drafting zones exhibit a slight but steady decrease of the first order entropy.
3.2. Second order entropy

The analysis of the 2nd order entropy output, for all the different studied angular directions and for all the drafting zones, exhibits a similar behaviour. The collected data are shown in table 2.

The 2nd order entropy for the 0° direction, thus for CD direction, presents a continued growth up to maximum value, which is nearly 20% of the drafting ratio. After this peek, a decrease of their values occur until it reaches a minimum value, approximately stable and slightly higher than the value of the initial entropy.

The 2nd order entropy for the 45° direction shows a slight decrease in the initial phase, which may be caused by a minor increase in the fibrous structure orientation in this direction. However, posteriorly it increases their value to a maximum which is achieved with higher drafting rates revolving around 20% to 30%, hence compensating the initial disorientation loss. Starting from this point is possible to see yet another entropy decreasing until reaching values slightly higher than the initial input values.

The 2nd order entropy for the 90° direction, commonly known as CD direction, denotes an initial diminishment for the early stages of the pre-needled web drafting process to a value close to 13,3% which produces a new reorientation of the fibrous structure along this direction and thus compensating the entropy gain obtained by the fibrous disorganization within the CD direction. Since this value, the entropy rises until reaching a maximum attained with a drafting ratio ranging between 20% and 26,7%. Afterward, we assist to an entropy decay tending to a limit value in which the output entropy is slightly higher than the initial one for all the analysed drafting zones.

The 2nd order entropy evolution for the 135° direction is marked by their continuous increment along with the increasing in the drafting rate, up to is peak, which is close to 20%. After this maximum, it starts a steady but slight decrease with a tendency to stabilize.

The overall behaviour for all the drafting zones exhibits only minor changes, apart from the initial stage of the drafting zone 4. As expected, the average 2nd order entropy, in all the different drafting zones, display a variation pattern analogous to their individual behaviour for all the diverse angular directions considered. It should be noted that the mean values of the 2nd order entropy demonstrate an increasing output evolution with lower values achieved with the drafting zone 1 and maximum values reached with the drafting zone 4.

4. Conclusions

The analysis of the variation of the studied textural descriptors - first and second order entropy – as a function of the variation of the drafting ratio permits the following conclusions: The evolution of the first order entropy along with the drafting ratio increasing, evidence a continuous growth until a maximum peak followed by a slowly, but steady, diminishment with the continued increase of the drafting rate. The behaviour of this variable is in accordance with the theoretical assumption, in which the fibrous disorganization induced by the rotation movement of the fibres (web horizontal structure) around the tufts (web vertical structure) is caused by a drafting rate limited to a set of optimal values. Higher drafting rate values will produce a new reordering of fibres, but in the opposite direction from the initial one and, consequently, the decrease of the entropy of exit of 1st order entropy. The analysis of the variation of 2nd order entropy along with the increasing drafting ratio, for all the different angular directions studied, also favours some interpretations consistent with the behaviour demonstrated by the 1st order entropy. The comparison of the behaviour of the 2nd order entropy variation, when a function of the drafting ratio increasing, for the concrete case of this experimental setup, allows to infer that the optimum drafting value to carry out the correction of the MD:CD ratio to values close to the intended unit value, revolves around, approximately, 20% a value from which a new reordering of the web fibres occurs in the opposite direction to the initial situation and induces a similar mechanical behaviour, but with an opposite value.
