Abstract

We have characterized the immune system involvement in the disease processes of idiopathic pulmonary fibrosis in novel ways. To do so, we analyzed lung tissue from 21 cases of idiopathic pulmonary fibrosis and 21 (non-fibrotic, non-cancerous) controls for immune cell and inflammation-related markers. The immunohistochemical analysis of the tissue was grouped by patterns of severity in disease pathology. There were significantly greater numbers of CD68+ and CD80+ cells, and significantly fewer CD3+, CD4+, and CD45RO+ cells in areas of relatively (histologically) normal lung in biopsies from idiopathic pulmonary fibrosis patients compared to controls. In zones of active disease, characterized by epithelial cell regeneration and fibrosis, there were significantly more cells expressing CD4, CD8, CD20, CD68, CD80, CCR6, S100, IL-17, tumor necrosis factor-α, and retinoic acid-related orphan receptors compared to histologically normal lung areas from idiopathic pulmonary fibrosis patients. Inflammation was implicated in these active regions by the cells that expressed retinoid orphan receptor-α, -β, and -γ, CCR6, and IL-17. The regenerating epithelial cells predominantly expressed these pro-inflammatory molecules, as evidenced by co-expression analyses with epithelial cytokeratins. Macrophages in pseudo-alveoli and CD3+ T cells in the fibrotic interstitium also expressed IL-17. Co-expression of IL-17 with retinoid orphan receptors, and epithelial cytoskeletal proteins, CD68, and CD3 in epithelial cells, macrophages, and T-cells, respectively, confirmed the production of IL-17 by...
these cell types. There was little staining for Foxp3, CD56, or CD34 in any idiopathic pulmonary fibrosis lung regions. The fibrotic regions had fewer immune cells overall. In summary, our study shows participation of innate and adaptive mononuclear cells in active-disease regions of idiopathic pulmonary fibrosis lung, where the regenerating epithelial cells appear to propagate inflammation. The regenerative mechanisms become skewed to ultimately result in lethal, fibrotic restriction of lung function.

Idiopathic pulmonary fibrosis; co-expression analysis; immunohistochemistry; inflammation; IL-17; retinoic acid-related orphan receptors; usual interstitial pneumonia

**Introduction**

Idiopathic pulmonary fibrosis is an incurable lung disease with a variable clinical course that eventually leads to death (1, 2). This disease involves lung parenchyma injury that is defined histologically but not epidemiologically (3). Idiopathic pulmonary fibrosis is temporally heterogeneous, with regions of lung injury and fibrosis interspersed with normal appearing lung (4, 5). The prognosis for patients remains grave and there are no effective treatments. There are many controversies regarding the disease including the role of inflammation (6), the causative agent(s) of the sporadic injury (7–9), and the defective regeneration processes that lead to fibrosis (10). We have examined inflammatory pathways at the cellular level in this study, extending the evidence for the role of the highly inflammatory cytokine, IL-17.

Some insights into understanding the course of pulmonary fibrosis have come from animal models of bleomycin-mediated lung injury, revealing participation of inflammatory mediators (11), hematopoietic progenitors (12, 13) and chemokines that attract cells into the sites of injury (14). Studies in human idiopathic pulmonary fibrosis indicate a role for circulating progenitor cells called fibrocytes (15–17). However, the source of the fibroblasts that mediate the interstitial deposition of collagen, formation of the fibroblastic foci and the “fibroblastic reticula” (18) characteristic of usual interstitial pneumonia is a controversial issue (19). It may be that both progenitor recruitment (fibrocytes) and epithelial-mesenchymal transition (20) occur in pulmonary fibrosis; definitive evidence remains to be presented.

The purpose of the current study was to analyze *in situ* the histologically normal, active, and fibrotic regions of idiopathic pulmonary fibrosis lung, to characterize the inflammatory cells and mediators present (21–24), and to provide a novel description of the cellular cytokine production associated with the disease processes. We examined tissue from control lungs and lungs from cases of idiopathic pulmonary fibrosis for the presence and co-expression of intra-and extra-cellular markers, pro-inflammatory cytokines and a pleiotropic family of molecules (S100) functioning inside and outside of cells. Our studies reveal disease region-specific expression patterns of inflammatory mediators, particularly in regenerating epithelial cells, which have not been previously described in human idiopathic pulmonary fibrosis.

Materials and methods

Patient selection

Lung tissue specimens from patients with idiopathic pulmonary fibrosis were available from the consult files of G. J. Nuovo or the surgical pathology files at The Ohio State University Medical Center. Tissue specimens were selected from patients without diagnosed autoimmune co-morbidity. Procurement of the tissue was done according to the guidelines of the approved protocol (Internal Review Board number-2002H0089). All tissues were formalin-fixed and paraffin-embedded. For controls, we studied an equal number of similarly-sized pieces of lung biopsies (that ranged from 1.0 to 2.0 centimeters in maximum diameter) with histologically unremarkable lung. The control specimens were obtained from patients with suspected emphysema, but not cancer or pulmonary fibrosis. Recuts of the original tissue stained with hematoxylin and eosin were reviewed by a board certified Anatomic Pathologist with expertise in lung pathology (GJN) to verify the original histologic diagnosis.

The patient demographics consisted of 21 idiopathic pulmonary fibrosis patients, including 8 males with a mean age of 61 ± 10 (± SD) years, 2 females with a mean age of 62 years, and 11 patients of unknown age and gender (de-identified idiopathic pulmonary fibrosis lung tissue provided by Dr. Moises Selman). The 21 controls included 13 males with a mean age of 68 ± 7 years, 7 females with a mean age of 66 ± 11 years, and one person of de-identified age and gender.

Histologic variables

The histologic features of the lungs from patients with idiopathic pulmonary fibrosis were divided into three categories based upon the pathological severity, all with the diagnosis of usual interstitial pneumonia. These were: Normal histologic findings (idiopathic pulmonary fibrosis Normal Lung Area), defined as lung tissue that at 200X could not be differentiated from the lung tissue of the controls; lung with alveolar damage, defined as loose myxomatous-like interstitial fibrosis associated with the presence of either persistent alveolar-lining epithelia and/or regenerating respiratory epithelial cells (idiopathic pulmonary fibrosis-epithelial dominant), frequently accompanied by inter-alveolar fibroblast foci; and a fibrosis-only stage (idiopathic pulmonary fibrosis-stromal dominant), defined as the presence of variable numbers of small blood vessels and dense fibrous tissue. Regenerating epithelial cells were lacking at this last stage, although entrapped pseudoalveolar spaces were common. In the latter two stages, scattered stromal inflammatory cells and either subpleural or perivascular large lymphocytic infiltrates (typically from 100 to >1000 cells) were commonly seen. It should be noted that these categories represent a continuing spectrum of disease severity, and all of the signature histological regions of usual interstitial pneumonia can be found in lung tissue from an idiopathic pulmonary fibrosis patient, defining the concept of temporal heterogeneity.

Immunohistochemistry

The immunohistochemistry testing was done as previously described (25). Formalin-fixed, paraffin-embedded tonsil tissues with chronic tonsillitis were used to optimize each
antibody. In brief, the optimization protocol included testing serial sections with no pretreatment, protease 1 (Ventana Medical Systems) digestion for 4 minutes, or Cell Conditioning One (CC1) solution (antigen retrieval) at 95°C for 30 minutes or, when necessary, 60 minutes (CC1 30, CC1 60) at two different primary antibody concentrations (26). Sections were then scored for signal and background to determine the optimal conditions. The use of tonsils as the positive control tissue provided another layer of specificity to the analyses as the expected histologic distribution of the immunophenotypic markers probed for in this study has been, in most cases, well characterized in tonsils.

**Primary antibodies and detection system**

The primary antibodies used in this study with their optimal condition are listed in Table 1. Antibodies that were used without dilution are described as ready-to-use. As previously reported (25), the Ultraview Universal Fast Red (Fast Red) and diaminobenzidine detection systems from Ventana Medical Systems were used for bound antibody detection following the manufacturer’s recommendations.

**Co-expression analyses**

Co-expression analyses were performed using the Nuance system (Cambridge Research Institute) according to the manufacturer’s specifications and as previously published (25). In brief, the Nuance system converts co-expression based colorimetric analysis (diaminobenzidine brown for one protein and Fast Red for the other protein, with blue hematoxylin counterstain for nuclei) into spectral signatures that can be digitally separated and then “mixed” to determine if a given cell is producing two distinct proteins. These images are depicted as pseudo-fluorescent for ease of visualization. The Nuance system will score a cell positive for co-expression even if the proteins are in different cell compartments, as long as the signals for each protein are within a 150 nanometer plane in 3-dimensional space (25, 27).

**Statistical analyses**

For each immunohistochemical analysis for a given antigen and disease pattern, a minimum of three 200X, non-overlapping fields were counted from one slide and averaged, and at least two slides from three patients with idiopathic pulmonary fibrosis as well as the same from two negative controls were analyzed. Statistical comparisons were made using GraphPad Prism 5.0 software and a two-sided Student’s T-test with the Bonferroni correction. The Bonferroni correction was applied to the p-values, which were adjusted by a factor equivalent to the number of comparisons made, usually four.

**Results**

**Description of lung tissue from idiopathic pulmonary fibrosis biopsies and control lung tissue**

We correlated the histologic features of 21 samples and 21 controls with the immunohistochemical detection of the following proteins: CD1a, CD3, CD4, CD8, CD20, CD34, CD45, CD45RO, CD56, CD68, CD80, retinoic acid-related orphan receptor (ROR)-α, ROR-β, ROR-γ, forkhead box p3 (Foxp3), chemokine receptor 6 (CCR6), S100, IL-17.
and TNF-α. All of the antibodies used are described in Table 1. In three of the idiopathic pulmonary fibrosis cases, there was sufficient tissue to test each of these antigens on serial 4 micron sections. For the other 18 idiopathic pulmonary fibrosis cases, where the amount of tissue was limited, at least 3 idiopathic pulmonary fibrosis cases and 2 control lung cases were used to test each antibody.

The control tissues showed normal lung tissue in the majority of microscopic fields. In some samples, scattered areas of alveolar wall breakdown consistent with early emphysema were seen. However, there were no patterns of increased interstitial fibrosis seen in controls. The idiopathic pulmonary fibrosis lungs globally showed a heterogeneous pattern of fibrosis. In all cases, there was extensive alteration of the parenchymal architecture with only small zones of relatively uninvolved parenchyma. Foci of active injury were characterized by conspicuous type II pneumocyte hyperplasia, fibroblastic foci, and expansion of discernible septa by lymphocytes, plasma cells, and histiocytes. Neutrophilic infiltrates were rare. It was common to observe sheets of macrophages with variable pigment deposition within the alveolar spaces, although this was not unusual in the control lungs as well. Variable vascular injury and hemorrhage were noted in more advanced areas of fibrosis. There was an obliterative pattern of fibrosis with large, irregular pseudoalveolar spaces characteristically exhibiting interlobar and subpleural accentuation.

Idiopathic pulmonary fibrosis normal lung tissue versus control lung tissue

Figure 1 shows the quantities of mononuclear cells and macrophages detected by immunohistochemistry using immunophenotypic markers to identify the cell types in control lung and the idiopathic pulmonary fibrosis lung grouped into three distinct stages. Given that the normal appearing areas of idiopathic pulmonary fibrosis lungs may have the earliest markers of disease, it is important to look for differences in these areas that may reveal the etiology of idiopathic pulmonary fibrosis. A comparison of histologically normal lung from the idiopathic pulmonary fibrosis cases and the control lung tissues found that fewer than 1 cell/200X field stained with the following markers: CD20, CD34, CCR6, and Foxp3 (Figures 1, 2, and data not shown). Alternatively, CD3, CD4, CD8, CD45, and CD45RO-positive cells were commonly detected in the histologically normal idiopathic pulmonary fibrosis lung tissue, corresponding at times to small foci of interstitial lymphocytic infiltration. Figures 1 and 2 show there were significantly more cells in the histologically normal lung tissue in idiopathic pulmonary fibrosis lung biopsies than in lung tissue from control cases that were stained for CD68 (p = 0.0304) and CD80 (p = 0.0116). Only CD68+ cells in the interstitium were counted; the alveolar macrophages were not counted. Although there were quantitatively more TNF-α+ cells in normal lung tissue in idiopathic pulmonary fibrosis biopsies than control lung tissue, the difference was not significant. Macrophages and dendritic cells appeared to be attracted to the normal-appearing interstitial areas in idiopathic pulmonary fibrosis; this was the first detected immune activity.

The comparison of histologically normal lung in idiopathic pulmonary fibrosis lung biopsy material to control lung tissue (Figure 1) revealed significantly fewer cells positive for CD3 (p = 0.0028), CD4 (p = 0.0488), and CD45RO (p< 0.0005). The numbers of CD8+ cells from the normal areas of the idiopathic pulmonary fibrosis lungs and controls were similar.
Although there were slightly more CD45 cells in the normal lung areas from patients with idiopathic pulmonary fibrosis compared to controls, the difference was not statistically significant. Fewer than expected T-helper cells (CD4+), including memory cells (CD45RO+), were present in the normal areas of the idiopathic pulmonary fibrosis lung biopsies. Figure 3 shows representative photomicrographs for the detection of various mononuclear cells in the control lungs (Figure 3; photos 3a, 3d, 3g, 3j, and 3m), for the normal areas of idiopathic pulmonary fibrosis lungs (Figure 3; photos 3b, 3e, 3h, 3k, and 3n), and for the epithelial dominant areas of idiopathic pulmonary fibrosis (Figure 3; photos 3c, 3f, 3i, 3l, and 3o).

**Inflammatory infiltrates**

Figure 4 shows examples of cell markers found in inflammatory infiltrates. The inflammatory cell infiltrates were most conspicuous in the areas corresponding to recent parenchymal injury. The density of each infiltrate was variable and ranged from 100 to over 1,000 cells, but it was never of the magnitude found in lymphocytic interstitial pneumonitis. Inflammatory infiltrates usually showed either subpleural or perivascular localization. The CD3+ T cells were located around the edges and CD20+ B-cells were in the center (Figure 4a and 4c), as previously described (28). Immunohistochemistry for the leukocyte common antigen, CD45, strongly stained the infiltrate cells (Figure 4b). Fewer cells were positive for CD45RO, a marker of memory T-helper cells and myeloid hematopoietic progenitors (29). Interestingly, Foxp3+ cells were visible with nuclear staining in the inflammatory infiltrates (Figure 4e), but not in the areas of active fibrosis (data not shown). IL-17+ cells were present in the inflammatory infiltrates (Figure 4g). ROR-β+ cells were not apparent among the lymphocytes, but some positive epithelial cells can be seen in the vicinity of the infiltrate (Figure 4f). Immunohistochemistry analysis for CCR6+ cells follows a similar pattern, with scattered staining of nearby epithelial cells, but no positive lymphocytes (Figure 4h).

**Idiopathic pulmonary fibrosis epithelial dominant lung tissue characterization**

Cells in sites of the active disease (idiopathic pulmonary fibrosis-epithelial dominant) were analyzed. The mean numbers of mononuclear cells and macrophages/200X field in the epithelial dominant areas of idiopathic pulmonary fibrosis are presented in Figure 1. The CD45RO+ population was smaller than in control lung tissue (p < 0.0005). CD45RO+ cells were present in the inflammatory cell infiltrates in idiopathic pulmonary fibrosis (Figure 4d), but were much less common in the areas of active or chronic fibrosis. Significantly more cells expressing CD20, CD45, and CD68 were detected in the epithelial dominant stage of idiopathic pulmonary fibrosis compared to controls (Figure 1, p = 0.0004, p < 0.0004, and p < 0.0004, respectively). CD3+, CD4+, CD8+, CD45+, and CD80+ cells were each abundant in the epithelial dominant regions of idiopathic pulmonary fibrosis lung (Figure 3, photos 3c, 3f, 3i, 3l, and 3o). Though many of the CD3+, CD4+, and CD8+ cells had the typical mononuclear cytology, others had spindle-like features. The CD80+ cells were actively regenerating epithelia (Figure 3o). The number of CD8+ cells was significantly greater in the idiopathic pulmonary fibrosis-epithelial dominant stage compared to the idiopathic pulmonary fibrosis-normal lung (p = 0.0076), but not when compared to the control lung tissue (Figure 1). Cells expressing CD45 were typically mononuclear cells (Figure 3k), but some were larger interstitial cells with myofibroblast features (Figure 3l) resembling cells...
reported to be derived from circulating fibrocytes (17). Cells expressing the regulatory T-cell marker Foxp3 or the NK marker CD56 were neither detected in the epithelial dominant phase of idiopathic pulmonary fibrosis (similar to the control) nor in the histologically normal idiopathic pulmonary fibrosis lung areas (data not shown).

Interestingly, the IL-17+ cells stained regenerating epithelial cells, and alveolar macrophages, and some interstitial cells were also positive (Figure 5e and 5f). Cytologic examination showed that the primary cells expressing TNF-α had the features of macrophages, though occasional, TNF-α+ regenerating epithelial cells were seen (Figure 5a and 5b).

The regenerating epithelial cells in the idiopathic pulmonary fibrosis epithelial dominant areas of lung sections expressed other markers such as the antigen-presenting marker CD80 (Figure 5c and 5d). CD80+ cells were sometimes seen in the stroma but were primarily regenerating epithelial cells. S100 is typically a protein found in and released by phagocytes (30, 31). S100+ cells were abundant in the active disease stage (Figure 2), and are present in the stroma (Figure 5g and 5h). The numbers of cells expressing S100 and CD80 were 50- to 100-fold higher (respectively) in idiopathic pulmonary fibrosis-epithelial dominant lung tissue than in control lung tissue (Figure 2).

CCR6 is expressed on memory T cells, Th-17s, and T-regs (32, 33). There were significantly more cells expressing CCR6 in the active idiopathic pulmonary fibrosis biopsy tissue than in controls (p = 0.0006; Figure 2). Given that regenerating epithelial cells appeared to be the major cell type expressing a variety of inflammatory antigens, we performed co-expression analyses to further address this point. Co-expression studies were done with serial sections to compare the same groups of cells in adjacent sections that are four microns thick (in comparison, the regenerating epithelial cells are typically around 15 to 20 microns in size). The tissue was probed with cytokeratin AE1/3 antibodies for epithelial antigens, (Table 1; Figure 6a–6f), and CCR6 (Figure 6a–6d) or IL-17 (Figure 6e and 6f). The cells that co-expressed CCR6 and cytokeratins were the regenerating epithelial cells (Figure 6a and 6d). IL-17+/cytokeratin AE1/3+ cells can be seen (36% of epithelial cells were stained; Figure 6f), and IL-17+/cytokeratin AE1/3− cells are visible in the surrounding stroma (Figure 6e and 6f).

**IL-17-producing macrophages and T-cells in idiopathic pulmonary fibrosis**

To determine the identity of the interstitial/stromal cells and to verify the identity of the alveolar macrophages expressing IL-17, idiopathic pulmonary fibrosis lung tissues were probed with antibody to IL-17, CD3 and CD68 (Figure 7). Some of the IL-17+ interstitial cells were CD3+, indicating that Th-17 lymphocytes were present in the stroma (Figure 7a and 7b). Cells positive for IL-17 and CD68 were macrophages (Figure 7c and 7d).

**IL-17-producing cells expressing RORs in idiopathic pulmonary fibrosis**

Th-17 lymphocytes can be identified by the presence of the nuclear orphan receptor ROR-γ (34), which controls IL-17-production and CCR6 expression (35). Like ROR-γ (36), ROR-α is necessary for lymphocyte development (37) and promotes Th-17 differentiation (38). A third member of the ROR family is ROR-β. Antibodies to these nuclear orphan receptors
were used to probe either control or idiopathic pulmonary fibrosis lung tissue. Expression of ROR-β and -γ was apparent in all stages of idiopathic pulmonary fibrosis (Figure 8). The numbers of cells positive for ROR-α, -β and -γ were significantly higher in the epithelial dominant stage of idiopathic pulmonary fibrosis than in control lung tissue (p = 0.0216, p = 0.0018, and p = 0.0009, respectively). Just like IL-17 and CCR6, the positive staining for all three RORs appeared to localize in regenerating epithelial cells. To clarify the identity of these cells, co-localization studies were performed (Figure 9).

Most of the ROR-α+ cells co-expressed epithelial cytokeratins (detected by cytokeratin AE1/3 Ab), suggesting they were lung epithelial cells (Figure 9j). Many cells expressing ROR-β (Figure 9k), ROR-γ (Figure 9l), and IL-17 (Figure 6f) also co-expressed these cytokeratins and were identified as regenerating epithelial cells. These results are surprising, because Th-17s, macrophages (39, 40), and histiocytes (41) are the reported sources of the cytokine IL-17. However, as evident in Figure 6e and 6f, stromal cells also expressed IL-17. RORs were evident on endothelial cells, defined as flattened cells lining small blood vessels (data not shown), scattered interstitial cells and inflammatory cells. Control lung epithelium was nearly devoid of cells positive for ROR-α, -β and -γ (Figure 9m, 9n, and 9o).

Characterization of the stromal dominant regions of idiopathic pulmonary fibrosis lung

The immunophenotypical profiles of the different antigens in the stromal dominant histologic areas of idiopathic pulmonary fibrosis lung tissues were also examined. This data is presented in Figures 1, 2, and 8. There was a marked decrease in the number of cells expressing CD3, CD8, CD20, CD45, and CD68 in the stromal dominant stage of idiopathic pulmonary fibrosis compared to the epithelial dominant stage. The trend for significantly fewer CD45RO+ cells across the histologic spectrum of idiopathic pulmonary fibrosis was demonstrated for the stromal dominant versus the epithelial dominant stage of idiopathic pulmonary fibrosis (p = 0.002). There were far fewer cells expressing TNF-α, CD80, IL-17, CCR6, S100, ROR-α, ROR-β, and ROR-γ in the stromal dominant stage of idiopathic pulmonary fibrosis versus the epithelial dominant stage. Similarly, there was minimal to no expression of Foxp3, CD34, and CD56 (data not shown). The overall decrease in the numbers of immune cells in the end stage of idiopathic pulmonary fibrosis may be attributed to the replacement of parenchymal tissue with fibrotic scar tissue.

Discussion

The major new finding of this study, confirmed by co-expression analyses, was that the regenerating lung epithelial cells in idiopathic pulmonary fibrosis express proteins previously thought to be expressed only by immune cells (Figure 9). A role for the highly inflammatory IL-17 has been implicated in human asthma (39, 42), COPD (43), experimental hypersensitivity pneumonitis (44), murine models of pulmonary fibrosis (11), and all autoimmune diseases that have been tested for its presence (45). Our results show the cell-specific expression of IL-17 in the lungs of idiopathic pulmonary fibrosis patients, unexpectedly localized to regenerating epithelial cells, as well as alveolar macrophages and T-cells. Molecules expressed by Th-17 cells including CCR6 (33, 35), ROR-γ (35) and ROR-α (38) were co-expressed with IL-17 in regenerating epithelial cells (Figures 6 and 9).
Figure 6d and 6f (respectively) show the co-expression of CCR6 and IL-17 with epithelial cytokeratins using the cytokeratin AE1/3 Ab, and Figure 9 shows the co-expression of ROR-\(\alpha\), ROR-\(\beta\), and ROR-\(\gamma\), with epithelial cytokeratins. Figure 7 shows co-expression of IL-17 with CD3 and CD68, verifying the cellular identity as Th-17 lymphocytes and macrophages, respectively. The novel, unexpected finding of IL-17, CCR6, and all three RORs in regenerating epithelial cells (but not histologically normal epithelium) in idiopathic pulmonary fibrosis warrants further exploration.

CCR6 was initially described as a chemokine receptor on memory T cells (32), in particular on T-regs (46), that was specific for chemokine ligand 20 (CCL20). The expression of CCR6 on Th-17s and T-regs requires the expression of the nuclear receptors ROR-\(\alpha\) and ROR-\(\gamma\), and regulates their migration into inflammatory tissue (47). We detected Th-17 lymphocytes in idiopathic pulmonary fibrosis lung stromal tissue (Figure 7a and 7b), but few Foxp3\(^{+}\) T-regs were found outside of inflammatory infiltrates (data not shown and Figure 4). This is consistent with an impaired regulatory T-cell response in idiopathic pulmonary fibrosis (48).

The constant presence of bacteria promotes production of CCL20 in the intestines, and the intestinal epithelial cells constitutively express CCR6 in the colon and in culture (49). Both ligands for CCR6, CCL20 and human \(\beta\) defensin-2, function in the activation of colonic epithelium for cellular migration and barrier repair via CCR6-regulated actin cytoskeleton pathways (50). The results of our co-localization experiments implicate a similar process taking place in the idiopathic pulmonary fibrosis lung epithelium, to repair the idiopathic damage in the alveoli.

The expression of the RORs by regenerating epithelium is intriguing, given that these are nuclear receptors affecting development of the immune and nervous systems, as demonstrated with ROR-\(\gamma\) (36), ROR-\(\alpha\) (37, 51), and ROR-\(\beta\) (52) knockout mice. ROR-\(\beta\) has been detected in the nervous system, leaving its function in idiopathic pulmonary fibrosis lung open for speculation. The RORs were initially named orphan receptors because their actual ligands were unknown. One ligand identified for ROR-\(\beta\) is all-trans retinoic acid (53). Rats treated with all-trans retinoic acid have pulmonary consequences in their alveoli, such as post-natally developing more alveolar tissue, and preventing dexamethasone-induced decreases in alveolar units (54). These interactions suggest a potential physiological role for the RORs in idiopathic pulmonary fibrosis lung epithelium regeneration.

Transformed hematopoietic stem cells express receptors for vitamin A metabolites (55). The expression of ROR-\(\beta\) on the regenerating epithelium deserves further investigation.

ROR-\(\alpha\) is located on chromosome 15q22.2, in a known common fragile site (FRA15A), where gene rearrangements tend to occur resulting in epithelial cancers of the breast, prostate and ovaries. Its transcription is down-regulated in cancer, while cellular stress, oxygen radicals, and toxins up-regulate its expression. Up-regulation of ROR-\(\alpha\) slows cellular growth. (56) Hypoxia also induces activation of ROR-\(\alpha\) (57). It is possible that lung tissue injury and resultant hypoxia in idiopathic pulmonary fibrosis triggers the expression of this gene in the regenerating epithelium.
Because IL-17 was detected in epithelial cells, we looked for ROR-γ to localize to the same cells. Co-localization of ROR-γ and ROR-α in the regenerating epithelium (Figure 9) provides evidence that these cells were producing IL-17, rather than binding it via receptors on their surface from other sources (58). These nuclear factors control the development of IL-17-producing Th-17 cells (34, 38). The results we present call into question the source of the regenerating epithelia. The wide range of molecules expressed suggests that these IL-17-producing cells may be derived from hematopoietic progenitor cells. Murine studies of lung injury and fibrosis have demonstrated the ability of bone marrow-derived cells to populate the alveoli and become type 1 pneumocytes (12, 13). The expression of the hematopoietic progenitor cell marker Thy-1 (29) by regenerating epithelial cells in idiopathic pulmonary fibrosis (59) indicates the potential for hematopoietic cells to enter the damaged regions of lung parenchyma to attempt to heal the injury. Future studies will be required to identify the origin of the regenerating epithelium in idiopathic pulmonary fibrosis.

Early changes in the lungs of idiopathic pulmonary fibrosis patients provide valuable information for discovery of the etiology and the treatment of idiopathic pulmonary fibrosis. Compared to controls, the significant inflammatory changes in histologically normal lung areas in idiopathic pulmonary fibrosis biopsies were macrophage recruitment into the interstitium and heightened cellular expression of the antigen-presenting molecule CD80 (Figures 1 and 2). The recruitment of these innate-immune system cells suggests the presence of a chemotactic mediator, such as a stress signal, emanating from the normal-appearing parenchyma (60, 61). Heightened alveolar macrophage proliferation has also been reported to characterize and distinguish usual interstitial pneumonia from other interstitial lung diseases (62). The relative timing of these phenomena would be interesting to determine.

Some of our results confirmed the location of immune cells previously described for idiopathic pulmonary fibrosis lung tissue. We found TNF-α expression in macrophages and regenerating epithelial cells (Figure 5a and 5b), similar to previous reports (63). Other inflammation-associated molecules detected were S100 proteins (Figure 5g and 5h), a family of intracellular and secreted calcium-binding proteins with regulatory activity (64). These are found in and produced by Langerhans dendritic cells, activated monocytes, macrophages, neutrophils (65), and fibrocytes (66). They function as toll-like receptor agonists and chemoattractants (30); and are functionally modified by oxidation (31). IL-17 enhances expression of S100 proteins in murine and human skin inflammation (33, 67). Our results clearly demonstrate inflammation in idiopathic pulmonary fibrosis and are consistent with previous reports of a role for adaptive auto-immunity in idiopathic pulmonary fibrosis (68). Once the epithelial dominant stage of idiopathic pulmonary fibrosis deteriorates to the stromal dominant stage, there is an apparent decrease in the numbers of cells expressing each of the immunomodulators studied. This underscores the realization that the end-stage of idiopathic pulmonary fibrosis is likely not reversible and that therapy needs to be directed to early disease events.

In summary, we detected and localized the inflammatory and autoimmune cytokine IL-17 (69) in idiopathic pulmonary fibrosis lung. This could be an indication that autoimmune reactivity is present in the disease as suggested by others (7, 8, 68), or this could be another...
disease in which IL-17 plays a role (33). Given the finding of IL-17-producing cells by Wilson et al. in a tracheal-injury murine model of pulmonary fibrosis (11), it is likely that this cytokine is not unique to idiopathic pulmonary fibrosis among the fibrotic lung diseases. This is the first report of co-localization of IL-17 with the orphan nuclear receptors ROR-α, -β, and -γ, and the chemokine receptor CCR6 in cells that are acting as regenerating epithelia in idiopathic pulmonary fibrosis. These results raise many important questions regarding the source of regenerating epithelial cells in the lung, and the potential pathological role that they play in their attempt to heal alveolar injury.

Acknowledgments

The authors would like to thank Kathleen Sergott for assistance with the immunohistochemical part of the study, Margaret Nuovo M.D. for her assistance with the photography and the creation of the figures, and Dr. Moises Selman for providing some of the idiopathic pulmonary fibrosis lung tissues analyzed in this study.

Figure 1.
Lymphocytes, Monocytes, and Macrophages
The mean ± standard error of the mean (SEM) of the numbers of cells stained positive for the labeled surface antigens on slides with lung tissue from the indicated idiopathic pulmonary fibrosis signature histological regions and control lung tissue. Asterisks indicate the p-values for comparison of the idiopathic pulmonary fibrosis tissues to the control lung tissue (*p < 0.05; **p < 0.005; ***p < 0.0005). Deltas indicate the p values for comparison of the differences involving the data bars that they appear between (δp < 0.05; δδp < 0.005; δδδp < 0.0005).
Figure 2.
Cell Markers and Cytokines
The mean ±SEM of the numbers of cells stained positive for the indicated antigens, chemokine receptors, or cytokines on slides with lung tissue from the indicated idiopathic pulmonary fibrosis signature histological regions or control lung tissue. Asterisks indicate the p-values for comparison of the idiopathic pulmonary fibrosis tissues to the control lung tissue (*p < 0.05; **p < 0.005; ***p < 0.0005). Deltas indicate the p values for comparison of the differences involving the data bars that they appear between (δp < 0.05; δδp < 0.005; δδδp < 0.0005).
Figure 3.
Control Lung, Idiopathic Pulmonary Fibrosis-Normal Lung, and Idiopathic Pulmonary Fibrosis-Epithelial Dominant Lung.
3a, 3d, 3g, 3j, and 3m show lung tissue from the controls probed for the indicated cellular markers; 3b, 3e, 3h, 3k, and 3n show the staining of histologically normal lung from idiopathic pulmonary fibrosis patients; and 3c, 3f, 3i, 3l, and 3o show the staining of the epithelial dominant or active phase of idiopathic pulmonary fibrosis. All photomicrographs show the tissue with a magnification of 200X. The tissues shown in photos 3a–3f were stained with diaminobenzidine; the tissues in photos 3g–3o were stained with Fast Red. The counterstain in each case was hematoxylin.
Figure 4.
Idiopathic Pulmonary Fibrosis Inflammatory Infiltrates
All photomicrographs show the tissue stained with Fast Red and hematoxylin counterstain. The photos in 4a–4f have a magnification of 200X; 4g and 4h are at 400X.
Figure 5.
Idiopathic Pulmonary Fibrosis-Epithelial Dominant Areas
5a–5f show idiopathic pulmonary fibrosis lung tissue stained with Fast Red and hematoxylin counterstain, and 5g and 5h show idiopathic pulmonary fibrosis lung tissue stained with diaminobenzidine and hematoxylin counterstain. 5a, 5c, 5e, and 5g have a magnification of 100X, the others have a magnification of 400X.
Figure 6.
Co-expression Analyses of Epithelial Cytokeratins, CCR6 and IL-17 in the Idiopathic Pulmonary Fibrosis-Epithelial Dominant Areas.

The images in 6a–6d are photos of the same slide, as are 6e and f. 6a shows the color-based image where the bound cytokeratin AE1/3 Ab appears brown (diaminobenzidine), CCR6 is red (Fast Red), and the counterstain (visible on nuclei) is blue (hematoxylin). The Nuance system converts diaminobenzidine to fluorescent green showing the cytokeratins in 6b. The CCR6 and IL-17 (Fast Red) are converted to fluorescent red (6c and 6e), fluorescent yellow marks cells with both targets (6d and 6f). The CCR6+ cells co-express cytokeratins (6d). Co-expression analyses with IL 17 (6f) shows that the epithelial IL 17+ cells are cytokeratin AE1/3 Ab+, but many IL-17+/cytokeratin AE1/3− cells are fluorescent red in the stroma.
Figure 7.
Co-expression Analyses of IL-17 with CD3 and CD68 in the Idiopathic Pulmonary Fibrosis-
Epithelial Dominant Stage.
7a shows the color-based image where the CD3 is stained brown (diaminobenzidine), IL-17 is red (Fast Red), and the counterstain is blue (hematoxylin). 7b shows the same image made fluorescent by the Nuance system. Some double-positive (yellow) stained cells are present in the interstitium (Th-17s), and some of the CD3$^+$ T cells are green, both have the morphology of lymphocytes. Fast Red-labeled cells (IL-17$^+$, non-T cells) are also apparent. 7c shows the regular color-based image with CD68$^+$ stained brown (diaminobenzidine) and the IL-17 is again stained with Fast Red. 7d shows the same image made fluorescent, with double-positive macrophages (yellow), some green macrophages (CD68$^+$) in the interstitium, and red fluorescent (IL-17$^+$) regenerating epithelial cells.
Figure 8.
Intracellular Retinoid-like Orphan Receptor-Positive Cells
The mean ± SEM of the numbers of interstitial cells stained positive for the ROR antigens on slides with areas of lung tissue representing the signature idiopathic pulmonary fibrosis histological regions and control lung tissue. Asterisks indicate the p-values for comparison of the idiopathic pulmonary fibrosis tissues to the control lung tissue (*p < 0.05; **p < 0.005; ***p < 0.0005). Deltas indicate the p values for comparison of the differences involving the data bars that they appear between (δp < 0.05; δδp < 0.005; δδδp < 0.0005).
Figure 9.
Co-expression Analyses of RORs and Cytokeratins in the Idiopathic Pulmonary Fibrosis-Epithelial Dominant Areas.
9a, 9b and 9c show the regular color-based images where the cytokeratin AE1/3 Ab is brown (diaminobenzidine); ROR-α, -β, and -γ are Fast Red labeled; and the counterstain is blue (hematoxylin). The same images (arranged vertically) are fluorescence-converted by the Nuance system in photos 9d–9l. Most of the ROR-expressing cells are stained positive with the cytokeratin AE1/3 Ab. Control lung tissues were double stained with the same antibodies and color reagents, the co-expression is shown and labeled in 9m, 9n, and 9o. Green fluorescence of the cytokeratin AE1/3 Ab can be seen, but co-expression with the RORs is absent.
Table 1

| Antibody name (anti-) | Description                                                                 | Source   | dilution | Tissue pre-treatment |
|-----------------------|-----------------------------------------------------------------------------|----------|----------|---------------------|
| CCR6                  | Chemokine receptor 6; ligands are CCL20 (MIP-3α or LARC) and human β-defensin-2 (50). Expressed on memory T-cells, B-cells and dendritic cells (32); highly expressed on Th17s (33). | Abcam    | 1:200    | CCl 30             |
| CD1a                  | (Leu6, OKT6) Found on T-cells, normal Langerhans cells, immature dendritic cells (70), and cortical thymocytes (71). It functions in dendritic cell presentation of glycolipid antigens (72) and dendritic cell anti-tumor response (73). In disease states it labels histiocytes (74) and leukemic thymocytes (71). | Abcam    | 1:10     | CCl 30             |
| CD3                   | (OKT3) An integral membrane protein complex that is part of the T-cell antigen receptor (75) | Ventana  | ready-to-use | CCl 30             |
| CD4                   | (OKT4, Ly1, Leu3) Marker of T-helper lymphocytes (76) | Ventana  | ready-to-use | CCl 30             |
| CD8                   | (OKT8, Ly2/Ly3, Leu2) Marker of Cytotoxic T lymphocytes (77), a coreceptor with CD3 for antigens displayed by MHC Class I* antigen presenting cells (78) | Ventana  | ready-to-use | CCl 30             |
| CD20                  | (L26) A common B-cell surface marker for all but the initial and final stages of B-cell differentiation (79), used as a target for eliminating B-cells with Rituximab in lymphomas and autoimmune diseases. | Ventana  | ready-to-use | CCl 30             |
| CD34                  | Common surface marker for adult hematopoietic progenitor cells (80), murine hematopoietic cells (81), fibrocytes (82) and endothelial cells (83, 84) | Ventana  | ready-to-use | CCl 30             |
| CD45                  | Leukocyte cell surface glycoprotein (85); mononuclear cells and fibrocytes (66) | Ventana  | ready-to-use | CCl 30             |
| CD45RO                | (UCHL1) Memory T-cells, fibrocytes, monocytes, and macrophages (66) | Ventana  | ready-to-use | none               |
| CD56                  | (N-CAM, NKH-1, Leu-19) Marker for Natural Killer cells (86) | Ventana  | ready-to-use | CCl 30             |
| CD68                  | (KP1, macrosonin) Glycosylated membrane protein expressed by tissue macrophages, Langerhans cells (87), monocytes, and fibrocytes (66) | Ventana  | ready-to-use | CCl 30             |
| CD80                  | (B7-1, BB1) A co-stimulatory molecule found on antigen-presenting cells, including dendritic cells (88), activated B-cells (89), macrophages, and epithelial cells (90). | Abcam    | 1:100    | none               |
| Cytokeratin AE1/AE3   | Labels the most of the cytokeratins of the cytoskeleton (91) in normal epithelia and epithelial carcinomas (92), some abnormal myofibroblasts, and normal smooth muscle cells (93). | DAKO     | 1:150    | Protease           |
| Foxp3                 | Forkhead-winged helix transcription factor that defines the regulatory T cells (24) | Abcam    | 1:100    | CCl 30             |
| IL-17                 | One member of a highly inflammatory cytokine family (IL-17α–f) with chemotactic properties that binds receptors on most cell types (23) | Abcam    | 1:200    | CCl 30             |
| ROR-α                 | Retinoic acid-related orphan receptor alpha, [nuclear receptor 1 (NR1F1), a thyroid hormone-like receptor], a transcription factor expressed in the epithelium of many tissues (51). Required for lymphocyte development (37, 56). A receptor for cholesterol and its derivatives (94). | Abcam    | 1:100    | CCl 30             |
| ROR-β                 | Retinoic acid-related orphan receptor beta (NR1F2), present in the brain and retina (52, 95). | Abcam    | 1:300    | CCl 30             |
| ROR-γ                 | Retinoic acid-related orphan receptor gamma (NR1F3), required for the lymphoid tissue development (36), found in thymocytes, Th17 lymphocytes (95), innate lymphoid cells (96), and skeletal muscle cells (97). | Abcam    | 1:200    | CCl 30             |
| S100                  | A family of intracellular and secreted calcium-binding proteins (30, 31). | Ventana  | ready-to-use | protease           |
| TNF-α                 | Part of the tumor necrosis factor (TNF) superfamily (98) | Abcam    | 1:100    | protease           |
