A formula to unitarize the leading-log BFKL-Pomeron amplitude is derived using a coherent property of two-body collision in the peripheral region. This procedure also allows an algebraic characterization of the Reggeon in QCD based on color, instead of the total angular momentum of the gluons being exchanged.

1. BASIC IDEA

I want to discuss a method to unitarize the leading-log BFKL Pomeron \[\tilde{\alpha}^2\], so that the growth of total cross section \(\sigma_T(s)\) with energy \(\sqrt{s}\) obeys the Froissart bound \(\ln^2 s\). The idea is very simple. Total cross section grows because the Yukawa cloud of the colliding particles overlap even at large impact parameters. At low energy the clouds are so tenuous and transparent that they do not contribute to the cross section. But as energy increases, the rarified overlap may contain sufficient energy to produce there a gluon jet, or a pair. When that happens the cloud becomes opaque and the effective radii increase. This continues until shadowing correction becomes important, at which time the rise is dampened and the Froissart bound is reached.

Now consider \(n\) bosons being emitted from an energetic source with vertex factors \(V_i\), as in Fig. 1(a). After Bose-Einstein symmetrization, i.e., summation over the \(n!\) permuted diagrams, it can be shown [2] that each diagram can be factorized into a product of quasi-particle amplitudes. A quasiparticle is made up of any number \(p\) of gluons, which couples to the source by the nested commutator \([V_1, [V_2, [V_3, \cdots, [V_{p-1}, V_p] \cdots]]]\). Therefore it is a colour-octet object just like a single gluon. Indicating factorization by a vertical bar, and a permuted diagram by the gluon lines in the order they appear, here are three examples showing how some \(n = 8\) diagrams factorize: \(1\,2\,3\,|\,4\,5\,6\,7\,8\), \([5\,7\,3]\,|\,2\,8\,4\,6\), \([1\,2\,3]\,|\,8\,5\,4\,7\,6\). The general rule is that a vertical bar is put after a number if no number to its right is smallest than it. Let \(C_m^i\) be the operator creating a quasiparticle with \(m\) bosons from the vacuum state \(|0\rangle\), then the bosons of these three examples are in the states \((C_1^1)^8|0\rangle\), \(C_4^1 C_4^1 C_2^1 C_2^1 |0\rangle\), \((C_1^1)^3 C_3^1 C_3^1 |0\rangle\), respectively. Summing over \(m\), the bosons emitted by the energetic particle is seen to be in a coherent state \(\exp(C_1^1 + C_4^1 + C_2^1 + C_3^1 + \cdots)|0\rangle\). Thus factorization and coherence are two sides of the same coin. It is however important to emphasize that this factorization occurs in the s-channel, so it is very different from the usual factorization between short and long distances which oc-
curs in the $t$-channel. Moreover, the collection of all single quasi-particles turns out to be nothing but a Reggeon, so the natural appearance of quasi-particle through factorization above can be regarded as an algebraic characterization of the Reggeon.

3. UNITARIZATION

Consider a two-body scattering diagram, Fig. 1(b). The central region is hot and highly incoherent. However, as noted in the last section, the peripheral tree amplitudes associated with the two energetic particles are factorizable and the peripheral regions are 'cool' and coherent. The precise manner factorization takes place depends on the numbering of the gluon lines, which can be specified at will once and for all for every set of permuted diagrams. We can use this property to factorize the scattering amplitude as follows. Suppose the central region of Fig. 1(b) falls into $k$ disconnected parts once the two energetic particles are removed. For example, $k = 3$ for Fig. 1(c). Then by suitably choosing the numbering of gluon lines, we can always produce vertical bars (cuts) between every disconnected components, as shown. Whether cuts occur inside each disconnected component depends on the particular permutation of the lines within that component. Fig. 1(c) illustrates the case when no (one, two) cut occurs in the first (second, third) disconnected component. The gluons between cuts form a single colour-octet quasi-particle, indicated in Fig. 1(c) by a single thick line. Thus the first (second, third) disconnected component is made up of the exchange of one (two mutually interacting, three mutually interacting) quasi-particle(s). One can show in the extended leading-log approximation, which keeps only terms with the lowest power of the fine structure constant $\alpha_s$ for fixed $\xi \equiv \alpha_s \ln s$ and for amplitudes with a fixed number of quasi-particles exchanged, that (A). The number of quasi-particles emerging from the bottom line of each disconnected component is equal to the number of top; those that are not equal are subleading in the approximation; (B). For fixed $\xi$ the amplitude with $m$ quasi-particle exchanged is of the form $\alpha_s^m d_m(\xi)$. Thus for example the amplitude in Fig. 1(c) is of order $\alpha_s^6$; and (C). The non-commuting parts of the colour matrices between different irreducible parts contribute to subleading terms so that we may effectively assume them to commute within the extended leading-log approximation.

Figure 1. (a) A tree diagram with vertices $V_i$; (b) a two-body scattering diagram; (c) factorization of the two-body amplitude. Thick vertical lines represent quasi-particle exchanges.
Summing up all possible diagrams we get the total amplitude in the extended leading-log approximation to be

\[ A(s, b) = 1 - \exp(2i\delta(s, b)), \]  
\[ \delta(s, b) = \sum_m \delta_m(s, b), \]

where \( \delta_m(s, b) \) is the contribution of a disconnected part with \( m \) mutually interacting quasi-particles being exchanged; each quasi-particle is a colour octet made up of any number of gluons with arbitrary complexity. We see from this eikonal form that \( \delta(s, b) \) is simply the phase shift at energy \( \sqrt{s} \) and impact parameter \( b \).

When the phase shift is small, we may replace the amplitude \( A(s, b) \) by its Born approximation \( A'(s, b) \). Using a subscript to denote the number of quasi-particles being exchanged, we have \( A'_1 = -2i\delta_1 \) and \( A'_2 = -2i\delta_2 + 2\delta_1^2 \). The former is of order \( \alpha_s \) and the exchanged object is a colour octet. This is nothing but the familiar Reggeon amplitude in the leading-log approximation. Thus quasi-particles turn out to be Reggeons in this context, but note that the concept of a quasi-particle is far more general than that of a Reggeon. The latter Born amplitude is of order \( \alpha_s^2 \) and two colour-octets are being exchanged. This contains (at least) a colour singlet and a colour octet. The octet amplitude is negligible compared to \( A'_2 \) and will be neglected. The singlet amplitude is nothing but the leading-log BFKL Pomeron amplitude.

The amplitude \( A(s, \Delta) \) with momentum transfer \( \Delta \) is given by the Fourier transform, and the total cross section \( \sigma_T(s) \) is given by the optical theorem, to be

\[ A(s, \Delta) = 2is \int d^2b \, e^{i\Delta b} A(s, b), \]  
\[ \sigma_T(s) = s^{-1} \text{Im} A(s, 0). \]

4. PHENOMENOLOGY

These formulas can also be used to compute the energy variation of total cross sections. Assuming the functions \( d_m(\xi) \) for \( m > 2 \) not to be substantially larger than their counter part at \( m = 1 \) or \( m = 2 \), the contribution from \( \delta_m \) for \( m > 2 \) can be ignored and \( \sigma_T(s) \) can be computed from \( \delta_1 \) and \( \delta_2 \), which in turn can be obtained from the leading-log Reggeon amplitude \( A'_1 \) and the BFKL amplitude \( A'_2 \).

The former is completely known but unfortunately the latter is only partially known. However, from direct perturbative calculations, scattering amplitudes are known to 8th orders. We can extract from such calculations phase shifts to the same order, and use it to calculate the total cross section in QCD. Unitarity is guaranteed, but since we have not used the full Reggeon and BFKL phase shifts to all orders, the calculation may not be numerically accurate. We refer the readers to Ref. [3] for the result of the calculation and comparison with the experimental data [3].

5. CONCLUSION

A unitary formula for total cross section is derived by making use of the coherent property in the peripheral region of the collision. The quasi-Particle so emerged turns out to be nothing but Reggeon fragments. In this way, not only Froissart bound is guaranteed to hold, but an algebraic characterization of the Reggeon is obtained.
