Electrochromic bilayers of Prussian blue and its Cr analogue†

Luke Hedley,†a Liz Porteous, a David Hutson, a,b Neil Robertson b and J. Olof Johansson a,*†

Multilayered thin films of functional materials play an important role in many applications in nanotechnology. The intense and tuneable colours of some molecular materials allow for the development of a unique spectral fingerprint of each layer in thin film heterostructures. Herein, we report on electrochromic switching of bilayer thin films composed of Prussian blue (FeIIFeIII) and its orange-coloured (FeIII CrIII) analogue. The films could be switched from green to orange by reducing the blue FeFe top layer. The distinct optical absorption spectra of the two layers allowed spectroelectrochemical measurements to probe the electrochemical activity of the individual layers during the switching of the Prussian blue layer. We found that for producing layers of equal optical density, the thickness of the layers had to be different due to a difference in oscillator strength for the metal-to-metal charge-transfer transition. The films used here had a thickness of 300 ± 70 nm and 30 ± 15 nm for the FeCr and FeFe sub-layers, respectively. The colouration efficiency was found to be 147.8 ± 0.8 cm² C⁻¹ for the multilayered film. These results show that it is possible to obtain bilayers of Prussian blues that, with a unique optical spectral fingerprint of each sub-layer, retain the electrochromic functionality and therefore enable layer-sensitive studies of charge-transfer processes in thin film heterostructures of multifunctional materials.

Introduction

Multilayered thin films and heterostructures are ubiquitous to a wide range of areas such as solar cells and spintronics. They can be used as smart materials because at the interface of nanoscale heterostructures, new phenomena can arise due to the large surface-to-volume ratio. However, it can be difficult to study charge-transfer and other processes of individual layers in multilayers and so a probe that is sensitive to all layers is desirable. Molecular-based materials that display strong optical charge-transfer transitions can often be modified to tune their absorption spectrum. Carefully choosing the layers such that each layer has a distinct optical spectrum, allows for obtaining a handle on each sub-layer in order to study charge transfer processes across interfaces in multilayers. In particular, electrochromic properties provide a visually pleasing example of achieving electrical control of the colour of the materials and to study the change in absorption spectrum after a redox process. Multilayers containing electrochromic components can be used in multi-coloured electrochromic devices, for applications in smart windows and displays.1,2

One of the most studied electrochromic materials is Prussian blue (PB), which can be switched from blue to transparent upon reduction. PB and its analogues are coordination polymers comprising transition metal ions linked by cyanide ligands in a rock-salt structure. A wealth of heterostructures exist which contain PB in combination with other materials, such as dye-sensitised titania3 and conductive polymers.4,5 There have also been a number of studies that employ multiple Prussian blue analogues (PBAs) to create heterostructures in the form of thin films or nanoparticles to study photo-induced magnetism6,7 and magneto-structural effects.8–10 Their electrochemical11 and optical12 properties have also been studied. In particular, Liao et al.12 made a PB and NiFe PBA composite material using a conductive polymer matrix, which exhibited electrochromic switching. To date, layer-by-layer deposition has been the most common way of making heterostructures of PBAs due to the high degree of control of layer thickness this method allows, which is critical in applications such as ion sieving,13,14 biosensing15 and for the synthesis of electrochromic materials.16 Notably, a sequential electrochemical approach was recently used by Prieto-Ruiz et al.9 to combine two magnetically ordered analogues of PB.

The strong colour of some PBAs, and indeed PB itself, arises due to metal-to-metal charge-transfer (MMCT) transitions, which can be tuned by varying the transition metals and the stoichiometry of the films.17,18 In this paper, we have tested the
Experimental

Electrochemistry

As a working electrode, 1 mm thick glass (aluminoborosilicate) substrates coated with a conductive fluorine-doped tin oxide (FTO) layer were used, with a sheet resistance of 8 Ω sq⁻¹. The substrates were cut to size (8 × 25 mm) and subsequently cleaned in water/detergent solution in an ultrasonic bath for 20 min. The process was repeated with isopropanol and methanol separately, rinsing with the previous solvent after each step to remove impurities on the surface. The cleaned substrates were then dried under a stream of nitrogen gas.

The electrochemical experiments were carried out using a Metrohm-Autolab µAUTOLAB III potentiostat with a saturated calomel reference electrode (SCE) and a Pt counter electrode used for the electrochemical depositions. For the FeCr deposition, concentrations of 37.5 and 25 mM of FeCl₃ and K₃[Cr(CN)_6] were used, respectively. For the subsequent FeFe deposition, a concentration of 7.5 mM was used for both the K₃[Fe(CN)₆] and FeCl₃. For all results presented here, 1 M of KCl (aq) was used as an electrolyte. From previous work, it is known that a more negative voltage is needed to produce FeCr (around 0.7 V) based on their elemental composition. Scanning electron microscopy (SEM) and energy dispersive X-ray spectroscopy (EDX) were used to study the individual layers in terms of their thickness and their elemental composition.

Results and discussion

Electrochemical formation of FeCr PBA

The FeCr PBA was first deposited on the FTO-coated glass substrate. The deposition time was adjusted to reach an optical transmission of ca. 35% at the peak of the MMCT band (corresponding to an absorbance of ca. 0.45), which occurred when the constant voltage was applied for 300 s. The resultant film on the FTO-coated glass substrate was orange (Fig. 1a) due to the MMCT absorption at 440 nm (Fig. 1b), in agreement with what has been described previously. The IR spectrum showed the CN⁻ asymmetric stretch at 2168 cm⁻¹, as expected (Fig. 1c).

The electrochemical experiments were carried out using FeCl₃ and K₃[Cr(CN)_6], with a constant voltage of 0.7 V based on the work of Ohkoshi et al. At this potential, solvated Fe³⁺ ions are reduced to Fe²⁺ at the surface of the electrode. This reduced cation subsequently binds to the hexacyanochromate anion to form the insoluble PBA directly on the substrate.

For FeCl₃ deposition, the electrochemical cell is filled with FeCl₃ and K₃[Cr(CN)_6] along with the electrolyte. The FeCl₃ film is used as an electrolyte in order to reduce the [Fe(CN)₆]³⁻ ions in solution to [Fe(CN)₆]⁴⁻, which subsequently reacts with Fe³⁺ cations at the electrode surface. The product is the insoluble PB created on the FeCr electrode surface. In contrast to FeCr, where a potentiostatic deposition resulted in the optically clearest films, the PB films were deposited galvanostatically at −40 μA. This was previously found to yield the most homogeneous films, which we also observed. After deposition, the films were thoroughly rinsed with distilled water and subsequently dried under continuous N₂ flow.
The EDX spectrum of the film confirm the elemental composition (Fig. S2, ESI†).

These observations therefore lead us to conclude that we have successfully deposited the FeCr PBA on the FTO electrode. The SEM images of the films indicated that they were polycrystalline with cubic crystals of width ca. 1 µm (Fig. 2a and d). The thickness was determined from AFM and was found to be 300 ± 70 nm. The width of the crystals is larger than the height due to lateral growth of the crystals before growing vertically. Analysis of the SEM images allowed us to estimate that the FeCr layer covers ca. 70–80% of the FTO surface (Fig. S3, ESI†).

Deposition of FeFe PB on FeCr PBA

Once the FeCr PBA film was made, cyclic voltammetry in KCl confirmed that there was no electrochemical activity at the voltage needed to make FeFe PB films, which is shown in Fig. 3a. The FeCr PBA is electrochemically active at more negative potentials around −1.0 V vs. SCE, as was shown by Ohkoshi et al.19 After rinsing the FeCr film with deionised water, the deposition of the FeFe film was carried out on top of the FeCr film. The absorption from the FeFe PB could clearly be seen in the transmission spectra as a drop at ca. 685 nm, corresponding to the MMCT transition. The deposition times were tuned to produce films of a similar optical density to the FeCr layer, which resulted in green films (Fig. 1a and b). The optimum deposition time for the FeFe layer was found to be 60 s. The cyclic voltammogram together with a typical absorption spectrum, (Fig. 3a and b), IR spectrum (CN stretching frequency at 2077 cm⁻¹, Fig. 1c) and the EDX (Fig. S2, ESI†), were all in agreement with the literature and indicated that we had produced FeFe PB on the FeCr PBA surface. The colour of the resulting films ranged from orange (short deposition time), to green (intermediate) and blue (long deposition time).
In order to confirm that a bilayer was formed, the CV was recorded and found to be slightly different compared to a bare FeFe PB film (Fig. 3a). These voltammograms were carried out using Pt pseudo-reference and counter electrodes as this replicates the conditions used in the spectroelectrochemical measurement. The electrochemical behaviour of the FeFe PB is maintained when it is deposited on top of the FeCr PBA film, although we see a shift when it is incorporated into the multilayer structure. The shift in potentials for the peaks could be due to the FeCr electrode having a different electrochemical behaviour to the FTO electrode. There is also a difference in the widths of the peak, the broader peaks of the isolated FeFe film suggest that the process is limited by the diffusion of ions in the solution whereas the switching in the multilayer is limited by the charge passing through the FeCr layer. The CVs do however demonstrate that we have deposited the FeFe PB film on top of the FeCr film, which confirms that a bilayer is formed. This is also seen in the SEM images, where Fig. 2f clearly shows a bilayer with small FeFe crystal grains deposited on the larger FeCr crystal grains. The film-to-substrate ratio of the FeCr film should be even larger than that estimated from the SEM images and is probably larger than at least 80% due to the three-dimensional morphology of the FeCr crystal grains (Fig. S3, ESI†). The surface area of the electrode, which is subsequently used for FeFe PB deposition, is therefore mainly comprised of FeCr sites. This in turn implies that a bilayer is formed. The FeCr PBA is conductive enough, confirmed using tunnelling AFM, to allow the growth of the FeFe PB directly on top of the FeCr crystals (Fig. S4, ESI†). The IR spectrum shows the two peaks at 2077 cm⁻¹ and 2168 cm⁻¹, from the FeFe and FeCr respectively. The EDX also showed the correct composition for both the individual films and the bi-layered films. The FeFe layer thickness was 30 ± 15 nm, determined from AFM of individual films produced under identical conditions to the bilayer film and on an FTO electrode.

Optical properties of bilayer

The bilayer films were generally transparent and optically very clear, which therefore make them suitable for optical applications. Interestingly, the SEM and AFM images showed an unexpected difference in the film thicknesses of the two layers despite that the optical density was similar for the two layers. We therefore studied the dependence of the optical density as a function of film thickness, which is shown in Fig. 4. It can be seen that the MMCT oscillator strength for the FeFe material is clearly higher than for the FeCr, which is due to the relative energies and overlap of the orbitals involved in the MMCT absorption.24–26 Based on these data, it appears that
the FeCr should be ca. 200 nm thicker than the FeFe films. This is in relatively good agreement with the AFM data, although the SEM images suggests a quite large difference in the size of the crystal grains in the film (Fig. 2f).

Spectroelectrochemistry and electrochromic switching

During the CV scan, it was visually clear that the FeFe PB colour could be completely switched from blue to transparent (ESI† video). The dependence of the optical transmission spectrum on the applied reductive potential is shown in Fig. 3a. As the potential is swept from positive to negative, the absorbance feature at 685 nm, corresponding to the FeFe MMCT, disappears as the film is reduced. As the potential is swept in the reverse direction, from negative to positive, the absorbance is restored. Throughout this reversible process, the FeCr film is not affected and retains its colour as it does not undergo any electrochemical redox processes. This can be observed in the CV scan of the isolated FeCr film in Fig. 3a. This therefore demonstrates the successful application of electrochromic PB layer in a PBA multilayered film. Because the vast majority of the FeFe PB crystals are deposited on top of FeCr crystals and because these can be completely reduced, as evidenced by the large colour-change, we conclude that charge is passed from the FeCr layer to the FeFe layer. This therefore implies that there is charge-transfer occurring between the two layers.

For the electrochromic switching, potentials of +0.5 V and −0.2 V were chosen from CVs in Fig. 3a, as this will drive the reduction and oxidation of the films to completion in order to measure the switching. The resulting modulation of the absorbance, measured at 685 nm, is shown in Fig. 5a. As can be seen, the colour could be reversibly switched for several cycles without degradation of the film. During the electrochromic switching, there appears to be a certain amount of charge building up in the material, this can be seen in the charge data for the switching process (Fig. S5, ESI†).

The colouration efficiency is a measure of the efficiency of the switching process and is defined as $\eta = \Delta \text{OD}/\Delta Q$. This relates the change in the optical density (ΔOD) to the charge (ΔQ) passed through the system. A plot of the absorbance against the supplied charge density will yield $\eta$ as the initial gradient, as shown in Fig. 5b. The value for $\eta$ was found to be 147.8 ± 0.8 cm² C⁻¹, for the blue to bleach process, which is of the same order of magnitude as reported in other studies employing the FeFe PB as part of an electrochromic device.³,27–30 The switching times are defined here as the time taken for 90% of the switch completion. For the blue to bleached state transformation the switching time is 4.4 ± 0.4 s.

**Conclusion**

We have successfully made bilayers of the FeFe PB and FeCr PBA using electrochemical deposition. When bilayers of equal optical transmission were made, polycrystalline films with thicknesses of 300 nm and 30 nm for the FeCr and FeFe films, respectively, were produced. The crystal grain widths were ca. 1 μm and 30 nm for the FeCr and FeFe layers, respectively. The colour of the FeFe layer could be switched electrically and we found a colouration efficiency of 147.8 ± 0.8 cm² C⁻¹ and switching time of 4.4 ± 0.4 s for the blue to bleach switch.

The demonstration of layer-sensitivity in bilayers of PBAs opens up possibilities to study electron charge-transfer processes in a range of different multilayers of PBAs, some of which are electrochemically active, display high-temperature magnetic ordering, and have bright and chemically tuneable colours. Several PBAs, in addition to those presented here, can be deposited on ITO/FTO coated substrates such as the CrCr,³¹ VCr⁷ and CoFe²⁺ PBAs. Layer-sensitive measurements applied to PBAs with novel photomagnetic and optical properties will be of importance for developing applications for photonic and spintronic devices.
