This work compares several versions of the equations of motion for a test particle encountering cyclotron resonance with a single, field-aligned whistler mode wave. The gyro-averaged Lorentz equation produces both widespread phase trapping (PT) and “positive phase bunching” of low pitch angle electrons by large amplitude waves. Approximations allow a Hamiltonian description to be reduced to a single pair of conjugate variables, which can account for PT as well as phase bunching at moderate pitch angle, and has recently been used to investigate this unexpected behavior at low pitch angle. Here, numerical simulations using the Lorentz equation and several versions of Hamiltonian-based equations of motion are compared. Similar behavior at low pitch angle is found in each case.

Keywords: wave-particle interactions, radiation belts, nonlinear, Hamiltonian, test particle simulation

1 INTRODUCTION

Cyclotron-resonant wave-particle interactions are a crucial ingredient in magnetospheric dynamics, especially in the radiation belts, and there is a vast tradition of simulating the process as quasi-linear diffusion of phase space density by a broad-band spectrum of small, incoherent waves (Thorne, 2010; Thorne et al., 2013), following the pioneering work of Lyons et al. (1971) and Lyons et al. (1972). A complementary approach is that of test particle simulation, most often in the presence of a single, coherent wave whose amplitude need not be small. Inan et al. (1978) noted both quasi-linear and nonlinear behavior, including the “loss cone reflection effect” whereby low pitch angles increase rather than decrease below zero. In the quasi-linear regime, connections between the two perspectives have been provided by Lemons et al. (2009), Lemons (2012), Allanson et al. (2022), and a unified picture of quasi-linear and nonlinear behavior was obtained by Albert (2001), Albert (2010). These studies all used specified and idealized models of the waves, while Liu et al. (2010), Liu et al. (2012) examined test particles driven by waves from self-consistent particle-in-cell simulations.

This work compares several versions of the equations of motion for a test particle encountering cyclotron resonance with a single, field-aligned whistler mode plane wave. The Lorentz force law, resolved into components parallel and perpendicular to the background magnetic field and gyro-averaged, is commonly used for such simulations. Hamiltonian descriptions are in principle equivalent, and with several approximations they allow the reduction to a one-dimensional (1D) system (one action-angle pair, plus the independent variable playing the role of time). If the time dependence is slow enough, particle motion is nearly along instantaneously drawn contours, with invariant breaking at separatrix crossings. There is a rich literature of work based on these concepts, which has been exploited in this context to some degree. Among others, Shklyar (1986) Albert (1993), Albert (2000), Artemyev et al. (2018) further approximated the Hamiltonian as equivalent to
that of a time-dependent pendulum and obtained quantitative estimates of energy and pitch angle changes, which have proved useful and reliable.

Recently, using the gyro-averaged Lorentz equation, Kitahara and Katoh (2019), Gan et al. (2020) found both widespread (or "anomalous") phase trapping (APT) and "positive phase bunching (PPB)" of low pitch angle electrons by large amplitude waves. Both phenomena lead to pitch angle increase, in contrast to the phase bunching behavior that is the usual alternative to phase trapping, and are associated with low pitch angle, which violates a certain approximation made in obtaining the pendulum Hamiltonian. Albert et al. (2021), Artemyev et al. (2021) presented generalizations of the pendulum Hamiltonian which avoid that specific approximation, but still relied on several others. In particular, differences in the first-order (in wave amplitude) term of the phase evolution equation are present among several versions of the equations of motion. This work shows numerically that, despite these differences, the generalized 1D Hamiltonian reproduces the behavior at low pitch angle, and is therefore an appropriate framework for the future development of refined analytical estimates.

2 GYRO-AVERAGED EQUATIONS OF MOTION

Starting with the Lorentz equation for a charged particle in a background magnetic field and a single whistler-mode wave,

$$\frac{dp}{dt} = q \left[ \mathbf{E}_0 + \mathbf{P} \times \mathbf{B}_0 \right], \quad \frac{dx}{dt} = \frac{p}{m},$$

(1)

where $p = mv$ is the mechanical momentum, $v$ is the relativistic factor, $B_0$ is the local geomagnetic field strength with equatorial value $B_{0\parallel}$ and $E_0$ and $B_0$ are the electric and magnetic fields of the wave. Gyro-averaged equations of motion valid near a single resonance have been obtained by many authors, including (Chang and Inan, 1983; Bell, 1984; Albert et al., 2012; Li et al., 2015; Kitahara and Katoh, 2019).

For primary resonance ($\ell = -1$) between an electron (charge $q = -e$) and a parallel-propagating whistler wave, equation 3 of Albert et al. (2012) simplifies to

$$\frac{dp}{dt} = -p_\perp \frac{d\Omega}{dz} + eB_w \frac{p_\perp}{mc} \cos \xi,$$

$$\frac{dp}{dt} = p_\parallel \frac{d\Omega}{dz} + eB_w \frac{p_\parallel}{mc} \cos \xi,$$

$$\frac{d\xi}{dt} = \left( \frac{\Omega}{\gamma} - \omega + \frac{kq}{my} \right) - eB_w \frac{p_\perp \gamma}{mc \eta p_\perp},$$

$$\frac{dz}{dt} = p_\parallel \frac{\gamma}{my}$$

(2)

The angle $\xi$ is a combination of wave phase and gyrophase, $\Omega$ is the local nonrelativistic electron gyrofrequency $eB_w/mc$, and $\eta$ is the refractive index $k\ell/\omega$. The standard resonance condition is just $d\xi/dt = 0$, neglecting the term proportional to $B_w$.

Equations 3–9 of Kitahara and Katoh (2019) are very similar after shifting $\xi$ by $\pi/2$, using $\eta B_w = B_0$ (in Gaussian units), and accounting for the opposite sign convention in wave phase:

$$\frac{dp}{dt} = -p_\perp \frac{d\Omega}{dz} + eB_w \frac{p_\perp}{mc} \cos \xi,$$

$$\frac{dp}{dt} = p_\parallel \frac{d\Omega}{dz} + eB_w \frac{p_\parallel}{mc} \cos \xi,$$

$$\frac{d\xi}{dt} = \left[ \frac{\Omega}{\gamma} - \omega + \frac{kq}{my} \right] - eB_w \frac{p_\perp \gamma}{mc \eta p_\perp},$$

$$\frac{dz}{dt} = p_\parallel \frac{\gamma}{my}$$

(3)

These two versions are brought into agreement by invoking the lowest-order resonance condition, which consists of setting the bracketed expression in the equation for $d\xi/dt$ to zero.

3 TIME-DEPENDENT HAMILTONIAN EQUATIONS

Ginet and Heinemann (1990), Ginet and Albert (1991) used a Hamiltonian version of the equations of motion near resonance with a constant-frequency wave propagating obliquely to a constant background magnetic field $B_0$. The Hamiltonian formulation uses canonical momentum $p = p + qA/c$, where $c$ is the speed of light, and $A$ is the vector potential that describes both $B_0$ and the wave electromagnetic field. A canonical transformation was made from $(x, P_x, y, P_y, z, P_z)$ to variables $(I, \phi, X, P_x, z, P_z)$, with $z$ the distance along $B_0$ in slab geometry. $I$ and $\phi$ correspond to standard first adiabatic invariant and gyrophase but have modifications proportional to the wave amplitude. After gyro-averaging, and specializing to the case of a parallel-propagating wave, the variables $(\phi, z, t)$ appeared only in the combination $\int kdc = \omega t - \phi$ (equation 19 of Ginet and Heinemann (1990) with $k_x = 0$ and $\theta^t = 1$). Albert (1993) generalized the treatment to include slow dependence of $\Omega$ and $\eta$ on $z$, obtaining the Hamiltonian

$$H(I, \phi, P_z, z, t) = Y + \frac{a_c}{2Y} \sin \xi$$

(4)

where

$$Y = \left( 1 + 2 \frac{\Omega}{\omega} I + P_z^2 \right)^{1/2}, \quad a_c = -\sqrt{2 \frac{\Omega}{\omega} I + \frac{1}{\eta} \frac{qB_0}{mc}}$$

(5)

and

$$\xi = \eta z - t + \phi,$$

(6)

using normalized variables $(oz/c, \omega t, o\ell/mc^2, P_\perp mc)$ as in Albert (1993). Appropriate partial derivatives of $H$ give equations of motion for $(I, \phi, P_z, z, e)$, e.g., $dI/dt = -\partial H/\partial \phi$ and $d\phi/dt = \partial H/\partial I$, from which

$$\frac{d\xi}{dt} = \frac{P_z}{Y} - 1 + \frac{d\phi}{dt}$$

(7)

It is also found that $dH/dt = \partial H/\partial t$ equals $dI/dt$, so that $I - H$ is a constant, denoted $c_2$:  

\[ \text{Frontiers in Astronomy and Space Sciences | www.frontiersin.org} \]

\[ \text{June 2022 | Volume 9 | Article 910224} \]
\[ I - H = c_2. \] (8)

Following Shklyar (1986), Albert (1993) solved this for \( P_z \) after approximating \( H \) by \( \Upsilon \), obtaining

\[ \Upsilon \approx \Upsilon_0 \equiv I - c_2, \quad P_z^2 = P_0^2 \equiv (I - c_2)^2 - 1 - \frac{2}{\omega} I. \] (9)

These can be used to eliminate \( P_z \) in the equations of motion, giving

\[ \frac{dI}{dt} = -\frac{a_\ell}{2Y_0} \cos \xi, \]
\[ \frac{d\xi}{dt} = \left[-\eta \frac{P_0}{Y_0} + \frac{\Omega}{\omega Y_0} - 1 \right] + \frac{a_\ell}{4IY_0^2} \sin \xi, \]
\[ \frac{dz}{dt} = \frac{P_0}{Y_0} + \frac{a_\ell}{2P_0 Y_0} \left(1 + \frac{2}{\omega} I\right) \sin \xi, \] (10)

as a closed set of equations in \((I, \xi, z, t)\). Since \( P_0 \) is defined as always positive, explicit minus signs account for the motion of the particle toward the equator. The bracketed expression in the equation for \( dz/dt \) gives the lowest order resonance condition.

Retaining the wave term in \( H \) to first order gives

\[ \Upsilon \approx Y_0 - \frac{a_\ell}{2Y_0} \sin \xi, \quad P_z \approx -P_0 + \frac{a_\ell}{2P_0} \sin \xi, \] (11)

again allowing \( P_z \) to be eliminated. The correction to \( P_\xi/\Upsilon \) significantly affects \( \text{Eq. 7} \), giving

\[ \frac{dI}{dt} = -\frac{a_\ell}{2Y_0} \cos \xi, \]
\[ \frac{d\xi}{dt} = \left[-\eta \frac{P_0}{Y_0} + \frac{\Omega}{\omega Y_0} - 1 \right] + \frac{a_\ell}{4IY_0^2} \left(P_0(1 + P_0^2) + 2\eta I \left(1 + \frac{2}{\omega} I\right) + 2I \left(1 + \frac{2}{\omega} I\right) \sin \xi, \right. \]
\[ \frac{dz}{dt} = \frac{P_0}{Y_0} + \frac{a_\ell}{2P_0 Y_0} \left(1 + \frac{2}{\omega} I\right) \sin \xi, \] (12)

which is also a closed set of equations in \((I, \xi, z, t)\).

### 4 POSITION-DEPENDENT HAMILTONIAN EQUATIONS

Ginet and Heinemann (1990) and Ginet and Albert (1991) proceeded to transform to variables \((\xi, P_\xi, \mu, P_\mu, \phi, I)\), with \( P_\xi \) canonically conjugate to \( \xi \). However, doing so in an inhomogeneous setting reintroduces explicit time dependence in place of \( z \) dependence (see equation 68 of Ginet and Albert, 1991).

Instead, following Shklyar (1986), Albert (1993) divided the equations for \( dI/dt \) and \( d\xi/dt \) by the equation for \( dz/dt \) and attempted to write the results in Hamiltonian form using \( z \) as the independent variable. With a Hamiltonian \( K \) of the form

\[ K(I, \xi, z) = K_0(I, z) + K_1(I, z) \sin \xi, \] (13)
the choice

$$K_1 = -\frac{a_\ell}{2P_0}$$  \hspace{1cm} (14)

gives

$$\frac{dI}{dz} = -K_1 \cos \xi,$$  \hspace{1cm} (15)

which agrees with \((dI/dt)/(dz/dt)\) from Eq. 10. Using

$$K_0 = \eta(I - c_z) + P_0$$  \hspace{1cm} (16)

then gives

$$\frac{d\xi}{dz} = \frac{\eta P_0 + \gamma_0 - \Omega/\omega - a_\ell P_0^2 - 2I(\gamma_0 - \Omega/\omega)}{2I}\sin \xi$$  \hspace{1cm} (17)

or, once more using the lowest-order resonance condition,

$$\frac{d\xi}{dz} = \frac{\eta P_0 + \gamma_0 - \Omega/\omega - a_\ell P_0 + 2\eta I}{2I}\sin \xi.$$  \hspace{1cm} (18)

It is clear that the first-order term in \(d\xi/dz\) obtained by this procedure, which enforces the form of Eq. 13, is not the same as that of \((d\xi/dt)/(dz/dt)\) from either Eq. 10 or Eq. 12. The analogous disagreement is evident between equations 3.8 and 3.10 of Shklyar (1986), who treated the simpler case of an electrostatic wave and nonrelativistic protons. (Both equations give versions of \(d\xi/ds\), the typesetting error in equation 3.8 notwithstanding.)

## 5 SIMULATIONS AND DISCUSSION

The consequences of the disagreement in the first-order terms of the various \(\xi\) evolution equations is studied here numerically. We choose wave and particle parameters following Kitahara and Katoh (2019); Gan et al. (2020). A Taylor expansion of the geodipole magnetic field about the equator gives the variation along a field line as

$$B/B_{eq} = 1 + 4.5z^2/(LRe)^2,$$

with \(L = 4\), where \(Re\) is the radius of the Earth and \(LRe\) is the field line equatorial crossing distance. The cold electron density is constant, and chosen to give the ratio of plasma frequency to gyrofrequency as \(f_{pe}/f_{ce} = 4\) at the equator. The field-aligned whistler mode wave has frequency such that \(\omega/\Omega_e = 0.3\) at the equator. We consider ensembles of 24 electrons, with energy 20 keV, uniformly distributed in initial gyrophase. We take equatorial pitch angle \(\alpha_0 = 5^\circ\) and \(B_w/B_{eq} = 3 \times 10^{-4}\) (with \(B_w\) fixed), since this case seems particularly complex, exhibiting a mixture of conventional phase trapping and “anomalous” phase trapping (as opposed to the oppositely directed change associated with phase bunching for larger pitch angles). The particles are launched towards the equator \((z = 0)\) from a distance of \(1 Re\), and the equations of motion are advanced with a standard Runge-Kutta integrator with variable step size.

Figure 1 shows results using Eq. 2 (in red) and Eq. 3 (in blue). The sets of trajectories are not expected to be identical because of accumulated phase differences far from resonance. Nevertheless the overall behavior is very similar, showing no significant change until reaching resonance around \(z/Re = 0.35\), after which the
Equatorial pitch angle increases either over a sustained period (conventional phase trapping, PT) or transiently. The long-time behavior of the phase angle $\xi$ is oscillatory for PT but monotonic otherwise. This corresponds to the NL1 regime of Gan et al. (2020), also referred to as positive phase bunching (PPB).

Numerically, PT was identified by a change of sign in $d\xi/dt$ from one time step to the next after crossing below $z/R_e = 0.1$. Of 24 simulated particles, 10 became PT using either Eq. 2 or Eq. 3.

Figure 2 shows results using Eq. 10 (blue) or Eq. 12 (red). The equatorial pitch angle $\alpha_0$ obtained from the normalized variables $(I, z)$ via

$$\frac{B}{B_{eq}} \sin^2 \alpha_0 = \sin^2 \alpha = \frac{p^2}{p^2} = \frac{2(\Omega/\omega)I}{(1 - c_z^2)^2 - 1} \quad (19)$$

The behavior turns out to be very similar to the previous run, with 9 instances of PT, leading to $\alpha_0 \approx 25^\circ$ at $z = 0$, with the rest of the particles ending up with $\alpha_0$ spread between about $4^\circ$ and $14^\circ$.

Finally, Figure 3 shows results using Eqs. 15, 18. Again the results are very similar in the final $\alpha_0$ values reached by PT or PPB particles, and in the number of each. The number of PT particles in this run is 8, which does not deviate much from the previous values given the small number (24) of particles in each simulation.

We conclude that the reduced Hamiltonian $K(I, \xi, z)$ of Eq. 13 captures the nature of the particle dynamics, including APT and PPB, with fidelity comparable to the other models. This is propitious because it allows access to a rich body of work on invariant breaking at separatrix crossings (e.g., Cary et al., 1986), enabling both qualitative understanding and quantitative analytical estimates.

Some steps have already been taken in that direction. Figure 4 shows the results of Figure 3 in the $(I, \xi)$ plane, with PT trajectories (identified as above) over the interval $0.4 > z > 0$ shown in red, and become limited in $\xi$ while reaching large values of $I$. The remaining paths, shown in blue (over the interval $0.4 > z > 0.22$, for clarity), do not reach such large values of $I$ but are less

![Figure 5](image-url) Contours of $K(I, \xi, z)$, at several values of $z$ shortly before and after resonance crossing, according to motion based on $K(I, \xi, z)$. O-points are shown as diamonds, and X-points (if present) are shown with an X symbol, with the contour through them is in cyan. The red, dashed curve shows the initial value of $I$. 

Albert et al. Equations of Motion
Figure 3 shows contours of \( K(I, \xi, z) \) at several fixed values of \( z \) chosen during the trapping process, based on Figure 3. They indicate that at early times (large values of \( z \)) there is only a single, O-type fixed point, while an X-point and separatrix, as well as another O-point, form around the time of the trapping process. Contours circling the O-point at \( \xi = \pi/2 \) correspond to the (red) PT trajectories, and PPB trajectories (in blue) are connected to the development of the O-point at low \( I \) and \( \xi = -\pi/2 \). Similar contours, developed from Eq. 13 with further approximation, were obtained and studied by Albert et al. (2021), Artemyev et al. (2021). Quantitative analysis of separatrix formation and crossing, invariant breaking, and energy and pitch angle change will be the subject of future work.
