(Dated: January 21, 2014)

Focusing on the efficient probe and manipulation of single-particle spin states, we investigate the coupled spin and orbital dynamics of a spin 1/2 particle in a harmonic potential subject to ultrastrong spin-orbit interaction and external magnetic field. The advantage of these systems is the clear visualization of the strong spin-orbit coupling in the orbital dynamics. We also investigate the effect of a time-dependent coupling: Its nonadiabatic change causes an interesting interplay of spin and orbital motion which is related to the direction and magnitude of the applied magnetic field. This result suggests that orbital state manipulation can be realized through ultrastrong spin-orbit interactions, becoming a useful tool for handling entangled spin and orbital degrees of freedom to produce, for example, spin desirable polarizations in time interesting for spintronics implementations.

PACS numbers: 72.25.Rb, 73.63.Kv, 71.70.Ej

Spin-orbit interactions have been proven very useful for realization of spintronics [1] with electrons in nanosystems. On one hand, it has been demonstrated in theory and experiment that spins can be tuned by various electric means. [2–7] On the other hand, since spin-orbit coupling entangles spin and orbital motion, spin read-out is reachable by electric means. [8] Such combination points to the possibility of probing and manipulating spins hosted by semiconductor quantum dots. [9, 10] Using only electric fields. [5] The spin-orbit control of qubits is a promising tool that suggests to investigate the ultrastrong spin-orbit coupling regime to see all features of this technique. Extreme spin-orbit interactions can be achieved at the surfaces of semiconductors coated with heavy metals (see, e.g. [11, 12]), which allow for spin manipulation by electric fields. [13, 14] Rashba performed a detailed analysis of two-dimensional quantum dots with the ultrastrong spin-orbit coupling [15]. Very recently, it was recognized that fully controllable strong interactions, greatly beyond the range reachable in semiconductors, can be produced in ultracold atomic Bose and Fermi gases by optical means. [16, 17] Similar to electrons in quantum dots, these systems are located in harmonic traps and can demonstrate changeable in time spin-orbit coupling, opening new venues for studies of related dynamics.

The spin dynamics in these systems can be studied theoretically by analyzing the interactions between a harmonic oscillator and a two-level spin, making it similar to the Jaynes-Cummings model in quantum optics, as suggested by Debald and Emary. [18] This is a wide-purpose model (see e.g. [19, 21, 22]) applied in different fields of condensed matter and quantum optics such as cavity quantum electrodynamics, trapped ions, and superconducting qubits (see [23, 24] for recent results). In addition, carbon nanotubes holding electron spins deeply coupled to the vibrational modes [25] can be described with the Jaynes-Cummings model.

The systems with spin-orbit couplings have several advantages not applicable elsewhere. We mention just two. First, the coordinate dependence of the spin density makes it possible to visualize the effects of strong coupling in terms of particle position and measurable spin densities. Second, spin-orbit interaction and the Zeeman field can be made time-dependent [26–28] making the relevant dynamics both in spin and coordinate spaces accessible. These effects provide strongly nontrivial extensions of the conventional Jaynes-Cummings model.

In a quantum dot, a spin-orbit strength \( \alpha = \xi e E_z \), where \( \xi \) is the material- and structure-dependent constant, can be induced by applying an external electric field \( E_z \). [29] A scheme for the experimental setup is given in Fig. 1. In cold atomic gases this time-dependent mod-

![FIG. 1: (Color online) (a) Setup scheme for external generation of spin-orbit coupling through a bias voltage. Bold solid curves indicate the confining parabolic potential. (b) A non-adiabatic time-dependent field can cause electron displacement with spin rotation.](image-url)
to the system to system. For InSb-based quantum dots, where $\Delta \approx \alpha/\sqrt{\langle n \rangle}$, ground state of the harmonic oscillator is the direct product of $|n\rangle$ where $m$ is the particle effective mass, $\Delta$ and $\alpha$ are the Zeeman splitting and tilt angle of the magnetic field, respectively, $\sigma_\Delta = \sigma_x \sin \theta + \sigma_z \cos \theta$ is the corresponding spin projection, and $\sigma_x, \sigma_z$ are the Pauli matrices. In the second quantization this Hamiltonian reads

$$\hat{H} = \hbar\omega(\hat{a}^\dagger \hat{a} + 1/2) + i\hbar g(t)(\hat{a}^\dagger - \hat{a})\sigma_x + \frac{\alpha}{2}\sigma_\Delta,$$  \hspace{1cm} (1)$$

where $\hat{a}^\dagger$ and $\hat{a}$ are the creation and annihilation operators, respectively, and $g = \alpha\sqrt{m/2\hbar \omega}$ is a dimensionless coupling constant, which can be understood as the ratio of the characteristic anomalous spin-dependent velocity $\alpha/h$ to the characteristic quantum velocity spread in the ground state of the harmonic oscillator $\sqrt{\hbar/m}$, or as the ratio of the quantum oscillator length $l_0 = \sqrt{\hbar/m\omega}$ to the spin precession length $h^2/m\alpha$.

We use the basis of spin orbitals $|n\rangle |\sigma\rangle$, composed of the eigenstates of $\hat{a}^\dagger \hat{a}$, $|n\rangle$, and those of $\sigma_x, |\sigma\rangle \equiv |\uparrow\rangle_z$ and $|\downarrow\rangle_z$ with respect to the $z$-axis. Numerical values of $g$ strongly vary from system to system. For InSb-based quantum dots, where $\alpha$ can reach $10^{-5}$ meV cm, $m$ is of the order of 0.02 of the free electron mass, and $\omega \sim 10^{12}$ s$^{-1}$, one can expect $g \approx 1$. For cold fermions such as $^{40}$K, where $\alpha/h$ can be of the order of 10 cm/s and $\omega \sim 10^3$ s$^{-1}$, $g$ can be of the order of 10.

To make connection to previous works on the ultrastrong regime (see, e.g., [19]), first we investigate the effect of a constant coupling. The eigenstates of the full Hamiltonian $|\phi_k\rangle$ have the form $\sum_n |n\rangle |\sigma\rangle |\uparrow\rangle_z + c^+_n |\downarrow\rangle_z$ with the expansion coefficients $c^+_n$ and $c^-_n$; the normalized orbitals are expressed in the $x$-representation as

$$\langle n|x \rangle = \left(\frac{1}{\pi l_0^2 2^n (n!)^2}\right)^{1/4} \exp \left[-\frac{x^2}{2l_0^2}\right] H_n \left[\frac{x}{l_0}\right],$$  \hspace{1cm} (3)$$

where $H_n$ is the $n$-th order Hermite polynomial. In the limit of a very weak coupling, $g \ll 1$, in an arbitrarily directed magnetic field, $|\phi_k\rangle$ contains five main contributions. The main one is the direct product of $|n\rangle$ and eigenstate of $\sigma_\Delta$. The other four are perturbative terms of direct products of $|n \pm 1\rangle$ and eigenstates of $\sigma_\Delta$. At $\theta = 0$, corresponding to the conventional Jaynes-Cummings model, spin selection rules exclude two of these four states. Moreover, at $\theta = 0$, in the eigenstates the contributions with different spatial parities have opposite spins. The expectation value of the velocity in the eigenstates is zero, $\langle v \rangle = d\langle x \rangle / dt = 0$; however, the mean momentum is finite:

$$\langle v \rangle = \frac{i}{\hbar} \langle [H, x] \rangle = \frac{\hbar}{m} \langle k \rangle + \frac{\alpha}{\hbar} \langle \sigma_x \rangle = 0,$$

$$\langle k \rangle = -\sqrt{\frac{g}{l_0}} \langle \sigma_x \rangle.$$  \hspace{1cm} (4)$$

Correspondingly, for the coordinate $\langle \phi_k | x | \phi_k \rangle = 0$. Equation (4) corresponds to zero mechanical momentum $\hbar \mathbf{k} - \mathcal{A}$ for the gauge $\mathcal{A} = - m \alpha \sigma_x / \hbar$. The total spectrum results from the magnetic-field mixing of two parabolic branches, that for $\langle k \rangle = -\sqrt{2g/l_0}$ when the spin state is $|\uparrow\rangle_x$, and that for $\langle k \rangle = \sqrt{2g/l_0}$ when it is $|\downarrow\rangle_x$.

To show the advantages of systems with spin-orbit coupling, we calculate the spatially resolved spin densities $\rho_j(x,y,z) = x,y,z$, providing valuable info about the system. For an arbitrary state $|\psi\rangle$, presented in the form $\sum_n |n\rangle (a^+_n \langle \uparrow\rangle_z + a^-_n \langle \downarrow\rangle_z)$, these functions are defined as

$$\rho_j(x) = \sum_{n,m} \langle n|x \rangle \langle m|a^*_n a^m_j \sigma_j (a^+_n a^-_m) \rangle.$$

We focus on a particle in the ground state and take $\theta = \pi/4$ as an example. The densities $\rho_j(x)$ are presented in Fig. 2. The integrals of $\rho_j(x)$ over the $x$-coordinate are the spin expectation values.

![FIG. 2: (Color online) Nonzero spin densities $\rho_{x,z}$ for different $g$ values when the electron is at the ground state. Note that $\rho_x$ and $\rho_z$ merge for smaller $g$ coupling. Here and below we use a truncated Hilbert space of 64 states, sufficient to study ultrastrong spin-orbit coupling. The Zeeman splitting in all calculations is taken as $\Delta = 0.5\hbar\omega$.](image-url)
Next, we analyze the coupled dynamics of a system put away from an eigenstate. For this purpose, we choose as a typical example an eigenstate of $\sigma_\Delta$ antiparallel to the magnetic field:

$$|\psi(0)\rangle = |0\rangle(-\sin(\theta/2)|\uparrow\rangle_z + \cos(\theta/2)|\downarrow\rangle_z).$$  (6)

The time dependence is obtained from $|\psi(t)\rangle = \sum_i \zeta_i |\phi_i\rangle e^{-iE_i t/\hbar}$, where $\zeta_i$ are the corresponding expansion coefficients. We study the dynamics of spin densities for $\theta = \pi/4$ and $g = 1$. The particle oscillations are shown in Fig. 3(a). The Gaussian-like shape of $\rho_x$ is robust against time; however, those of $\rho_y$ and $\rho_z$ (not shown in the Figure) are fully changed. As a consequence, we see a strong correlation between spin state and position of the particle even in the dynamical regime.

One of the main advantages of quantum dots and cold atoms is the ability to manipulate the strength of spin-orbit coupling and, thus, to cause dynamics in the orbital and spin channels. The time-dependent spin-orbit coupling can be used for generation of spin currents in two-dimensional electron gas [30] and spin separation in two-electron quantum dots similar to that predicted in Ref. [31]. Here we take a single-period perturbation

$$g(t) = g_0 \sin(\Omega t)$$ at frequency $\Omega$, fast enough to yield an appreciable nonadiabatic behavior, but being sufficiently slow to allow using the available electrical and optical means to generate the spin-orbit interaction. To clearly see the effects of strong spin-orbit coupling, we compare below the obtained numerically exact result with the perturbation theory.

To use the perturbation theory we take the basis of first four eigenstates

$$\psi_1 = |0\rangle|\downarrow\rangle_z, \quad \psi_2 = |0\rangle|\uparrow\rangle_z, \quad \psi_3 = |1\rangle|\downarrow\rangle_z, \quad \psi_4 = |1\rangle|\uparrow\rangle_z$$  (7)

where time-dependent wavefunction becomes

$$\psi(t) = a_1(t)\psi_1 + a_3(t)\psi_3 e^{-i\omega t} + a_4(t)\psi_4 e^{-i(\omega + \Delta)t}.$$  (8)

The assumption time-dependence yields the expansion coefficients

$$a_3(t) = -g_0 \sin \theta \int_0^t \sin(\Omega \tau e^{i\omega \tau}) d\tau$$  (9)

$$a_4(t) = g_0 \cos \theta \int_0^t \sin(\Omega \tau) e^{i(\omega + \Delta)\tau} d\tau.$$  (10)

The expectation values of coordinate and spin projection onto the magnetic are expressed as:

$$\langle x(t) \rangle \equiv \langle \psi(t) | \hat{x} | \psi(t) \rangle = \frac{1}{\sqrt{2}} (a_3(t)e^{-i\omega t} + \text{c.c.})$$  (11)

$$\langle \sigma_\Delta(t) \rangle \equiv \langle \psi(t) | \sigma_\Delta | \psi(t) \rangle = -1 + 2 |a_4(t)|^2.$$  (12)

These perturbation theory formulas show the role of the direction of magnetic field on the spin and spatial dynamics, not present in the conventional Jaynes-Cummings model and allowing to extend the abilities for coordinate and spin manipulation.

We treat the problem numerically for a single period $T = 2\pi/\Omega$ [32], beginning with $\theta = 0$, where Zeeman and spin-orbit fields are orthogonal, similar to the Jaynes-Cummings model. Figure 4 demonstrates time dependence of $\langle \sigma_\Delta(t) \rangle$ for different couplings $g_0$ and comparison with the perturbation result for $g_0 = 0.5$ in the inset. As it can be seen in Fig. 4 spin projection at the magnetic field changes strongly with time, corresponding to the spin rotation due to the spin-orbit coupling, and remains constant, as expected, after the change stops. The value of this projection after the end of the perturbation corresponds to the degree of nonadiabaticity of this process. It is interesting to mention the appearance of plateaus at strong spin-orbit coupling regime. These plateaus show that even a low-frequency dynamics is strongly nonadiabatic. The reason is the following. In the presence of spin-orbit coupling and magnetic field with $\theta = 0$, the splitting of the ground-state doublet, $\Delta \exp(-2g^2) \ll \Delta$, is small due to weakly overlapping eigenstates in the momentum space, as discussed after Eq. [33]. As a result, even very slow changes in the system parameters cannot...
be treated adiabatically. Here spatial motion does not occur \( \langle x(t) \rangle = 0 \), in agreement with Eq. (11).

Next, we take the state of Eq. (6), with \( \theta = \pi/4 \) as the initial one to demonstrate the qualitative role of the magnetic field direction. First qualitative effect is nonzero oscillations of the coordinate, nonmonochromatic at \( t < T \), as depicted in Fig. 5. The oscillations in \( \langle x(t) \rangle \) are caused mainly by transitions between ground and first excited eigenstates of the model Hamiltonian; these states get mixed by the strong coupling. The amplitude of oscillations increases with \( g_0 \), as expected, but also with \( \Omega \). The behavior strongly depends on the frequency and amplitude of spin-orbit coupling, as can be seen by comparison of adiabatic and nonadiabatic plots. After the end of perturbation, the coordinate oscillates at the frequency \( \omega \). Next qualitative difference is in the behavior of \( \langle \sigma_\Delta(t) \rangle \). Here, in the case of a strong static spin-orbit coupling, the splitting of the lowest doublet is \( \Delta \cos \theta \). We see the effects of nonadiabatic perturbation and strong coupling in Fig. 6. Dependent on \( g_0 \) and \( \Omega \), different regimes in the dynamics of \( \langle \sigma_\Delta(t) \rangle \) are possible: the system either returns to the initial state after the end of perturbation or switches to other states. The switching effect depends on the frequency of the field. At a small frequency, the dynamics is more adiabatic and perturbative, while for the larger frequency the switching can occur. The inset shows that the perturbation theory works at short time, while at longer times more states participate, and the results become different. From this plot we can formulate the condition of strong spin-orbit coupling for a given system as a transition from peak-like (“weak” or “moderate” coupling) to step-like (“strong”) evolution of \( \langle \sigma_\Delta(t) \rangle \). It is interesting to mention that the transition and, therefore, the definition of the coupling strength in

FIG. 5: (Color online) Dynamics of particle mean coordinate under time-dependent strength \( g(t) = g_0 \sin(\Omega t) \). Lines are marked by corresponding \( g_0 \) values. Inset shows comparison of the exact (dashed line) and perturbation theory (solid line) results for \( g_0 = 0.5 \).

a dynamical system depends on the frequency of the applied external field.

In summary, we have investigated how strong dynamical spin-orbit couplings can be applied to probe and manipulate spins of electrons in semiconductor quantum dots and cold atoms in parabolic confinement through the correlated spin and orbital motion. We reveal the importance of the tilt angle of the applied magnetic field, the effect strongly beyond the conventional Jaynes-Cummings model. The obtained dynamics shows that, under a strong constant coupling, a particle oscillates in correlation with its spin orientation. The motion of the particle can be influenced by time-dependent coupling with the result strongly dependent on all parameters. We observe a transition from periodic to step-like behavior of spin component parallel to the magnetic field with increasing the coupling strength. This fact clarifies the way to define qualitative effect if the ultrastrong spin-orbit coupling. The present work widens the applicability of the spin-orbit control, as it covers different strengths for the induced interaction and tilt angles for the applied magnetic field. It also emphasizes the usability of electric and optical fields for spin probe and manipulation, which are crucial for spintronics. These results may also be of interest for quantum optics and quantum information realizations.
