Abstract

We present a calculation of interference effects in $Hjj$ production via gluon fusion and via vector boson fusion, respectively, beyond tree level. We reproduce results recently discussed in the literature, but go beyond this calculation by including a class of diagrams not considered previously. Special care is taken in developing a numerically stable and flexible parton level Monte-Carlo program which allows us to study cross sections and kinematic distributions within experimentally relevant selection cuts. Loop-induced interference contributions are found to exhibit kinematical distributions different in shape from vector boson fusion. Due to the small interference cross section and cancelation among different quark flavor contributions their impact on the signal process is found to be negligible in all regions of phase space, however.
1 Introduction

Higgs production via weak boson fusion (WBF), i.e., the reaction $pp \rightarrow H jj$, mediated by $t$-channel weak boson exchange, constitutes a particularly promising production mechanism for the Higgs boson. Due to the distinctive signature of two hard jets accompanying the decay products of the Higgs boson, this channel is discussed as possible discovery mode for a scalar, CP-even boson as predicted by the Standard Model (SM) \cite{1,2}, and as powerful tool for a later determination of its couplings \cite{3}. Furthermore, WBF could be employed in studying deviations from the SM expectations and help to spot signatures of physics beyond the standard model. This can only be achieved, however, if accurate measurements are matched by precision calculations of SM signal and background processes and predictions for possible new physics scenarios.

Next-to-leading order (NLO) QCD corrections to the SM $pp \rightarrow H jj$ WBF signal are available for cross sections \cite{4} and distributions \cite{5}. At the same level of accuracy, some of the most important background processes such as $V jj$ \cite{6} and $VV jj$ \cite{7} production in WBF, $tt$ \cite{8} and $ttj$ \cite{9} production are known. Beyond the standard model, Monte Carlo studies have been performed for WBF $H jj$ production in the presence of anomalous gauge boson couplings \cite{10} and in the context of supersymmetric models \cite{11}. Recently, NLO electroweak (EW) corrections for cross sections and distributions have been presented \cite{12}. Finite parts of the NNLO-QCD corrections have been calculated in \cite{13} and found to be negligible.

An irreducible background to the Higgs signal in WBF is constituted by $H jj$ production via gluon fusion (GF). Higgs production via GF is mediated by a heavy quark loop. An exact calculation of $pp \rightarrow H jj$ via GF at the lowest non-vanishing order has been performed in \cite{14}. NLO-QCD calculations have made use of the large top mass limit, where the coupling of the Higgs to gluons is parameterized by an effective vertex \cite{15}. Phenomenological studies have revealed the complementary features of the WBF and the GF $H jj$ production processes, suggesting search strategies for suppressing the GF channel as background to the clean WBF signature. More recently, GF has also been considered as a signal process \cite{16}, because the dijet angular correlation is sensitive to the CP parity of the Higgs boson.

Although GF and WBF are usually considered as separate reactions, their interference in the $qq \rightarrow qqH$ subprocesses is possible. In Refs. \cite{17,18} interference effects at tree-level due to identical flavor effects have explicitly been shown to be tiny and entirely negligible for cross sections and distributions. The authors of \cite{18} speculated that loop-induced interference effects should be large. An explicit calculation revealed, however, that loop-induced interference effects are also small \cite{19}.

We present a similar calculation for the same process, studying interference effects between GF and WBF which emerge beyond tree level. Being performed with entirely different methods, our work confirms the main findings of Ref. \cite{19} and extends it in two respects:
First, we include a class of real emission contributions which has been neglected in [19]. Second, we develop a fully flexible parton level Monte Carlo program which allows us to study cross sections as well as arbitrary distributions within experimentally feasible selection cuts. Being implemented in the modular vbfnlo environment [20], the impact of the interference contributions on the WBF signal is studied in detail.

We give a thorough outline of our calculation in Sec. 2. Numerical results are discussed in Sec. 3. We conclude with a brief summary in Sec. 4.

2 Elements of the calculation

2.1 General framework

$Hjj$ production in WBF mainly proceeds via quark scattering, $qq\rightarrow qqH$. In Ref. [17] contributions from identical-flavor annihilation processes such as $q\bar{q}\rightarrow Z^*\rightarrowZH$ with subsequent decay $Z\rightarrow q\bar{q}$ or similar $WH$ production channels have been shown to be entirely negligible in the phase-space regions where WBF can be observed experimentally. In the same work, identical quark interference effects from $qq\rightarrow qqH$ and crossing-related channels were demonstrated to affect cross sections and kinematic distributions at an insignificant level. This finding was confirmed by Ref. [18]. In the following we will therefore restrict our discussion to quark scattering via exchange of a weak boson in the $t$-channel, i.e. the reaction $qq'\rightarrow qq'H$, where $q$ and $q'$ stand for quarks of different flavor, see Fig. 1. We will refer to the respective tree level scattering amplitude by $\mathcal{M}^{(0)}_{WBF}$. Color factors are not included in $\mathcal{M}^{(0)}_{WBF}$ and will be denoted separately. Adaptation for the crossed processes $qq'\rightarrow q\bar{q}'H$, $\bar{q}q'\rightarrow q\bar{q}'H$, and $\bar{q}q\rightarrow \bar{q}\bar{q}'H$ is straightforward.

Higgs production in quark scattering reactions, mediated by a gluon in the $t$-channel which couples to the Higgs boson via a top-quark loop is depicted in Fig. 2(a). For a Higgs mass well below the top-pair production threshold, the coupling of the gluon to a scalar,
CP-even Higgs boson can be parameterized by an effective Lagrangian of the form

$$\mathcal{L}_{\text{eff}} = \frac{\alpha_s}{12\pi v} H G_{\mu\nu}^a G^{a\mu\nu}, \quad (2.1)$$

where $G$ denotes the gluonic field tensor and $v = 246$ GeV the vacuum expectation value of the Higgs boson. The respective Feynman diagram is depicted in Fig. 2(b). Throughout this work we will employ this effective coupling for the $Hgg$ vertex. In the following, we denote the lowest order scattering amplitude for $qq' \to qq'H$ via GF by $\mathcal{M}^{(0)}_{\text{GF}}$. Analogous to the WBF case, color factors are not included in the amplitude $\mathcal{M}^{(0)}_{\text{GF}}$.

At tree level, the GF and WBF production channels for $qq' \to qq'H$ do not interfere due to the color structure of the two processes. An interference between GF and the neutral-current contributions to WBF becomes possible, however, if an additional gluon emission is considered. Flavor-changing $WW$-fusion diagrams cannot interfere with the flavor-conserving gluon exchange diagrams. For the neutral-current mode, two types of loop contributions emerge:

1. One-loop diagrams, where a gluon is exchanged between the upper and the lower fermion line in the WBF diagram of Fig. 1 (for $V = Z$). The respective loop amplitude $\mathcal{M}_{\text{WBF}}^{(1-\text{loop})}$ yields non-vanishing contributions at order $\mathcal{O}(\alpha^2 \alpha_s^3)$ when interfering with the tree-level GF production amplitude $\mathcal{M}_{\text{GF}}^{(0)}$. Here, we count the $HZZ$ coupling as $\alpha v$ and the $Hgg$ coupling as $\alpha_s/v$; see Fig. 3 for a representative Feynman graph.

2. GF diagrams with an extra gluon exchanged between the upper and the lower quark line, $\mathcal{M}_{\text{GF}}^{(1-\text{loop})}$, also contribute at order $\mathcal{O}(\alpha^2 \alpha_s^3)$ when interfering with the tree-level $ZZ$-fusion amplitude $\mathcal{M}_{\text{WBF}}^{(0)}$ as depicted in Fig. 4.

All relevant loop diagrams involve pentagon diagrams. Box, triangle, and bubble diagrams do not contribute due to color conservation.

At the same order in the perturbative expansion, real emission diagrams have to be considered. Non-vanishing neutral-current contributions to the $qq' \to qq'gH$ process arise...
Figure 3: Representative loop contribution to the interference cross section for $qq' \rightarrow qq'H$ via WBF and GF, respectively, at order $\mathcal{O}(\alpha^2\alpha_s^3)$, where the 1-loop WBF amplitude interferes with the tree-level GF amplitude.

Figure 4: Representative loop contribution to the interference cross section for $qq' \rightarrow qq'H$ via WBF and GF, respectively, at order $\mathcal{O}(\alpha^2\alpha_s^3)$, where the 1-loop GF amplitude interferes with the tree-level WBF amplitude.

from the interference of scattering diagrams like those depicted in Fig. 5. The upper diagram shows an interference between gluon emission from the $q$-line in the WBF amplitude and from the $q'$-line in the GF amplitude. In the lower diagram the inverse configuration is illustrated. Interference graphs where both gluons are emitted from the same quark line cancel out when colors are summed over. The same applies to those graphs of the GF amplitude where a gluon is attached to the internal gluon line or to the $Hgg$ vertex. We denote the real emission amplitudes for $qq' \rightarrow qq'gH$ that do not cancel by $\mathcal{M}_{\text{WBF}}^{(\text{real})}$ and $\mathcal{M}_{\text{GF}}^{(\text{real},t)}$, respectively. Further contributions to $qq' \rightarrow qq'gH$ scattering via GF, referred to as $\mathcal{M}_{\text{GF}}^{(\text{real},f)}$, arise from a topology absent in $qq' \rightarrow qq'H$, where the Higgs boson is radiated off the final-state gluon rather than the $t$-channel exchange boson, see Fig. 6.

Since only diagrams with gluons being emitted from different quark lines contribute to the real emission, no collinearly divergent configurations emerge. Singularities arise, however, when the final-state gluon in $\mathcal{M}_{\text{WBF}}^{(\text{real})}$ or $\mathcal{M}_{\text{GF}}^{(\text{real},t)}$ is soft. Such divergences in the real emission diagrams are eventually canceled by respective singularities in the virtual contributions. To isolate them in intermediate steps of the calculation, a proper regularization scheme has to be utilized. We therefore perform our calculation in $d = 4 - 2\epsilon$ dimensions, implementing both the dimensional regularization and the dimensional reduction prescriptions [21].
Figure 5: Representative cut amplitudes for the $qq' \rightarrow qq'gH$ process via the interference of WBF and GF amplitudes, at order $\mathcal{O}(\alpha^2\alpha_s^3)$.

Figure 6: Representative diagram contributing to the interference of $qq' \rightarrow qq'gH$ via WBF and GF, respectively, at order $\mathcal{O}(\alpha^2\alpha_s^3)$.

that both schemes yield the same results provides a test of our calculation.

2.2 Virtual contributions

For the discussion of the loop contributions to $Hjjj$ production via WBF and GF, respectively, we resort to the quark-quark scattering process

$$q(p_a) + q'(p_b) \rightarrow q(p_1) + q'(p_2) + H(p_H).$$  (2.2)
The one-loop amplitudes we are considering,

$$\mathcal{M}_{WBF}^{(1\text{-loop})} = \sum_{k=1}^{13} F_{k}^{WBF} (p_a, p_1; p_b, p_2) \hat{M}_k,$$

$$\mathcal{M}_{GF}^{(1\text{-loop})} = \sum_{k=1}^{13} F_{k}^{GF} (p_a, p_1; p_b, p_2) \hat{M}_k,$$

(2.3) (2.4)

can be expressed as linear combinations of process-dependent pre-factors, $F_{k}^{WBF}$ and $F_{k}^{GF}$, and fermion spinor chains $\hat{M}_k$, so-called “standard-matrix elements” (SME). Following Ref. [22], we introduce

$$\Gamma_{\{\alpha,\alpha\beta\gamma\}}^{qq} = \bar{u}(p_1, \lambda_1) \{\gamma_\alpha, \gamma_\alpha \gamma_\beta \gamma_\gamma\} u(p_a, \lambda_a),$$

$$\Gamma_{\{\alpha,\alpha\beta\gamma\}}^{q'q'} = \bar{u}(p_2, \lambda_2) \{\gamma_\alpha, \gamma_\alpha \gamma_\beta \gamma_\gamma\} u(p_b, \lambda_b),$$

(2.5) (2.6)

where $u(p_i, \lambda_i)$ denotes the quark spinor for fermion $i$ with momentum $p_i$ and helicity $\lambda_i = \pm 1/2$. For contractions with an arbitrary momentum $p$ we use the shorthand notation $\Gamma_p \equiv \Gamma_{\mu \mu}$. For the reaction (2.2), 13 SME emerge,

$$\hat{M}_{\{1,2\}} = \Gamma_{\alpha}^{qq} \Gamma_{\alpha,\alpha\beta\gamma}^{q'q'}, \hat{M}_{\{3,4\}} = \Gamma_{\alpha\beta\gamma}^{q'q'} \Gamma_{\alpha,\alpha\beta\gamma}^{p,p_b},$$

$$\hat{M}_{\{5,6\}} = \Gamma_{\alpha}^{qq} \Gamma_{\alpha,\alpha\beta\gamma}^{q'q'}, \hat{M}_{\{7,8\}} = \Gamma_{\alpha\beta\gamma}^{q'q'} \Gamma_{\alpha,\alpha\beta\gamma}^{p,p_1},$$

$$\hat{M}_{\{9,10\}} = \Gamma_{\alpha\beta\gamma}^{qq} \Gamma_{\alpha,\alpha\beta\gamma}^{q'q'}, \hat{M}_{\{11,12\}} = \Gamma_{\alpha\beta\gamma}^{q'q'} \Gamma_{\alpha,\alpha\beta\gamma}^{p_p, p_{p_1}},$$

$$\hat{M}_{13} = \Gamma_{\alpha\beta\gamma}^{qq} \Gamma_{\alpha\beta\gamma}^{q'q'}.$$

(2.7)

The SME are computed in two independent ways by means of the helicity amplitude formalism of Ref. [23] and the Weyl–van der Waerden formalism of Ref. [24], respectively.

The coefficients $F_{k}^{WBF}$ and $F_{k}^{GF}$ contain coupling factors and remnants of scalar and tensor loop integrals, up to rank two and up to five propagator denominators. For the computation of the tensor coefficients we have employed two different methods and developed two completely independent computer codes. These codes agree with a relative accuracy better than $10^{-8}$ for non-exceptional phase-space points away from the zeroes of the Gram determinant. The basic features of the two implementations are described in the following.

**Passarino–Veltman type tensor reduction:**

In one of our implementations, we have used the conventional Passarino–Veltman (PV) reduction formalism [25, 26] for the computation of tensor integrals up to boxes, generalizing the method in a straightforward manner to pentagons in the framework of dimensional regularization. All tensor coefficients are expressed in terms of scalar master integrals in $(4-2\epsilon)$ dimensions with a regularization scale $\mu$. Singularities are manifested as single or double poles in $\epsilon$. For GF, only integrals with vanishing internal masses emerge. Expressions for the
respective four-point integrals with up to two external off-shell legs are taken from Ref. [27].
The infrared divergent two- and three-point integrals can be extracted from Refs. [26, 28]. For WBF, scalar integrals with up to two massive propagators are needed. We have calculated the divergent box integrals by extracting corresponding expressions in mass regularization from Refs. [29, 30]. Employing the method described in Ref. [28] these expressions are then transformed to dimensional regularization (see App. A). The remaining finite scalar integrals were calculated with LoopTools [31], and have been compared numerically to the expressions given in Ref. [19].

The double and single pole terms of the coefficients $F_{k}^{\text{WBF}}$ and $F_{k}^{\text{GF}}$ are calculated analytically with the help of mathematica. To this end, we perform the tensor reduction in two steps: first for the singular pieces in $d = 4 - 2\epsilon$ dimensions, and then in four dimensions for the non-singular terms. For tensor integrals up to rank two this separation is trivial, since poles do not mix with the finite terms when the reduction formalism is applied. Due to the absence of collinear configurations in the interference process we are focusing on, all double poles present in divergent scalar integrals cancel in the full loop amplitudes. This cancelation occurs for each coefficient $F_{k}^{\text{GF}}, F_{k}^{\text{WBF}} (k = 1, \ldots, 13)$ separately. The remaining single poles for the GF and WBF contributions are proportional to the respective tree-level amplitudes such that the singular parts of the loop-induced interference contribution take the form

$$
\sum 2\text{Re} \left[ \mathcal{M}_{\text{WBF}}^{(1-\text{loop})} \mathcal{M}_{\text{GF}}^{(0)*} + \mathcal{M}_{\text{GF}}^{(1-\text{loop})} \mathcal{M}_{\text{WBF}}^{(0)*} \right]_{\text{sing}} = -\frac{\alpha_s}{2\pi} \Gamma(1 + \epsilon) \mu^{2\epsilon} \frac{1}{\epsilon} \sum 2\text{Re} \left[ \mathcal{M}_{\text{WBF}}^{(0)} \mathcal{M}_{\text{GF}}^{(0)*} + \mathcal{M}_{\text{GF}}^{(0)} \mathcal{M}_{\text{WBF}}^{(0)*} \right] \times \left[ \ln \left( \frac{s_{ab}}{4\pi \mu^2} \right) - \ln \left( \frac{-s_{a2}}{4\pi \mu^2} \right) - \ln \left( \frac{-s_{b1}}{4\pi \mu^2} \right) + \ln \left( \frac{s_{12}}{4\pi \mu^2} \right) \right],
$$

where $\sum$ denotes averaging over initial-state spin degrees of freedom and summation over final-state ones. Here, we have introduced the notation $s_{ij} = 2p_i \cdot p_j$. We will see below that the divergent pieces are canceled exactly by respective poles in the real emission contributions. In our Monte-Carlo program we thus retain only the finite parts of the scalar integrals.

The tensor reduction for the non-singular terms can then be performed numerically.

**Denner–Dittmaier type tensor reduction:**

In an independent implementation, we have performed the reduction from five-point to four-point integrals by means of the Denner–Dittmaier (DD) reduction formalism [32], while still reducing the four-point integrals with the conventional PV tensor reduction discussed above. Like the PV method the DD reduction is formulated in $d$ dimensions, but has the advantage of avoiding subtle cancelations, which can spoil the numerical integration. Such cancelations originate from terms with a very small Gram determinant in the denominator.

---

1. We identified a misprint in one of the respective expressions of Ref. [19].
If two or more external momenta are linearly dependent, the Gram determinant vanishes and we encounter numerical instabilities in the respective phase-space regions. In the PV approach, one power of the Gram determinant appears, in general, in each step of the iterative reduction to lower-rank tensors, and also when an \( N \)-point function is reduced to \( (N - 1) \)-point integrals. In contrast to the PV reduction, the DD approach avoids Gram determinants in the denominator in the reduction from five-point to four-point integrals. In addition, it reduces the rank of the emerging four-point tensor integrals by one. A similar reduction formalism has also been given in [33].

As expected, the DD method turns out to be numerically far more stable than the PV reduction. Throughout our numerical studies, we will therefore resort to the DD formalism. The PV reduction is used only to test our results.

\[ q(p_a) + q'(p_b) \rightarrow q(p_1) + q'(p_2) + g(p_g) + H(p_H) \] (2.9)

\[ M^{(\text{real})}_{WBF} + M^{(\text{real})}_{GF} = M^{(\text{real},t)}_{GF} + M^{(\text{real},f)}_{GF} \]

\[ \sum 2 \text{Re} \left[ M^{(\text{real})}_{WBF} M^{(\text{real})*}_{GF} + M^{(\text{real})}_{GF} M^{(\text{real})*}_{WBF} \right] \]

\[ \text{madgraph} [34] \] and found complete agreement within the numerical accuracy of our program.

2.4 Subtraction procedure

The real emission contributions contain soft divergences which eventually cancel the corresponding poles in the virtual contributions, cf. Eq. (2.8). A convenient method for isolating the singularities is the so-called phase-space slicing procedure. It relies on splitting the \( q'q'gH \) phase space into soft and hard regions by a suitable cutoff parameter and performing the integration of the real emission contributions in the two regimes separately. To check our results we implement two conceptually different slicing methods: The two-cutoff slicing method of Ref. [35] which has been developed in the context of mass regularization, and the phase-space slicing method of Ref. [36] which utilizes a Lorentz-invariant cutoff and dimensional regularization.
2.4.1 Lorentz-invariant phase-space slicing

The slicing method of Ref. \[36\] divides the phase space of the final-state particles into a hard region where all partons can be resolved and an infrared region for soft and collinear configurations. In general, special care is necessary to separate soft and collinear regions in order to avoid double counting of singular configurations. Since the interference contributions of our interest are free of collinear singularities, the formalism can be greatly simplified, however. In the case of $qq'\rightarrow qq'gH$ the gluon is considered as infrared when

$$s_{ig} = 2p_i \cdot p_g < s_{\text{min}}, \quad \text{with } i = a, b, 1, 2$$

for an arbitrarily small cutoff parameter $s_{\text{min}}$, where we closely follow the notation of Ref. \[37\]. While for collinear configurations only one $s_{ig}$ is small, the soft region is defined by requiring at least two invariants to be smaller than $s_{\text{min}}$. The partonic real emission cross section can then be decomposed into a soft and a hard part,

$$\hat{\sigma}^{\text{real}} = \hat{\sigma}^{\text{soft}} + \hat{\sigma}^{\text{hard}}.$$  \hspace{1cm} (2.11)

The integration over the gluonic degrees of freedom is performed analytically in $\hat{\sigma}^{\text{soft}}$, but purely numerically in $\hat{\sigma}^{\text{hard}}$.

In order to calculate $\hat{\sigma}^{\text{soft}}$ we use the factorization properties of the real emission amplitude in the soft limit. As the energy of the emitted gluon becomes small, the $qq'\rightarrow qq'gH$ interference amplitudes can be approximated by the tree-level interference amplitudes multiplied by a sum of eikonal terms,

$$\sum 2\text{Re} \left[ M_{\text{WBF}}^{(\text{real})} M_{\text{GF}}^{(\text{real})} + M_{\text{GF}}^{(\text{real})} M_{\text{WBF}}^{(\text{real})} \right]_{\text{soft}} = (4\pi \alpha_s) \mu^{2\epsilon} \sum 2\text{Re} \left[ M_{\text{WBF}}^{(0)} M_{\text{GF}}^{(0)*} + M_{\text{GF}}^{(0)} M_{\text{WBF}}^{(0)*} \right]$$

$$\times \left[ \frac{2s_{ab}}{s_{ag}s_{bg}} - \frac{2s_{a2}}{s_{ag}s_{2g}} - \frac{2s_{b1}}{s_{bg}s_{1g}} + \frac{2s_{12}}{s_{1g}s_{2g}} \right].$$  \hspace{1cm} (2.12)

The color structure of the soft contribution will be considered below. In the soft region, the four-particle $qq'gH$ phase space factorizes into a three-particle $qq'H$ phase space and the soft gluon phase space for the respective configuration,

$$[d(PS_4)]^{\text{soft}} = d(PS_3) d(PS_g)^{\text{soft}}(i, j, g),$$

where $d(PS_3)$ contains the flux factor, $1/(2\hat{s})$, with $\hat{s}$ denoting the partonic center-of-mass energy squared. For two outgoing partons $i$ and $j$, $d(PS_g)^{\text{soft}}(i, j, g)$ is given by \[36\]

$$d(PS_g)^{\text{soft}}(i, j, g) = \frac{(4\pi)^{\epsilon}}{16\pi^2} \frac{s_{ab}^{2\epsilon-1}}{\Gamma(1-\epsilon)} [s_{ig}s_{jj}s_{ij}]^{-\epsilon} ds_{ig}ds_{jj}\theta(s_{\text{min}} - s_{ig})\theta(s_{\text{min}} - s_{jj}).$$  \hspace{1cm} (2.14)
The integration over the soft gluon phase space can be performed for each term in the soft interference amplitude Eq. (2.12) explicitly, using
\[ g_s^2 \mu^{2\epsilon} \int d(PS_g)_{\text{soft}}(i,j,g) \frac{2s_{ij}}{s_{ig}^2 s_{jg}^2} = \frac{g_s^2}{8\pi^2} \frac{1}{\Gamma(1-\epsilon)} \left( \frac{4\pi \mu^2}{s_{\text{min}}} \right)^\epsilon \frac{1}{\epsilon^2} \left( \frac{s_{ij}}{s_{\text{min}}} \right)^\epsilon. \] (2.15)

The generalization of this expression to cases where one of the partons \( i, j \) is incoming rather than outgoing is straightforward. The soft part of the real emission cross section then takes the form
\[ \dot{\sigma}_{\text{soft}} = \frac{\alpha_s^2}{2\pi} \Gamma(1+\epsilon) \frac{C_A C_F}{2} \int d(PS_3) \sum 2\text{Re} \left[ M_{\text{WBF}}^{(\text{real})} M_{\text{GF}}^{(\text{real})} + M_{\text{GF}}^{(\text{real})} M_{\text{WBF}}^{(\text{real})} \right]_{\text{soft}} \]
\[ \times \left\{ \frac{1}{\epsilon} \ln \left( \frac{s_{ab}}{s_{\text{min}}} \right) - \ln \left( \frac{s_{a2}}{s_{\text{min}}} \right) - \ln \left( \frac{s_{bl}}{s_{\text{min}}} \right) + \ln \left( \frac{s_{12}}{s_{\text{min}}} \right) \right\}, \] (2.16)

where we have included the color factor \( C_A C_F/2 = 2 \). When \( \dot{\sigma}_{\text{soft}} \) is combined with the virtual contributions,
\[ \dot{\sigma}_{qq'H} = \dot{\sigma}_{\text{virt}} + \dot{\sigma}_{\text{soft}}, \] (2.17)
all \( 1/\epsilon \) poles cancel [cf. Eq. (2.8)]. The remaining terms are finite and can be integrated over the three-particle phase space of the \( qq'H \) system and convoluted with the parton distributions of the incoming fermions numerically. The resulting three-particle contribution, \( \sigma_{qq'H} \), depends on the unphysical cutoff parameter \( s_{\text{min}} \). This dependence cancels, however, once \( \sigma_{qq'H} \) is combined with the hard part of the real emission cross section,
\[ \sigma_{\text{full}} = \sigma_{\text{hard}} + \sigma_{qq'H}. \] (2.18)

Checking that the full NLO interference cross section is independent of the cutoff parameter therefore provides another important test of our calculation.

### 2.4.2 Phase-space slicing with energy-cutoff

The phase-space slicing method of Ref. [35] in principle requires two cutoff parameters for separating finite from collinear and soft divergent regions. For our application, however, no collinear singular configurations emerge. Thus, applying a single cutoff on the energy of the potentially soft gluon is sufficient.
In analogy to the Lorentz-invariant slicing method described previously, the real emission contribution can be evaluated numerically in the “hard” region of phase space above the cutoff, where it is completely finite. Below the energy cutoff, however, the phase-space integration over the gluonic degrees of freedom is performed analytically. Following Refs. [38, 39], this “soft” contribution to the partonic cross section can be written as

$$\hat{\sigma}^{\text{soft},E-\text{cut}} = \frac{\alpha_s}{2\pi} \frac{C_AC_F}{2} \int d(PS_3) \sum \text{2Re} \left[ M_{\text{WBF}^0} M_{\text{GF}^0}^* + M_{\text{GF}^0}^* M_{\text{WBF}^0} \right]$$

$$\times \int_{E_3<\Delta E \mid p_g^2=E_3^2-\lambda^2} d^3p_g \left[ \frac{2s_{ab}}{s_{ag}s_{bg}} - \frac{2s_{a2}}{s_{ag}s_{2g}} - \frac{2s_{b1}}{s_{bg}s_{1g}} + \frac{2s_{12}}{s_{1g}s_{2g}} \right].$$

(2.19)

where $E_3$ is the gluon energy, $\Delta E$ the energy cutoff in the rest frame of the two incoming partons and $\lambda$ a mass used as regulator. As above, $d(PS_3)$ denotes the $qq'H$ phase space. Evaluating the integrals over the gluonic degrees of freedom in Eq. (2.19) and rewriting the mass-regulated result in terms of dimensional regularization, the corresponding soft cross section is of the form

$$\hat{\sigma}^{\text{soft},E-\text{cut}} = \frac{\alpha_s}{2\pi} \frac{C_AC_F}{2} \int d(PS_3) \sum \text{2Re} \left[ M_{\text{WBF}^0} M_{\text{GF}^0}^* + M_{\text{GF}^0}^* M_{\text{WBF}^0} \right]$$

$$\times \left\{ \frac{\Gamma(1+\epsilon)}{\epsilon} \left( \frac{\pi \mu^2}{\Delta E^2} \right)^\epsilon \left[ \ln \left( \frac{s_{ab}}{4\pi \mu^2} \right) - \ln \left( \frac{-s_{a2}}{4\pi \mu^2} \right) - \ln \left( \frac{-s_{b1}}{4\pi \mu^2} \right) + \ln \left( \frac{s_{12}}{4\pi \mu^2} \right) \right] \right.\right.$$  

$$\left. + \text{Li}_2 \left( 1 - \frac{4E_1E_2}{s_{12}} \right) \right) \left. - \text{Li}_2 \left( 1 - \frac{4E_1E_2}{s_{12}} \right) \right) \right\},$$

(2.20)

where the $E_i$ denote the quark energies in the partonic rest frame. In complete analogy to the Lorentz-invariant phase-space slicing, the soft contribution to the partonic cross section is combined with the virtual cross section. The resulting sum is then free of soft poles and can be evaluated numerically. Upon adding the hard part of the real emission contribution, the dependence on the cutoff parameter $\Delta E$ cancels.

### 2.4.3 Checks

We have checked that the total $pp\rightarrow Hjj$ interference cross section at the LHC within typical WBF cuts (for details, see our standard definition of cuts in Sec. 3) is independent of the cutoff parameter for both phase-space slicing schemes.

For the Lorentz-invariant slicing method, we have varied $s_{\text{min}}$ in the range $1 \text{ GeV}^2 < s_{\text{min}} < 10^3 \text{ GeV}^2$. For smaller cutoff values, large logarithms arise and numerical instabilities
Figure 7: Dependence of the interference cross section for \(pp\to Hjj\) production at the LHC within standard selection cuts on the cutoff of the Lorentz-invariant phase-space slicing method (a) and of the energy-cutoff slicing method (b). Shown are \(\sigma_{\text{hard}}\) (blue), \(\sigma_{qq'H}\) (green), and their sum, \(\sigma_{\text{full}}\) (red).

are to be expected. If, on the other hand, a very large value is chosen for \(s_{\text{min}}\), the soft approximation used for determining \(\hat{\sigma}_{\text{soft}}\) is not applicable anymore. Fig. 7(a) demonstrates that the two contributions \(\sigma_{qq'H}\) and \(\sigma_{\text{hard}}\) individually depend on \(s_{\text{min}}\), while the sum \(\sigma_{\text{full}}\) is constant in the considered range of the cutoff parameter.

A very similar pattern arises for the energy-cutoff slicing method, depicted in Fig. 7(b). We have normalized the energy cutoff \(\Delta E\) by \(\sqrt{s}\) for this study.

3 Numerical results

The cross-section contributions discussed above have been implemented in a fully flexible parton level Monte-Carlo program, structured analogous to the \texttt{vbfnlo} code [20] which has been developed for the study of WBF-type production processes at the LHC.

The loop-induced interference contributions for \(Hjj\) production via GF and WBF we consider are a gauge-invariant sub-class of the full NLO-QCD corrections to the scattering process \(pp\to Hjj\). For the parton distribution functions of the proton we therefore use the CTEQ6M set at NLO [40] with \(\alpha_s(M_Z) = 0.118\). We set quark masses to zero throughout and neglect contributions from external top or bottom quarks. As electroweak input parameters
we have chosen $m_Z = 91.188 \text{ GeV}$, $m_W = 80.419 \text{ GeV}$, and the measured value of $G_F = 1.166 \times 10^{-5}/ \text{ GeV}^2$. Thereof, we compute $\sin^2 \theta_W$ and $\alpha$ using LO electroweak relations. For reconstructing jets from final-state partons, we use the $k_T$ algorithm \cite{41} with resolution parameter $R^{k_T} = 0.8$.

Since we want to study the impact of the interference contributions on the Higgs signal in WBF, we apply cuts that are typical for WBF studies at the LHC. We require at least two hard jets with

$$p_{Tj} \geq 20 \text{ GeV}, \quad |y_j| \leq 4.5, \quad (3.1)$$

where $p_{Tj}$ is the transverse component and $y_j$ the rapidity of the (massive) jet momentum which is reconstructed as the four-vector sum of massless partons of pseudorapidity $|\eta| < 5$. We refer to the two reconstructed jets of highest transverse momentum as “tagging jets”. The Higgs boson decay products, which we generically call “leptons” in the following, are required to be located between the two tagging jets and they should be well observable.

To simulate a generic Higgs decay without specifying a particular channel we generate an isotropic Higgs boson decay into two massless particles (which represent $\gamma \gamma$ or $b\bar{b}$ final states) and require

$$p_{T\ell} \geq 20 \text{ GeV}, \quad |\eta_{\ell}| \leq 2.5, \quad \Delta R_{j\ell} \geq 0.6, \quad (3.2)$$

where $\Delta R_{j\ell}$ denotes the jet-lepton separation in the rapidity-azimuthal angle plane. In addition, the leptons need to fall between the rapidities of the two tagging jets

$$y_{j,\text{min}} < \eta_{\ell} < y_{j,\text{max}}. \quad (3.3)$$

Furthermore, we impose large rapidity separation of the two tagging jets,

$$\Delta y_{jj} = |y_{j1} - y_{j2}| > 4, \quad (3.4)$$

and demand that the two tagging jets be located in opposite detector hemispheres,

$$y_{j1} \times y_{j2} < 0, \quad (3.5)$$

with an invariant mass

$$M_{jj} > 600 \text{ GeV}. \quad (3.6)$$

To ensure the reliability of our calculation, we have compared our results to those of Ref. \cite{19} and found agreement with their main predictions. Diagrams where the Higgs boson is radiated off the final-state gluon rather than the $t$-channel exchange boson as in Fig. \cite{6} have not been considered in \cite{19}. This approximation seems reasonable, as we found that contributions from these graphs amount to only about 0.3% of the total interference cross section. For individual subprocesses they can be larger, however. For the $dd \to ddH$ channel, for instance, they yield approximately 5% of the subprocess-cross section.

In Fig. \cite{8} we show the total cross section $\sigma^{\text{cuts}}_{\text{int}}$ for the interference contribution within the
Figure 8: Dependence of the total interference cross section $\sigma_{\text{int}}^{\text{cuts}}$ for $H jj$ production at the LHC on the factorization and renormalization scales for the two different scenarios described in the text. The factorization scale $\mu_f$ and the renormalization scale $\mu_r$ are scaled as $m_H$ for (a) and as the jets’ transverse momenta in (b), cf. Eqs. (3.7) and (3.8), respectively. The curves show $\sigma_{\text{int}}^{\text{cuts}}$ as a function of the scale parameter $\xi$ for three different cases: $\xi_r = \xi_f = \xi$ (solid red), $\xi_f = \xi$ and $\xi_r = 1.0$ (dot-dashed blue), $\xi_r = \xi$ and $\xi_f = 1.0$ (dashed green).

cuts of Eqs. (3.1)–(3.6) and for a Higgs mass of $m_H = 120$ GeV. The factorization scale, $\mu_f$, and the renormalization scale, $\mu_r$, which enters the strong coupling are chosen as follows: In panel (a), we set

$$\mu_f = \xi_f m_H, \quad \alpha_s^3(\mu_r) = \alpha_s^3(\xi_r m_H).$$

(3.7)

In panel (b), we associate the scale for gluon emission from either quark line with the transverse momentum of the corresponding jet by setting

$$\mu_f = \xi_f p_{Tj}, \quad \alpha_s^3(\mu_r) = \alpha_s(\xi_f p_{T1}) \cdot \alpha_s(\xi_f p_{T2}) \cdot \alpha_s(\xi_r m_H).$$

(3.8)

Due to the absence of collinear singularities, $\mu_f$ enters only via the parton distribution functions of the incoming fermions, which are mainly probed at rather large values of Feynman $x$. In this regime, the valence and sea quark distributions depend on the factorization scale only mildly. Thus, the variation of $\sigma_{\text{int}}^{\text{cuts}}$ with $\mu_f$ is very small. On the other hand, the interference cross section exhibits a pronounced dependence on $\mu_r$. Since the loop-induced GF×WBF interference in $qq'\rightarrow qq'H$ production, $\sigma_{\text{int}}^{\text{cuts}}$, represents the first non-vanishing contribution in the perturbative expansion, the renormalization scale enters only via the strong coupling constant. Thus, the entire $\mu_r$ dependence of the interference cross section can be traced back.
Table 1: Contributions of various neutral current (NC) flavor combinations to $\sigma_{\text{cuts}}$ (in ab) and $\sigma_{\text{cuts, WBF}}$ (in fb), and of the charged current (CC) contributions to WBF. Also shown is their sum within the cuts of Eqs. (3.1)–(3.6).

| initial-state flavor combination                                      | $\sigma_{\text{cuts}}$ [ab] | $\sigma_{\text{cuts, WBF}}$ [fb] |

| CC: $(\bar{u} + \bar{c})(\bar{d} + \bar{s})$                     | -                            | 25.7                              |
| sum                                                                 | 1.5                         | 896.9                             |

to the variation of the $\alpha_3^3(\mu_r)$ coupling factor with the renormalization scale. Reminiscent of what has been observed for pure WBF production processes (cf., e.g., Ref. [42]) a dynamical scale choice as in Eq. (3.8), see Fig. 8(b), yields predictions with a somewhat reduced scale dependence as compared to the fixed scale option of Eq. (3.7), shown in Fig. 8(a).

Compared to the total WBF cross section within typical selection cuts, the interference contribution we have calculated is almost negligible in magnitude. In Tab. 1 we list $\sigma_{\text{cuts}}$ for both, interference and pure WBF cross sections for the various flavor combinations of the scattering quarks and antiquarks, setting $\mu_f = \mu_r = m_H$. For WBF, we consider neutral and charged current subprocesses at $\mathcal{O}(\alpha^3)$. No $W$-exchange diagrams contribute to the interference cross section. Tab. 1 reveals the strong cancelations occurring in $\sigma_{\text{cuts}}$ among the separate channels. While some contributions, in particular for the $qq'$ subprocesses, are sizeable, their sum amounts to 1.5 ab only. We will show below that the subtle cancelation between the same and opposite isospin $qq$, $q\bar{q}$, and $\bar{q}q$ scattering contributions leads to unexpected shapes of kinematic distributions in flavor-blind experiments.

Figure 9 depicts the shapes of the transverse-momentum distributions for “pure” WBF $Hjj$ production and for the WBF$\times$GF interference contribution we have calculated. The very hard $p_T$ distribution encountered for the interference significantly differs from the shape of the WBF curve. The small size of the $p_T$ distribution at low momentum transfer is mainly due to strong cancelations among the different flavor contributions to the full $pp \to Hjj$...
Figure 9: Panel (a) shows the normalized transverse momentum distributions for the tagging jet with the highest $p_T$ for WBF (dashed blue line) and for the WBF×GF interference contribution (solid red line). In panel (b) the sum of all positive (dashed green line) and the magnitude of all negative contributions (dashed black line) are shown separately. The solid red line gives the sum of all contributions, multiplied by a factor of 10.

The interference cross section, as illustrated by Fig. 9(b), where the contributions for same isospin and opposite isospin $qq + q\bar{q} + \bar{q}q$ scattering, $\sigma_{\text{int}}^{\text{pos}}$ and $\sigma_{\text{int}}^{\text{neg}}$, are shown separately. The two contributions cancel almost precisely to give the total interference contribution, $\sigma_{\text{int}}^{\text{pos}} + \sigma_{\text{int}}^{\text{neg}} = \sigma_{\text{int}}$. At high $p_T$, the cancelation effects are less pronounced. In short, the interference contribution has a harder transverse-momentum spectrum than expected, because of a very efficient cancelation around $p_{T,\text{tag}}^{\text{max}} \sim 100$ GeV, where the individual distributions peak.

This cancelation pattern is reflected by the tagging-jet invariant mass $M_{jj}$. For studying the corresponding shapes of the pure EW and of the mixed QCD-EW production processes, we have switched off the invariant mass cut of Eq. (3.6). The emerging curves are displayed in Fig. 10. While the interference cross section is negative at small values of the dijet-invariant mass, it is relatively large at high $M_{jj}$. Indeed, is is remarkable to find that the interference cross section yields an even harder $M_{jj}$ distribution than the pure WBF cross section does. This behavior is somewhat unexpected if considering the rather soft invariant mass distribution of the pure GF $Hjj$ production process which has been reported in the literature [14]. The full GF $pp \rightarrow Hjj$ cross section, however, is dominated by gluon-initiated partonic channels such as $gg \rightarrow ggH$ and $qg \rightarrow qgH$. To the interference cross section, on the other hand, only quark (and anti-quark) initiated subprocesses contribute, which tend to give larger values of $M_{jj}$ than gluonic contributions. More importantly, the cancelation effects reported above in the context of the tagging-jet transverse-momentum distribution affect
Figure 10: Panel (a) shows the normalized tagging-jet invariant mass distributions for WBF (dashed blue line) and for the WBF × GF interference contribution (solid red line). Panel (b) depicts the sum of all positive contributions, $\sigma_{\text{pos}}$ (dashed green line), the magnitude of all negative contributions, $-\sigma_{\text{neg}}$ (dashed black line), and their sum $\sigma_{\text{int}}$, multiplied by a factor of 10 (solid red line).

The summation over the various flavor contributions to the dijet-invariant mass distribution in a similar manner, thereby giving rise to a broad invariant-mass distribution which is very small at low values of $M_{jj}$.

The afore-mentioned cancelations have different effects on the rapidity distribution of the third, non-tagged jet with respect to the tagged jet located in the positive-rapidity hemisphere,

$$y_{\text{diff}} = y_3 - \max(y_1, y_2),$$

which is shown in Fig. 11 for the interference contribution and the “pure” WBF cross section. The separation of the lowest $p_T$-jet from the tagged jet located in the negative-rapidity hemisphere, $-y_3 + \min(y_1, y_2)$, would be a mirror copy thereof due to our symmetric selection cuts. For generating the distribution, we required a minimum transverse momentum of $p_{T3} \geq 10 \text{ GeV}$ for the third jet in addition to the selection cuts of Eqs. (3.1)–(3.6). The peak of the distribution at small $|y_{\text{diff}}|$ emphasizes that the “soft” jet prefers being close in rapidity to the hard jet in the respective detector hemisphere for both, interference and WBF contributions. While in WBF the third jet prefers rapidities larger than the associated tag jet, $y_{\text{diff}} > 0$, for the interference contribution $y_{\text{diff}}$ peaks at negative values for the various flavor contributions and their sum, indicating that the soft jet is typically located in between the two tagged jets. This may indicate that the rapidity gap for a color singlet EW-boson exchange may in general be filled by the EW-QCD interference contribution.
Figure 11: Panel (a) shows the normalized rapidity-separation distribution of the non-tagged jet for WBF (dashed blue line) and for the WBF×GF interference contribution (solid red line). Panel (b) depicts the sum of all positive contributions, $\sigma_{\text{int}}^{\text{pos}}$ (dashed green line), the magnitude of all negative contributions, $-\sigma_{\text{int}}^{\text{neg}}$ (dashed black line), and their sum $\sigma_{\text{int}}$, multiplied by a factor of 10 (solid red line).

4 Summary and conclusions

In this article we have computed the order $O(\alpha^2\alpha_s^3)$ interference contributions to the $Hjj$ production cross section in $pp$ collisions at the LHC via GF and WBF. Since results for the total interference cross section and angular distributions have already been discussed in the literature [19], we have put special emphasis on technical and phenomenological aspects of the calculation which have not been discussed elsewhere. In particular, we have given a detailed outline of the methods used for the evaluation of loop contributions, the subtraction of singularities present in intermediate steps of the calculation, and of the checks we have performed to ensure the reliability of our results. In the real emission contributions we have included a finite class of diagrams that has not been considered previously. We found the numerical value of these contributions small, however.

Having implemented the interference amplitudes in a flexible Monte-Carlo program based on the vbfnlo framework of Ref. [20], we are able to provide total cross sections and arbitrary kinematic distributions within experimentally feasible selection cuts. Considering the interference cross section as possible “contamination” of the clean WBF $Hjj$ production signature, we have studied the associated contributions within typical WBF cuts with widely separated hard tag-jets and compared the shape of some characteristic distributions to those
of the respective pure WBF curves. We found that, indeed, the interference contributions exhibit features rather different from the WBF signal which are caused by strong cancelations among the separate flavor channels. However, due to the small size of the interference cross section which is found to be in the atto-barn range only, the impact of this contribution to both, integrated cross sections and differential distributions, is negligible.

Figure 12: Momentum and mass assignments for a general scalar box diagram.

A Infrared divergent scalar box integrals

In this appendix, we denote the infrared-divergent box integrals with massive propagators which emerge in the calculation of the loop corrections to VBF-induced pentagon diagrams. We do not list the other scalar loop integrals encountered in our calculation, since they can be found elsewhere (see, e.g., [27, 19, 31]).

We obtained the respective soft and collinear singular box diagrams by extracting appropriate expressions from Refs. [29, 30] in the limit of small quark masses. According to Ref. [28], a relation between different regularization schemes can be established making use of the genuine singularity structure of infrared-divergent triangle integrals. With the help of this property, we transformed the divergent four-point integrals from mass regularization to dimensional regularization.

In the following, we refer to a genuine scalar four-point function as depicted in Fig. 12

\[
D_0(q_1, q_2, q_3; m_1, m_2, m_3, m_4) = \frac{(2\pi\mu)^{4-d}}{(i\pi^2)} \int d^d q \frac{1}{[q^2 - m_1^2 + i\delta][(q + q_1)^2 - m_2^2 + i\delta][\bar{s} + i\delta][(q + q_1 + q_2)^2 - m_3^2 + i\delta][(q + q_1 + q_2 + q_3)^2 - m_4^2 + i\delta]}
\]

\[
\equiv I_4^d(s_1, s_2, s_3, s_4; s_{12}, s_{23}; m_1^2, m_2^2, m_3^2, m_4^2),
\]

(A.1)

where the \( q_i \) denote incoming momenta of the external legs and the \( m_i \) correspond to the masses of the internally propagating particles. The kinematic invariants, \( s_i \) and \( s_{ij} \), are related to the external momenta via \( s_i = q_i^2 \) and \( s_{ij} = (q_i + q_j)^2 \). Overlined quantities are defined as \( \bar{s} = s + i\delta \), etc.

In this notation, the collinear divergent box integral with two equal internal and two different external mass scales, which is sketched in Fig. 13, takes the form
Figure 13: Momentum and mass assignments for the collinear divergent scalar box diagram of Eq. (A.2). Unlabeled thin lines correspond to massless particles.

\[ I_4^d(m_H^2, 0, 0, s_4; s, t; m^2, m^2, 0, 0) = \frac{1}{D_1} \left\{ \right. \]

\[ \frac{\Gamma(1 + \epsilon)}{\epsilon} \left( \frac{4\pi\mu^2}{m^2} \right)^\epsilon \left[ \ln \left( \frac{m^2 - s_4}{m^2 - s} \right) + \ln \left( \frac{m^2}{m^2 - t} \right) \right] \]

\[-\frac{1}{2} \ln^2 \left( \frac{-D_1}{m^2(m^2 - s_4)}(1 + i\delta) \right) + \frac{1}{2} \ln^2(-x_{14}k_1) + \frac{1}{2} \ln^2 \left( \frac{-x_{14}}{k_1} \right) - \frac{1}{2} \ln^2(-k_2x_{14}) \]

\[-2\pi i\theta \left( \frac{(m^2 - s)(m^2 - s_4)}{D_1} \right) \left[ \theta \left( \frac{m_H^2 - 2m^2}{m^2} \right) \ln(x_{14}k_1) + \theta \left( \frac{2m^2 - m_H^2}{m^2} \right) \ln \left( \frac{x_{14}}{k_1} \right) \right] \]

\[-\theta \left( \frac{s_4 - t}{m^2} \right) \ln(k_2x_{14}) \]

\[-2\pi i\theta \left( \frac{s - m^2}{m^2} \right) \theta \left( \frac{m^2(m^2 - s_4)}{D_1} \right) \left[ \ln \left( \frac{D_1(m^2 - s)}{m^2(m^2 - s_4)} \right)(1 + i\delta) + \ln \left( \frac{m^2 - t}{m^2 - i\delta} \right) \right] \]

\[-\frac{\pi^2}{6} + 2\text{Li}_2 \left( \frac{s - s_4}{m^2 - s_4} \right) - 2\text{Li}_2 \left( \frac{-t}{m^2 - t} \right) + \text{Li}_2 \left( 1 + \frac{D_1}{m^2(m^2 - s_4)}(1 + i\delta) \right) \]

\[-\text{Li}_2 \left( 1 + \frac{D_2}{D_1(m^2 - s)} - i\delta \frac{m^2(m^2 - s_4)}{D_1} \right) + \text{Li}_2 \left( 1 + \frac{x_{24}}{k_1} \right) + \eta \left( -x_{24}, \frac{1}{k_1} \right) \ln \left( 1 + \frac{x_{24}}{k_1} \right) \]

\[+ \text{Li}_2(1 + x_{24}k_1) + \eta(-x_{24}, k_1) \ln(1 + x_{24}k_1) - \text{Li}_2(1 + x_{24}k_2) - \eta(-x_{24}, k_2) \ln(1 + x_{24}k_2) \]

\[+ 2\pi i\theta \left( \frac{s - m^2}{m^2} \right) \theta \left( \frac{m^2(s_4 - m^2)}{D_1} \right) \left[ \ln \left( \frac{(m_H^2(m^2 - s) + s^2)m^2}{D_1(m^2 - s)} - i\delta \frac{m^2(m^2 - s)}{D_1} \right) \right] \]

\[+ \ln \left( \frac{m^2 - t}{m^2 - i\delta} \right) \right\}, \quad (A.2) \]

with

\[ \eta(a, b) = \ln(ab) - \ln(a) - \ln(b), \]

\[ D_1 = (s - m^2)(t - m^2) + (s_4 - m^2)m^2, \]

\[ D_2 = m_H^2(m^2 - s)(m^2 - t) + m^2[m^2(s + t - s_4) + s(s_4 - 2t)]. \]
Figure 14: Momentum and mass assignments for the soft divergent scalar box diagram of Eq. (A.4). Unlabeled thin lines correspond to massless particles.

\[ \beta = \sqrt{1 - 4 \frac{m^2}{m_H^2} + 2i\delta \frac{m^2}{m_H^2} (m_H^2 - 2m^2) \theta(4m^2 - m_H^2)}, \]

\[ x_{14} = \frac{D_1(m^2 - s)}{m^4(m^2 - s_4)}, \]

\[ x_{24} = \frac{D_2}{D_1 m^2} - i\delta \frac{(m^2 - s)(m^2 - s_4)}{D_1}, \]

\[ k_1 = \frac{2m^2 - (1 + \beta)m_H^2}{2m^2} + i\delta \frac{2m^2 - (1 + \beta)m_H^2}{2\beta m_H^2}, \]

\[ k_2 = \frac{m^2 - s_4}{m^2 - t} + i\delta \frac{m^2(t - s_4)}{(m^2 - t)^2}. \] (A.3)

The soft divergent box integral with one internal and one external mass scale shown in Fig. 14 is given by

\[ I_4^d(s_1, 0, 0, 0; s, t; 0, m^2, 0, 0) = \frac{1}{s(t - m^2)} \left\{ \Gamma(1 + \epsilon) \left( \frac{4\pi \mu^2}{-s} \right) + \Gamma(1 + \epsilon) \left( \frac{4\pi \mu^2}{m^2} \right) \epsilon \left[ \ln \left( \frac{m^2 - s_1}{m^2 - t} \right) + \ln \left( \frac{m^2}{m^2 - t} \right) \right] \right. \]

\[ - \frac{1}{2} \ln^2 \left( -\frac{s}{m^2} \right) - 2 \ln \left( -\frac{s}{m^2} \right) \ln \left( \frac{m^2}{m^2 - t} \right) - \ln^2 \left( \frac{m^2 - s_1}{m^2} \right) + \text{Li}_2 \left( \frac{s_1 - m^2}{s} \right) \]

\[ - 2\text{Li}_2 \left( \frac{s_1 - t}{m^2 - t} \right) - 2\text{Li}_2 \left( \frac{t}{m^2 - t} \right) - \ln \left( \frac{s}{s_1 - m^2} \right) \ln \left( 1 - \frac{s_1 - m^2}{s} \right) - \frac{\pi^2}{2} \right\}. \] (A.4)

We would like to note that our results agree with those of Ref. [19], if \( \mu^2 \) is replaced by \( \mu \) in all terms of Eq. (A.19) in [19].
