Abstract

If equipped with several radar emitters, a target will produce more than one measurement per time step and is denoted as an extended target. However, due to the requirement of all possible measurement set partitions, the exact probability hypothesis density filter for extended target tracking is computationally intractable. To reduce the computational burden, a fast partitioning algorithm based on hierarchy clustering is proposed in this paper. It combines the two most similar cells to obtain new partitions step by step. The pseudo-likelihoods in the Gaussian-mixture probability hypothesis density filter can then be computed iteratively. Furthermore, considering the additional measurement information from the emitter target, the signal feature is also used in partitioning the measurement set to improve the tracking performance. The simulation results show that the proposed method can perform better with lower computational complexity in scenarios with different clutter densities.

Introduction

As a means of avoiding the complicated problem of data association, the probability hypothesis density (PHD) filter [1] has received considerable attention in multi-target tracking [2–9]. Like traditional tracking algorithms, the standard PHD filter assumes that each target produces at most one measurement per time step. However, with the application of high-resolution sensors, one object (e.g., large airplane and ship) may yield several measurements at each time step and is then denoted as an extended target. In a passive tracking system, the sensor (e.g., electronic support measure sensor) usually locates the target by detecting the electromagnetic wave emitted by the target’s radar. When there are several radars equipped on the target, the sensor will receive more than one measurement from...
the target at a given time step. Thus, emitter target tracking relates to the problem of extended target tracking, which has been a research hotspot in recent years. Gilholm et al. suggested a non-homogeneous Poisson point process measurement model in extended target and group tracking [10]. On that basis, an improved PHD filter for handling extended targets was proposed by Mahler [11]. Then, Granstrom et al. presented a Gaussian-mixture implementation of the PHD filter for extended target tracking in the linear Gaussian system [12]. Similarly, a Gaussian-mixture implementation of the CPHD filter is also presented in reference [13], where experiments using real data from a laser sensor show that the extended target CPHD filter exhibits better performance than the PHD filter in estimating the number of targets.

The purpose of a measurement set partition is to cluster the measurements from the same target into one cell, which is used to update the intensity. It is an important part of the extended target PHD filter (ET-PHD). The validity of the measurement set partition directly affects the tracking performance; however, the computational complexity increases sharply as the number of possible partitions increases. A simple solution is to use K-means clustering to generate partitions according to different values of K. In view of its sensitivity to the initialization of the algorithm, an improved version called K-means++ [14] can be chosen to overcome this problem. Granstrom et al. proposed a distance partitioning method using a set of distance thresholds to obtain the cells [12]. Furthermore, a sub-partitioning approach is added to handle the close-spaced targets [15]. After distance partitioning, the method takes advantage of the maximum likelihood (ML) algorithm to estimate the number of targets in each cell. If the number is larger than one, the cell will be split into smaller cells. In their recent work [16], Zhang and Ji presented a novel fast partitioning algorithm based on the Neural Network (NN), where the Fuzzy ART model is used with different vigilance values to partition the measurement set. However, certain shortcomings may still exist in the above methods, such as high computational complexity, inaccurate partitions and the difficulty of setting parameters. Therefore, a fast, simple and valid partitioning algorithm for the ET-PHD filter is necessary. In this paper, a new partitioning algorithm based on hierarchy clustering is proposed. It iteratively computes the pseudo-likelihoods to achieve fast tracking of extended targets through the use of the neighboring partitions.

Additionally, in a passive tracking system, certain signal features of the emitter, such as radio frequency (RF), pulse repetition interval (PRI) and pulse width (PW), can be received in addition to the location information. They represent the characteristics of the emitter and play an important role in the classification and recognition of the emitter [17–19]. As a result, this paper tries to incorporate the signal features into the ET-PHD filter to improve tracking performance in cluttered environment.

The remainder of this paper is organized as follows. The Background section mainly reviews the Gaussian-mixture implementation of the ET-PHD (ET-GM-PHD) filter. The measurement set partition based on hierarchy clustering and the modified ET-GM-PHD filter incorporating the signal features of the emitter are
detailed in the Method section. Then, in Results and Discussion, the simulation results are analyzed to validate the proposed method. **Conclusions** are presented in the final section.

**Background**

In a linear Gaussian system, the GM-PHD filter can easily estimate the target statements and the number of targets. Without considering the spawned target, the Gaussian-mixture implementation of the ET-PHD filter can be given by the following three steps \([3, 12, 15]\) which present a closed form solution to the PHD recursion.

**Prediction**

Assume that the posterior intensity at time \(k-1\) is a Gaussian-mixture form

\[
D_{k-1|k-1}(x_{k-1}) = \sum_{i=1}^{N} \omega_{k-1}^{(i)} N(x_{k-1}; m_{k-1}^{(i)}, P_{k-1}^{(i)})
\]

where \(x_{k-1}\) represents the target statement at time \(k-1\), \(\omega_{k-1}^{(i)}\) is the weight of the \(i^{th}\) component, and \(N(x; m, P)\) denotes a Gaussian density with mean \(m\) and covariance \(P\). Then, the predicted intensity at time \(k\) is given by

\[
D_{k|k-1}(x_{k}) = \gamma_{k}(x_{k}) + \sum_{i=1}^{N} \omega_{k|k-1}^{(i)} N(x_{k}; m_{k|k-1}^{(i)}, P_{k|k-1}^{(i)})
\]

where \(\gamma_{k}(x_{k})\) is the birth intensity

\[
\gamma_{k}(x_{k}) = \sum_{i=1}^{N} \omega_{\gamma,k}^{(i)} N(x_{k}; m_{\gamma,k}^{(i)}, P_{\gamma,k}^{(i)})
\]

\[
\omega_{k|k-1}^{(i)} = P_{S,k} \omega_{k-1}^{(i)}
\]

\[
m_{k|k-1}^{(i)} = F_{k-1} m_{k-1}^{(i)}
\]

\[
P_{k|k-1}^{(i)} = Q_{k-1} + F_{k-1} P_{k-1}^{(i)} F_{k-1}^T
\]

where \(P_{S,k}\) represents the survival probability, \(F_{k-1}\) is the transition matrix of the system, and \(Q_{k-1}\) is the process noise covariance.

**Update**

Because the birth intensity is also a Gaussian-mixture form, the predicted intensity can be expressed as

\[
D_{k|k-1}(x_{k}) = \sum_{i=1}^{N} \omega_{k|k-1}^{(i)} N(x_{k}; m_{k|k-1}^{(i)}, P_{k|k-1}^{(i)})
\]
where \( J_{k|k-1} = J_{k-1} + J_{j,k} \). Then, the posterior intensity \( D_{k|k}(x_k) \) can be updated by

\[
D_{k|k}(x_k) = D_{k|k}^{ND}(x_k) + \sum_{\varnothing \subset \mathcal{Z}_k} \sum_{W \in \varnothing} D_{k|k}^D(x_k, W)
\] (5)

The notation \( \varnothing \subset \mathcal{Z}_k \) means that \( \varnothing \) partitions the measurement set \( \mathcal{Z}_k \) into cells \( W \). Under assumption 8 in reference [15], \( D_{k|k}^{ND}(\cdot) \) handling the no detection cases can be given by

\[
D_{k|k}^{ND}(x_k) = \sum_{i=1}^{J_{k|k-1}} \omega_{k|k-1}^{(i)} \mathcal{N}(x_k; m_{k|k-1}^{(i)}, P_{k|k-1}^{(i)})
\] (6)

where

\[
\omega_{k|k}^{(i)} = \left(1 - (1 - \hat{\gamma}^{(i)}) p_{D,k}\right) \omega_{k|k-1}^{(i)}
\] (7a)

\[
m_{k|k}^{(i)} = m_{k|k-1}^{(i)}
\] (7b)

\[
P_{k|k}^{(i)} = P_{k|k-1}^{(i)}
\] (7c)

where \( \gamma^{(i)} = \gamma(m_{k|k-1}^{(i)}) \) is the approximation of the expected number of generated measurements \( \gamma(x_k) \), and \( p_{D,k} \) denotes the detection probability. Similarly, \( D_{k|k}^D(x_k, W) \) handling the detected target cases is given by

\[
D_{k|k}^D(x_k, W) = \sum_{i=1}^{J_{k|k-1}} \omega_{k|k-1}^{(i)} \mathcal{N}(x_k; m_{k|k-1}^{(i)}, P_{k|k-1}^{(i)})
\] (8)

and the weight is

\[
\omega_{k|k}^{(i)} = \omega_{\varnothing}^{(i)} \frac{\Gamma_{W}^{(i)} p_{D,k}^{(i)} \omega_{k|k-1}^{(i)} \Phi_{W}^{(i)}}{d_{W}}
\] (9a)

\[
\Gamma_{W}^{(i)} = e^{-\gamma^{(i)} \left( \gamma^{(i)} \right)^{|W|}}
\] (9b)

\[
\Phi_{W}^{(i)} = \phi_{W}^{(i)} \prod_{z \in W} \frac{1}{\lambda_c V c_z(z)}
\] (9c)

where \(|W|\) is the number of elements in \( W \), \( \lambda_c \) is the average clutter density, \( V \) is the surveillance region, and \( c_z(z) \) is the probability density of the spatial distribution of clutters. The coefficient \( \phi_{W}^{(i)} \) can be given by

\[
\phi_{W}^{(i)} = \mathcal{N}(z_W; H_{W} m_{k|k-1}^{(i)}, H_{W} P_{k|k-1}^{(i)} H_{W}^T + R_{W})
\] (10a)
\[
\begin{align*}
\mathbf{z}_W &= [\mathbf{z}_1^T, \mathbf{z}_2^T, \cdots, \mathbf{z}_{|W|}^T]^T \\
\mathbf{H}_W &= \left[ \mathbf{H}_k^T, \mathbf{H}_k^T, \cdots, \mathbf{H}_k^T \right]^T \\
\mathbf{R}_W &= \text{blkdiag} \left( \mathbf{R}_k, \mathbf{R}_k, \cdots, \mathbf{R}_k \right)
\end{align*}
\]  

(10b)

(10c)

(10d)

where \( \mathbf{H}_k \) is the measurement matrix of the sensor, and \( \mathbf{R}_k \) is the observation noise covariance. The weight of partition \( \varphi \) is

\[
\omega_{\varphi} = \frac{\Pi_{W \in \varphi} d_W}{\sum_{\varphi'} \Pi_{W' \in \varphi'} d_{W'}}
\]

(11a)

(11b)

where \( \delta_{ij} \) is the Kronecker delta. The means and covariances of the Gaussian-mixture \( D^{(i)}_{k|k}(x_k, W) \) are

\[
\begin{align*}
\mathbf{m}_{k|k}^{(i)} &= \mathbf{m}_{k|k-1}^{(i)} + \mathbf{K}_{k}^{(i)} (\mathbf{z}_W - \mathbf{H}_W \mathbf{m}_{k|k-1}^{(i)}) \\
\mathbf{P}_{k|k}^{(i)} &= [\mathbf{I} - \mathbf{K}_{k}^{(i)} \mathbf{H}_W] \mathbf{P}_{k|k-1}^{(i)} \\
\mathbf{K}_k^{(i)} &= \mathbf{P}_{k|k-1}^{(i)} \mathbf{H}_W^T (\mathbf{H}_W \mathbf{P}_{k|k-1}^{(i)} \mathbf{H}_W^T + \mathbf{R}_W)^{-1}
\end{align*}
\]

(12a)

(12b)

(12c)

From the above equations, we can see that these coefficients need to be calculated over again for each partition, which will cost much time in the recursion.

**Target statement estimation**

After the update, the pruning and merging procedures are always used to reduce the number of Gaussian components \( [3] \). The new intensity can be rewritten as

\[
D_{k|k}(x_k) = \sum_{i=1}^{k} \omega_k^{(i)} \mathcal{N}(x_k; \mathbf{m}_k^{(i)}, \mathbf{P}_k^{(i)})
\]

(13)

Then, the means of the Gaussians with greater weights can be selected as the estimates of the target statements. For example,
\[
\hat{X}_k = \{(m_k^{(i)}, P_k^{(i)}) | \phi_k^{(i)} > 0.5, i = 1, 2, ..., J_k \}
\]  (14a)

\[
\hat{N}_k = |\hat{X}_k|
\]  (14b)

where |·| is the cardinality of the set, and the number of targets \(\hat{N}_k\) can also be estimated.

Methods

For the purpose of reducing the computation in the update step and having a good performance, the partitioning algorithm for the measurement set based on the hierarchy clustering is presented at first in this section. Secondly, we describe how to make use of the partitioning algorithm to iteratively calculate the coefficients in the ET-GM-PHD filter. Then, the signal feature of extended emitter target is used to improve the tracking performance. Finally, the computational complexity of the proposed method is analyzed.

Partitioning the measurement set

The number of all possible partitions in the ET-PHD filter will increase sharply with the number of measurements. Thus, this filter is computationally intractable for real application. Therefore, a partitioning algorithm with a set of parameters is usually used to approximate the measurement set partitions. The hierarchical agglomerative clustering algorithm is a commonly used method in data analysis that continuously combines the clusters to partition the data set. In view of its simplicity and low computational complexity, the single-link (SL) hierarchical method is chosen to partition the measurement set, which is described as follows:

Input: the measurement set \(Z_k = \{z_i, 1 \leq i \leq N_k\}\), where \(N_k\) is the number of measurements.

Step 1. (Initialization)

For each \(1 \leq i \leq N_k\), let \(W_i = \{z_i\}\). Let \(\Omega_1 = \{W_1, W_2, \ldots, W_{N_k}\}\) and \(N_p = 1\). Define a distance matrix \(C_{2N_k \times 2N_k}\) where \(C_{ij} = d(z_i, z_j)\) for \(1 \leq i \neq j \leq N_k\). The values of other elements in \(C_{2N_k \times 2N_k}\) are set to be \(\text{Inf}\) (positive infinity).

Step 2. (Loop)

While \(\Omega_{N_p} > 1\)

Find \((m, n) = \arg\min_{i,j} C_{ij}\). Let \(t = N_k + N_p\) and \(N_p = N_p + 1\). Then, we can obtain a new partition \(\Omega_{N_p}' = (\Omega_{N_p} - \{W_m, W_n\}) \cup \{W_t\}\), where \(W_t = W_m \cup W_n\).

Update the distance matrix. Calculate the new distance \(C_{ij} = \min(d_{m,i}, d_{n,i})\) for each \(W_i \in (\Omega_{N_p} - \{W_t\})\). Let \(C_{m*,m} = C_{m*,m} = \text{Inf}\) and \(C_{n*,n} = C_{n*,n} = \text{Inf}\).

End
Output: the measurement set partitions \( \{ \varphi_i = \{ W_j \}, 1 \leq i \leq N_p \} \), where \( W_j \) is the cell, and \( N_p \) is the number of partitions.

It can be seen that the proposed algorithm only combines the two cells with the shortest distance from the last partition to obtain a new partition at each time point. Consequently, the cells in the two neighboring partitions \( \varphi_i \) and \( \varphi_{i+1} \) are almost the same. This characteristic can save substantial time in computing the pseudo-likelihoods in the update step of the PHD filter.

ET-GM-PHD filter based on hierarchy clustering partitions
As shown in Background, the measurement set partition only affects the Gaussian-mixture \( D_{kk}^{(k)}(x_k, W) \). Supposing that there are \( N_p \) partitions, the updated posterior intensity can be changed as follows in form:

\[
D_{kk}^{(k)}(x_k) = D_{kk}^{ND}(x_k) + \sum_{\varphi \in \mathcal{F}} \sum_{W \in \varphi} D_{kk}^{(k)}(x_k, W) = D_{kk}^{ND}(x_k) + \frac{1}{N_p} \sum_{j=1}^{N_p} \omega_{ij}^{(j)} d_W
\]

where

\[
\omega_{ij}^{(j)} = \prod_{W \in \varphi_j} d_W
\]

\[
S_{ij}^{(j)} = \sum_{W \in \varphi_j} \sum_{i=1}^{k_{j-1}} \omega_{ij}^{(i)} N(x_k; m_{ij}^{(i)}, P_{ij}^{(i)})
\]

\[
\omega_{ij}^{(k)} = \frac{F_{ij}^{(k)} P_{ij}^{(k)} \omega_{ij}^{(k-1)} \phi_{ij}^{(k)}}{d_W}
\]

Then, we assume that \( M_j = |\varphi_j| \) is the number of cells in the \( j \)th partition denoted as \( \varphi_j = \{ W^{(j)}_1, W^{(j)}_2, \ldots, W^{(j)}_{M_j} \} \), and let \( C_{m,n}^{(j)} = \min (C^{(j)}) \). Using the partitioning algorithm described in the above, the new partition can be denoted as \( \varphi_{j+1} = \{ W^{(j)}_1, \ldots, W^{(j)}_{M_{j-1}}, W^{(j)}_{m-1}, \ldots, W^{(j)}_{n-1}, W^{(j)}_{n+1}, \ldots, W^{(j+1)}_{M_{j+1}} \} \), where \( W^{(j+1)}_{M_{j+1}} = W^{(j)}_m \cup W^{(j)}_n \). According to Equation (16a–c), we have

\[
\omega_{ij}^{(j+1)} = \frac{\omega_{ij}^{(j)} d_{W_{M_{j+1}}}^{(j)}}{d_W^{(j)}}
\]
Extended Emitter Target Tracking and GM-PHD

\[ S_{j+1} = S_0 + \sum_{i=1}^{J_{k|k}} \omega_{W_{M_{j+1}}}^{(i)} \mathcal{N}(x_k; m_{i,k|k}^{(i)}, P_{i,k|k}^{(i)}) - \]
\[ \left( \sum_{i=1}^{J_{k|k}} \omega_{W_{M_{j+1}}}^{(i)} \mathcal{N}(x_k; m_{i,k|k}^{(i)}, P_{i,k|k}^{(i)}) + \sum_{i=1}^{J_{k|k}+1} \omega_{W_{M_{j+1}}}^{(i)} \mathcal{N}(x_k; m_{i,k|k}^{(i)}, P_{i,k|k}^{(i)}) \right) \] (18)

Thus, \( \omega_{j+1} \) and \( S_{j+1} \) can be calculated iteratively, and the additional computation only relates to the new cell \( W_{M_{j+1}} = W_m \cup W_n \). The number of new Gaussian components generated by the new partition \( \omega_{j+1} \) is only \( J_{k|k} \). The other Gaussian components in \( \omega_{j+1} \) are the same as those in \( S_{j+1} \), and the weights can be accumulated directly in the update step. As a result, the ET-GM-PHD filter based on hierarchy clustering can effectively reduce the number of new Gaussian components, as well as the computation caused by the different partitions, through the iterative process.

Combining extended emitter target tracking with signal features

To improve the performance of the extended emitter target tracking, we try to incorporate the signal features into the ET-GM-PHD filter. Suppose that the augmented emitter target statement consists of the kinetic information \( x = (x, \dot{x}, y, \dot{y})^T \) and the signal feature information \( e = \{ r_{fi} \} \). (For convenience, we assume that the signal feature only contains RF information.) It should be noted that there may be more than one RF, which means that one emitter target may generate several measurements per time step. The augmented statement of the extended emitter target is denoted as

\[ \tilde{x} = [x; e] \] (19)

Assuming that the signal feature is independent of the target motion statement and not time-varying, the posterior intensity at time \( k-1 \) can be denoted as

\[ D_{k-1|k-1}(\tilde{x}_{k-1}) = \sum_{i=1}^{J_{k-1}} \omega_{k-1}^{(i)} \delta(x_{k-1} - e_{k-1}^{(i)}) \mathcal{N}(x_{k-1}; m_{k-1}^{(i)}, P_{k-1}^{(i)}) \] (20)

where \( \delta(\cdot) \) is the Dirac delta. The birth intensity can also be denoted as

\[ \gamma_k(\tilde{x}_k) = \sum_{i=1}^{J_{k}} \omega_{j,k}^{(i)} \delta(x_{j,k} - e_{j,k}^{(i)}) \mathcal{N}(x_k; m_{j,k}^{(i)}, P_{j,k}^{(i)}) \] (21)

And the predicted intensity at time \( k \) can be given by

\[ D_{k|k-1}(\tilde{x}_k) = \gamma_k(\tilde{x}_k) + \sum_{i=1}^{J_{k-1}} \omega_{k-1,k}^{(i)} \delta(x_{k-1} - e_{k-1}^{(i)}) \mathcal{N}(x_k; m_{k-1}^{(i)}, P_{k-1}^{(i)}) \]
\[ = \sum_{i=1}^{J_{k}} \omega_{k|k}^{(i)} \delta(x_{k} - e_{k}^{(i)}) \mathcal{N}(x_k; m_{k|k}^{(i)}, P_{k|k}^{(i)}) \] (22)
Suppose that the measurement is
\[ \tilde{z} = [z; r_f'] \]
where \( z \) is the measurement information of the target location, and \( r_f' \) is the measurement information of RF.

Then, the signal feature can be integrated into the measurement set partition. The distance between two arbitrary measurements \( \tilde{z}_i \) and \( \tilde{z}_j \) can be defined as
\[ C_{i,j} = \rho d(z_i, z_j) + (1 - \rho)q(r_f', r_f') \]  
where \( 0 \leq \rho \leq 1 \) is a free parameter, \( d(z_i, z_j) \) represents the location distance, and \( q(r_f', r_f') \) represents the distance of the signal feature, which is related to the emitter target. For example, assuming that \( r_f' \) is very different from \( r_f' \), \( d(z_i, z_j) \) will be small when they come from the same target. To partition them into the same cell, \( q(r_f', r_f') \) must be small as well. However, when they are from different targets, \( q(r_f', r_f') \) should be large to avoid putting them in the same cell. Thus, the distance \( q(r_f', r_f') \) is defined as
\[ q(r_f', r_f') = \min\left( |r_f' - r_f'|, d_{r_f'} \right) \]  
\[ d_{r_f'} = \min_{1 \leq t \leq k} \left( \min_{1 \leq l \leq |\phi_f|} |r_{f_i} - r_{f_l}| + \min_{1 \leq l \leq |\phi_f|} |r_{f_j} - r_{f_l}| \right) \]

Intuitively, it can be interpreted as follows:
Suppose that there are \( J_{k-1} \) middle nodes in the network. From the start node \( i \) to the end node \( j \), one can either select a direct route \( i \to j \) or an indirect route \( i \to t \to j \) through a middle node \( t \). Then, \( q(r_f', r_f') \) represents the shortest walking distance between nodes \( i \) and \( j \). When given a parameter \( \rho \), the measurement set can be partitioned by the hierarchy method described in the first part of this section.

**Computational complexity analysis**

Since different parameters will lead to different number of measurement set partitions for the algorithm, in order to facilitate the analysis, we assume that all the algorithms have the same number of the partitions. To obtain a new partition \( \phi_f \), the complexity of Distance Partitioning [12] is approximated as \( O(N_k^2) \) (\( N_k = |Z_k| \) is the number of the measurements), the complexity of K-means++ Partitioning [15] is approximated as \( O(\tau M_f N_k) \) (\( \tau \) is the iterative time, and \( M_f = |\phi_f| \) is the number of the cells in the partition), and the complexity of Fuzzy ART Partitioning [16] is \( O(\tau M_f N_k) \) as well. Whereas, the complexity of our
partitioning algorithm is only $O(M_j^2)$ because the new partition $\phi_j$ can be obtained directly from the last partition $\phi_{j-1}$.

When given a new partition, in most cases, the coefficients need to be calculated over again in the update step because the new partition is always very different from the acquired partitions. The complexity of other existing algorithms is approximated as $O(N_k J_{k|k-1}) (J_{k|k-1}$ is the number of Gaussian components in the predicted intensity $D_{k|k-1}$). However, due to the similarity between the two neighboring partitions $\phi_{j-1}$ and $\phi_j$ the complexity of the proposed algorithm is approximated as $O(n_k J_{k|k-1}) (n_k = |W_{M_{j+1}}^{(j+1)}|$ is the number of measurements in the new cell, and $n_k$ is not larger than $N_k$ obviously). In summary, our method has a lower computational complexity than other existing algorithms.

**Results and Discussion**

The elapsed time and the optimal subpattern assignment (OSPA) metric [22], which can measure errors in both location and target number, are adopted for performance evaluation. The algorithm with smaller OSPA distance will exhibit better performance. Details can be found in reference [22].

**Materials**

Assuming that the sensors and targets are in a uniform Cartesian coordinates system, the target statement vector is denoted as $X=(x,\dot{x},y,\dot{y})^T$, which contains the positions and velocities of the X-axis and Y-axis. The motion model of the target is constant velocity (CV),

$$
X_k = \begin{bmatrix}
1 & T & 0 & 0 \\
0 & 1 & 0 & 0 \\
0 & 0 & 1 & T \\
0 & 0 & 0 & 1 \\
\end{bmatrix} X_{k-1} + \begin{bmatrix}
T^2/2 & 0 \\
T & 0 \\
0 & T^2/2 \\
0 & T \\
\end{bmatrix} V
$$

where $T=1$(s) is the sampling interval, and the process noise $V$ is a sequence of zero-mean Gaussian noise with covariance matrix $Q$

$$
Q = \begin{bmatrix}
\sigma_w^2 & 0 \\
0 & \sigma_w^2 \\
\end{bmatrix}
$$

where $\sigma_w = 2$(m/s$^2$) in the experiments. The measurement is given by

$$
Z_k = \begin{bmatrix}
1 & 0 & 0 & 0 \\
0 & 0 & 1 & 0 \\
\end{bmatrix} X_k + W
$$

where the measurement noise $W$ is also a sequence of zero-mean Gaussian noise whose covariance matrix is

\[ R = \begin{bmatrix} \sigma_x^2 & 0 \\ 0 & \sigma_y^2 \end{bmatrix} \quad (29) \]

where \( \sigma_x = \sigma_y = 10 \text{(m)} \) in the experiments.

The probability of target detection is \( p_{D,k} = 0.98 \), and the length of the time step is \( K = 50 \text{(s)} \). The location of clutter with Poisson RFS is uniform over the surveillance region \( V = [0, 1200] \times [0, 1200] \text{(m}^2) \). The radio frequency of the clutter is uniform in the range of \( [0, 5000] \text{(MHz)} \). In the ET-GM-PHD filter, the probability of survival is \( p_{S,k} = 0.95 \), the maximum number of Gaussian component is \( J_{max} = 100 \), and the pruning and merging thresholds are \( T_{prune} = 10^{-5} \) and \( U_{merge} = 4 \) respectively. The parameters of the OSPA metric are set to \( p = 2 \) and \( c = 100 \).

We conducted two series of experiments in this section. First, the proposed partitioning algorithm based on hierarchy clustering is compared with three other methods for the ET-GM-PHD filter. Second, the effect of the signal features on improving the tracking performance is validated. Monte Carlo experiments are repeated 200 times for each case. The simulations are implemented in MATLAB on an Intel Core i5-2320 3.00 GHz processor with 3.5 GB RAM. There are 3 targets moving in the surveillance region, as illustrated in Fig. 1.

**Experiment 1**

Without considering the signal features of the emitter target, the first series of experiments mainly compares the performance of the proposed method with other partitioning algorithms based on K-means++ \[15\], Distance Partitioning \[12\], and Fuzzy ART \[16\]. The number of clusters is \( 1 \leq K \leq |Z_k| \) in K-means++; the probability threshold is \( 0.3 \leq P_G \leq 0.8 \) in Distance Partitioning; and in Fuzzy ART, the vigilance threshold is set to be \( 0.89 \leq \rho_1 \leq 0.98 \) with \( \Delta = 0.01 \). The birth intensity is given by

\[
\gamma_k(x_k) = \sum_{i=1}^3 \omega_i^{(i)} \mathcal{N}(x_k; m_i^{(i)}, P_i^{(i)}) \quad (30)
\]

where

\[
\omega_i^{(1)} = \omega_i^{(2)} = \omega_i^{(3)} = 0.1 \quad (31a)
\]

\[

\[
m_i^{(3)} = (1100, 0, 800, 0)^T \quad (31d)
\]
Let \( \gamma(\cdot) = \gamma \) be a constant in the ET-GM-PHD filter. With clutter density \( \lambda_c = 5 \times 10^{-6} \) (i.e., seven clutter returns per scan over the region), the impacts of different expected numbers of generated measurements on the algorithms are shown in Fig. 2 and Fig. 3.

From Fig. 2, it can be seen that the partitioning algorithms based on Fuzzy ART, Distance Partitioning and hierarchy clustering perform better as the expected number increases, which is because the clutter will have less negative effect on the tracking performance when the number of the measurements from targets increases, and the clutter density is invariable. Similarly, a high signal to noise ratio (SNR) will lead to good performance. However, the partition based on
K-means++ does not perform well. The main reason is that K-means++ often fails to obtain the correct partitions due to the existence of counter-intuitive local optima for the implicit cost function [16]. In addition, as shown in Fig. 3, we can see that the elapsed times increase only slightly with the expected number increasing except for the partition based on K-means++. The proposed partitioning algorithm based on hierarchy clustering has a clear advantage in both tracking performance and elapsed time.

To further validate our approach, another experiment is performed in scenarios with different clutter densities. The results are illustrated in Fig. 4 and Fig. 5 when

the expected number of generated measurements is $\gamma = 4$. Fig. 4 shows that the performances will drop as a whole when the clutter density becomes large. However, the performance of the partition based on Fuzzy ART changes greatly. One reason may be that the vigilance thresholds are not adapted to our simulation, which causes overestimation of the target number and leads to a large average OSPA distance. From Fig. 5, it can be seen that the elapsed time of the partition based on K-means++ increases sharply with increasing clutter density. Overall, the ET-GM-PHD filter with the proposed partitioning algorithm can handle extended target tracking better in cluttered environment.

**Experiment 2**

In the second experiment, we want to know whether the PHD filter combined with the signal feature exhibits better performance for extended emitter target tracking. For simplicity, we assume that the signal of emitter (RF) is not time-varying and only has some jitter:

$$rf_k = (1 + u(-\varepsilon, \varepsilon))rf$$  \hspace{1cm} (32)

where $u(-\varepsilon, \varepsilon)$ is a uniform distribution in the range of $[-\varepsilon, \varepsilon]$ ($= 2\%$ in the experiments). The measurement is given by

$$rf'_k = rf_k + w_e$$  \hspace{1cm} (33)

where $w_e$ is zero-mean Gaussian white noise with standard deviation $r_e$. The birth intensity is given by

$$\gamma_k(x_k) = \sum_{i=1}^{3} \omega_i^{(i)} \delta(e_i - e_i^{(i)})N(x_k; m_i^{(i)}, P_i^{(i)})$$  \hspace{1cm} (34)

where

\[
\begin{align*}
\omega_{\gamma}^{(1)} = \omega_{\gamma}^{(2)} &= \omega_{\gamma}^{(3)} = 0.1 \\
\mathbf{e}_{\gamma}^{(1)} &= \{500,2000\} \\
\mathbf{m}_{\gamma}^{(1)} &= (150,0,50,0)^T \\
\mathbf{e}_{\gamma}^{(2)} &= \{1000,2000\} \\
\mathbf{m}_{\gamma}^{(2)} &= (50,0,300,0)^T \\
\mathbf{e}_{\gamma}^{(3)} &= \{500,1000,2000\} \\
\mathbf{m}_{\gamma}^{(3)} &= (1100,0,800,0)^T \\
\mathbf{P}_{\gamma}^{(1)} &= \mathbf{P}_{\gamma}^{(2)} &= \mathbf{P}_{\gamma}^{(3)} &= \text{diag}(100,400,100,400)^T
\end{align*}
\]  

Let \(\gamma^{(i)} = |\mathbf{e}^{(i)}|\) in the ET-GM-PHD filter, meaning that the expected number of measurements generated by the emitter target is equal to the number of equipped
radars and is reasonable in real application. Incorporating the signal feature (RF) into the measurement set partition, the tracking performances with different values of the free parameter $\rho$ in Equation (24) are illustrated in Fig. 6 and Fig. 7. From these figures, we can see that neither considering only the location information ($\rho=1$) nor considering only the RF information ($\rho=0$) exhibits good performance. This result is because that high clutter density will have a bad effect on the partitioning algorithm based on the location information, but there is overlapping of RF between different targets so that a measurement set partition based solely on the RF information will not be correct. In contrast, considering
both the location and the RF information \((0<\rho<1)\) will improve the performance of the modified ET-GM-PHD filter to varying degrees, effectively validating the auxiliary function of the signal feature information. In addition, Fig. 6 shows that there are few differences in the improvements of the algorithm performance with different values of \(\rho (\rho=0.2, \rho=0.5, \rho=0.8)\) when the measurement noise of location \((\sigma_x=\sigma_y=10)\) and the measurement noise of RF \((r_e=10)\) are small. However, when the measurement noise of RF \((r_e=100)\) is large, considering the relatively accurate location information \((\rho=0.8)\) more heavily is more conducive to improving the tracking performance.

**Conclusions**

To address the problem of measurement set partitioning in the ET-PHD filter, this paper proposes a fast partition method based on hierarchy clustering. It can iteratively compute pseudo-likelihoods according to the neighboring partitions. In addition, the signal feature is incorporated into the modified ET-GM-PHD filter for extended emitter target tracking. The simulation results show that compared with other partitioning algorithms, the proposed partition algorithm based on hierarchy clustering not only exhibits better performance but greatly reduces the computational complexity. Combining the PHD filter with the signal features can effectively improve tracking performance in the simulated scenarios.

Because the CPHD filter has an advantage in the estimation of the target number, another future work is to extend the proposed approaches to the ET-CPHD filter.

**Author Contributions**

Conceived and designed the experiments: YQZ SLZ HXZ. Performed the experiments: YQZ GG LL. Analyzed the data: YQZ SLZ GG LL. Contributed reagents/materials/analysis tools: YQZ HXZ. Wrote the paper: YQZ GG.
