Chapter

Hepatic Involvement in Hemophagocytic Lymphohistiocytosis

Somanath Padhi, RajLaxmi Sarangi, Susama Patra and Subash Chandra Samal

Abstract

Hemophagocytic lymphohistiocytosis (HLH) is a hyperinflammatory syndrome which results in uncontrolled systemic proliferation of benign macrophages in all reticuloendothelial organs producing worsening peripheral blood cytopenia(s); hypercytokinemia leading to hepatic injury producing hyperferritinemia, hypertriglyceridemia, hypofibrinogenemia; and if not diagnosed and treated early may lead to disseminated intravascular coagulation (DIC), multiorgan dysfunction, and death in nearly all individuals. It is postulated that hepatic injury/dysfunction starts early in the course of the disease which may mimic nonspecific hepatitis like prodrome to fulminant hepatic failure; possibly requiring liver transplant. While HLH as an entity is being increasingly recognized nowadays across wide specialties (both pediatric and adults); hepatic involvement in this setting has been poorly characterized. This chapter is aimed to highlight on the diagnosis and classification of HLH with a special emphasis on the pathophysiology of hepatic dysfunction, histomorphology of liver; and the current concept and controversies on the role of liver transplantation in this clinical setting.

Keywords: cytokine storm, HLH, liver, transplant, outcome

1. Introduction

Hemophagocytic lymphohistiocytosis (HLH) or hemophagocytic syndrome is a potentially catastrophic hyperinflammatory syndrome occurring in genetically susceptible individuals which results due to hyperactive, yet inappropriate, immune system going runamock [1]. This results due to impaired cytotoxic T lymphocyte (CTL)/natural killer (NK) cell activity producing uncontrolled proliferation of benign macrophages in all reticuloendothelial organs such as bone marrow, spleen, liver, and lymph nodes; causing histiocytic hemophagocytosis, worsening unexplained peripheral blood cytopenia (s), cytokine storm, cytokine mediated hepatic injury/ dysfunction producing spectrum of biochemical alteration such as hyperferritinemia, hypertriglyceridemia, hypofibrinogenemia, coagulopathy, disseminated intravascular coagulation (DIC), multi organ dysfunction (MOD); and if not diagnosed and treated early, may lead to death in virtually all case [2]. Since the first description of cases coined as “histiocytic medullary reticulocytosis” by Scott Robin and Smith in 1939, there has been a sequential change in nomenclature of this entity [3–6]. While HLH
as an entity is being increasingly recognized nowadays across wide specialties (both pediatric and adults); hepatic involvement in this setting has been poorly characterized [7–9]. Hepatomegaly and hepatic dysfunction, including elevated serum transaminases and bilirubin, cholestasis, and coagulopathy typically occur early in the disease and are associated with marked hematologic and/or neurological abnormalities. In rare instances acute hepatic failure may dominate the clinical picture, which in combination with hyperferritinemia, may mimic neonatal hemochromatosis [10].

2. Classification of HLH

Traditionally, HLH has been broadly classified into two forms: (i) primary HLH which is known to harbor documented genetic abnormalities implicated in the cytotoxic functions of the NK cell/CTL; and (ii) a secondary form which occurs in adults/elderly population without any genetic abnormality. However, upon the realization that HLH defining genetic abnormality can occur in any age, that these defects may be uncommon even in pediatric age group, the designations primary and secondary have become less relevant; and stratification into genetic and acquired forms seems more appropriate [11]. The genetic variant is again subdivided into autosomal recessive familial HLH (FHL) involving the several mutations in the CTL/NK

| Type | Examples with proportions in parentheses |
|------|------------------------------------------|
| A. Genetic | |
| i. Autosomal recessive/familial HLH | PFR1/perforin 1 (20–50%), UNC13D/Munc 13-4 (20%), STX11/syntaxin 11 (1%), STXB2/syntaxin binding protein 2 or UNC18B (unknown) |
| ii. Associated with primary immunodeficiency syndromes | Chediak-Higashi syndrome (LYST), Griscelli syndrome type 2 (RAB27A/Rab27a), Hermansky-Pudlak syndrome type 2 (AP3B1), X-linked proliferative syndrome (XLP) type 1 (SH2D1A/SAP protein), X-linked proliferative syndrome (XLP) type 2 (BIRC4/XIAP protein) |
| B. Acquired | |
| i. Virus associated | Herpes viruses (EBV, CMV, HHV-8, HSV), HIV, HTLV, adenovirus, HAV, HBV, HCV, measles, mumps, rubella, dengue, hantavirus, parvovirus B19, Enterovirus, influenza |
| ii. Bacteria associated | Staphylococcus aureus, Campylobacter spp., Fusobacterium spp., Mycoplasma spp., Chlamydia spp., Legionella spp., Salmonella typhi, Rickettsia spp., Brucella spp., Ehrlichia spp., Borrelia burgdorferi, Mycobacterium tuberculosis |
| iii. Fungal associated | Candida spp., Cryptococcus spp., Pneumocystis spp., Histoplasma spp., Aspergillus spp., Fusarium spp. |
| iv. Parasitic | Plasmodium falciparum, Plasmodium vivax, Toxoplasma spp., Babesia spp., Strongyloides spp., Leishmania spp. |
| v. Malignancy associated | Peripheral T-cell/NK-cell lymphomas, ALCL, ALL, Hodgkin lymphoma, multiple myeloma, acute erythroid leukemia Prostate and lung cancer, hepatocellular carcinoma |
| vi. Autoimmune disease associated (macrophage activation syndrome, MAS) | Systemic-onset juvenile idiopathic arthritis, Kawasaki disease, systemic lupus erythematosus, seronegative spondyloarthropathies |

Table 1. Classification of hemophagocytic lymphohistiocytosis (HLH) (adopted from Rosado et al. [1] and Gholam et al. [12]).
cell cytotoxic pathways [PFIR1/perforin 1 (20–50%), UNC13D/Munc 13-4 (20%),
STX11/syntaxin 11 (1%), STXB2/syntaxin binding protein 2 or UNC18B (unknown)]
and those associated with primary immunodeficiency syndromes such as Chédiak-
Higashi syndrome (LYST), Griscelli syndrome type 2 (RAB27A/Rab27a), Hermansky-
Pudlak syndrome type 2 (AP3B1), and X-linked proliferative syndrome (XLP) type 1
(SHD2D1A/SAP protein) and type 2 (BIRC4/XIAP protein) [12] (Table 1).

Acquired form of HLH is known to be triggered by diverse etiologies in suscep-
tible individuals; and are segregated as (i) infection associated secondary to viruses
(notably EVB, CMV, HHV-8, HSV, dengue, parvo B19, HAV, HBV, HCV, etc.; any
bacteria, fungi, parasites such as Plasmodia, Leishmania, Strongyloides),
(ii) malignancy associated (NK-T cell lymphoma/leukemia, anaplastic large
cell lymphoma, plasma cell myeloma, Hodgkin lymphoma, B cell non Hodgkin
lymphoma, acute lymphoid and myeloid leukemias; and solid malignancies such
as lung cancer, hepatocellular carcinoma, etc.), and (iii) macrophage activation
syndrome or MAS (associated with autoimmune disorders) [1, 3, 13].

3. Diagnostic criteria

There has been a paradigm shift of focus in the diagnosis of HLH since 2004
(Table 2) [3]. The 2004 diagnostic criteria developed for the pediatric HLH have been
widely adopted in adult medicine without systematic validation. Both 2004 and 2009
guidelines incorporated mutational/genetic analysis as a “major criterion” which has
subsequently been taken out, especially for adult HLH case. Moreover, two important
parameters that were incorporated in previous criteria such as “impaired NK cell activ
ity” and “increased soluble interleukin 2 receptor” are likely to be removed sooner or
later as these tests are available in only very few specialized centers all over the world
and are very costly. Therefore, in practice, the necessary five out of eight criteria as per
the HLH 2004 guidelines are actually five out of six parameters tested. In addition, the
criteria of “bone marrow hemophagocytosis” is becoming increasingly less important
nowadays as histiocytic hemophagocytosis has a poor specificity in the diagnosis
of HLH and this may not even be evident during initial marrow evaluation [1]! In
order to overcome these shortcomings, the French investigators proposed to adopt a
new objective scoring system (HLH probability score or HScore) (Table 3). A total
probability score of 169 was found to have a higher sensitivity and specificity for the
diagnosis of HLH [6]. Furthermore, simpler routine laboratory parameters (extended
variables) have been incorporated to diagnose the disease early. These include periph
eral blood monocytosis, hyponatremia, elevated lactate dehydrogenase, elevated β2
microglobulin, impaired coagulation parameters, and CSF pleocytosis [14].

Another interesting change has been made in regard to the measurement of
serum ferritin. A ≥500 μg/L cut off among pediatric population (up to 18 years
of age) was found to have 84% sensitivity in HLH-1994 trial and therefore was
included in the HLH 2004 guidelines [15]. Subsequently, pediatricians have revised
their ferritin cut off value to ≥10,000 μg/L with a higher sensitivity and near 100%
specificity for the diagnosis of HLH [16]. On the contrary, recent reports from adult
intensive care units (ICUs) have suggested a lower ferritin cut off value of 3000
to 4000 μg/L with >80% sensitivity and specificity in HLH diagnosis [17]. While
hyperferritinemia is not specific to HLH, the same in the clinical context of fever,
worsening cytopenia (s), and splenomegaly is highly valuable in the ICUs where
sepsis is the major overlapping clinical condition [18]. Recent studies have shown
that a high serum soluble interleukin 2 receptor to ferritin ratio is an important
biomarker in distinguishing lymphoma associated HLH compared to benign disease
associated HLH (8.56 vs. 0.66, respectively, P = 0.0004) [19].
Hepatitis A

4. Pathophysiology of HLH

Genetic HLH results due to inability to clear the antigenic stimulus and thus turn off the inflammatory response is what ultimately leads to cytokine storm characteristic of HLH. In healthy individuals, viral and tumor antigenic stimuli leads to Th1 mediated cytokine response (IFN-γ, TNF-α, GM-CSF) which in turn, stimulates CTL and NK cells to clear off target cells (viral infected cells, tumor cells, etc.) through release of perforin and granzyme granules at the synaptic site. Perforin is a key cytolytic protein that acts by inserting itself in the membrane of the target cell and creating pores that lead to osmotic lysis of the target cell. The normal production of vesicle granule content requires orchestrated steps of maturation, polarization, docking, fusion, and finally degranulation in the immunological synapse. All the genetic defects described in FHL involve either inadequate levels of perforin itself (FHL2) or improper granule exocytosis (FHL3–5 and immunodeficiency syndromes) (see above in the classification) (Figure 1) [2, 20].
5. Pathophysiology of hepatic dysfunction: the cytokine theory

It is now postulated that hepatic injury/dysfunction HLH is mainly due to cytokine storm which results due to impaired NK/Cytotoxic T lymphocyte function in a genetically susceptible individual while triggering factors playing a crucial role. The up regulation of granulocytic monocytic colony stimulating factor receptor on the macrophages along with macrophage proliferation leads to splenohepato-megaly. The macrophage derived IL-2, IFN-γ, and TNF-α mediated inflammation is reported to be predominantly porto-sinusoidal rather than lobular without any significant alteration in lobular architecture; which in turn produces raised transaminases, hepatocyte hemosiderosis; sinusoidal dilatation and congestion, Kupffer cell hyperplasia and hypertrophy producing hemosiderosis and hemophagocytosis. Furthermore, lymphocyte or lymphohistiocyte mediated biliary ductular injury

### Table 3.
Hemophagocytic lymphohistiocytosis probability score (HScore) as proposed by Fardet et al. [6].

| Parameters                                      | Number of points (criteria for scoring) |
|-------------------------------------------------|----------------------------------------|
| Known immunosuppression                          | 0 (no) or 18 (yes)                     |
| Temperature (°C)                                 | 0 (<38.4), 33 (38.4-39.4), or 49 (>39.4) |
| Organomegaly                                     | 0 (no), 23 (hepatomegaly or splenomegaly), or 38 (hepatomegaly and splenomegaly) |
| Number of cytopenia (s)                          | 0 (1 lineage), 24 (2 lineages), or 34 (3 lineages) |
| Ferritin (µg/L)                                  | 0 (<2000), 35 (2000–6000), or 50 (>6000) |
| Triglyceride (mmoles/L)                          | 0 (<1.5), 44 (1.5–4), or 64 (>4)       |
| Fibrinogen (g/L)                                 | 0 (>2.5), or 30 (<2.5)                 |
| Serum SGOT (IU/L)                                | 0 (< 30), or 19 (≥ 30)                 |
| Hemophagocytosis in marrow aspirate              | 0 (no) or 35 (yes)                     |

5 Human immunodeficiency virus or receiving long term immunosuppressive therapy (glucocorticoids, cyclosporine, azathioprine).

1 Hb ≤ 92 g/L, total leukocyte count ≤ 5000/mm³, platelet count ≤ 110,000/mm³.

Immune response in healthy subjects and uncontrolled, ineffective immune response in patients with genetic HLH. Adopted and modified from Janka GE [2].
Hepatitis A

and cytokine (IL 1, IL 6, and TNF-α) mediated impaired lipoprotein lipase activity causes cholestasis, hyperbilirubinemia and hypertriglyceridemia. Finally, hyperferritinemia so characteristic of HLH, is nothing but the result of acute phase reaction as well as increased erythrophagocytosis by Kupffer cells. All these cytokine basis of hepatic injury may culminate in severe hepatic functional compromise leading to hypofibrinogenemia, hypoalbuminemia, disseminated intravascular coagulation, and multiorgan dysfunction with a fatal outcome (Figure 2).

6. Histology of liver in HLH

The morphology of liver in HLH is not well characterized because of insufficient biopsy data, late diagnosis, sampling bias (needle biopsy vs. wedge biopsy); and associated triggering factors such as virus associated histological alterations; especially in acquired cases (Table 4).

Morphological changes as observed in several large series of liver biopsy specimens have shown relatively well-preserved hepatic parenchyma with a portal and sinusoidal lymphohistiocytic, CD 3+, CD8+, Granzyme B+, and variable perforin+ T cell-rich infiltrate [7–9, 21, 22]. Diverse histological patterns have been described in such cases (Table 4): (i) adult type chronic hepatitis like characterized by mild portal lymphocytic infiltrate with mild bile duct injury and endothelialitis, reported to be so characteristic of neonatal/childhood HLH; (ii) leukemia like pattern characterized by extensive portal, lymphohistiocytic infiltrate expanding the tracts and encroaching upon the lobular periphery blurring the portal limiting plate and infiltrating the sinusoids; (iii) histiocytic storage disorder-like pattern characterized by massive infiltration of histiocyte rich infiltrate plugging and distending the sinusoids and venules; (iv) neonatal giant cell hepatitis-like pattern characterized by extensive giant cell transformation of hepatocytes with prominent architectural disarray; (v) increased hepatic hemosiderosis along with marked hyperferritinemia and features of acute liver failure mimicking neonatal hemochromatosis; (vi) post stem cell transplantation graft

Table 4. Histopathology of liver in cases with hemophagocytic lymphohistiocytosis as described in several series (Chen et al. [10], n = 19; Ost et al. [8], n = 27; de Kerguenec et al. [9], n = 30).
versus host disease related changes; (vii) lymphocyte depleted morphology unrelated to prior immunosuppressive or immunomodulator therapy; especially later in the course of the disease or as a part of aberrant cytokine modulation [10].

Common to all specimens and helpful in diagnosing HLH are a constellation of additional features that included distinctive lymphocyte-mediated bile duct injury, significant endothelialitis of terminal portal and central veins, sinusoidal congestion and dilatation, increased Kupffer cell activity with or without hemosiderosis, erythropagocytosis, and histiocytic hemophagocytosis which is reported as inconspicuous to florid. Steatosis and cholestasis were also usually present [8–10]. The lymphocyte-mediated bile duct injury is characterized by nests or circumferential sheaths of lymphomononuclear cells interposed between the epithelium and the basal lamina eliciting little damage to the epithelium. The portal inflammation with cholangitis observed in FHL is reminiscent of primary sclerosing cholangitis, primary biliary cirrhosis, and vanishing bile duct syndrome; though neutrophils, plasma cells, granulomatous inflammation, periductal sclerosis, or ductopenia common in latter conditions are reported to be rare in HLH cases [10]. Endothelialitis of terminal hepatic and portal veins may result in transmural phlebitis and hemorrhage and extensive apoptosis of perivenular hepatocytes. The degree of inflammation, bile duct damage, endothelialitis, cholestasis, and steatosis seem to reflect the clinical stage of the disease.

7. Liver transplantation: current concept and controversies

The mortality rate is very high in HLH associated acute liver failure cases. However, this association is extremely rare. Moreover, the presence of two clinical conditions (HLH and acute liver failure) together makes its further complicated and delays the diagnosis. The average time from earliest diagnosis of liver failure to a definitive diagnosis of HLH has been reported to be 17.27 days [23]. This suggests that HLH is a late occurring phenomenon in the process of ALF. On the contrary, there are reports which support the viewpoint of HLH causing liver injury and thus culminating in ALF [24, 25]. The exact mechanism is still not known, as far as HLH induced liver injury is concerned. It is most probably the infiltration of activated macrophage or over production of cytokine in HLH can explain the degree of liver injury. In a clinical scenario, where the patient present with prolonged fever, jaundice and pancytopenia; HLH should be considered as a differential diagnosis [23].

The role of liver transplantation in the treatment of HLH – ALF is controversial. It is so, because of the primarily systemic nature of the disease, the risk of hepatic recurrence of HLH during the post-transplant period, increased in rejection rate and poor general condition of the patient to tolerate the transplant procedure [26]. The post-transplant survival at the end of 6 months is only 33% for the primary HLH – ALF patient [27]. However, a small clinical series involving nine pediatric patients, reported a better survival rate among the secondary HLH – ALF group [26].

In the secondary form of HLH, the liver transplantation is also not very helpful in the situation such as absence of ALF (MELD score < 20–22); when the clinical severity is due to the combined effect of ALF and HLH, rather than ALF alone; and when the HLH is severe and highly likely to be irreversible. In these situations, high mortality from advanced and likely irreversible HLH may limit the benefits of liver transplantation [28]. Liver biopsy should be performed to decide the extent of the liver injury and the role played by the hepatic injury vs. systemic HLH in the patients with ALF. However, liver transplant is still an option in HLH – ALF cases with predominant liver involvement from HLH and this should be undertaken before the highly lethal complication of HLH, such as, septic shock, DIC, bone marrow failure, explosive immune activation from HLH supervenes.
