Abstract. The starburst galaxy M 82 has been mapped at λ 1.2 mm using the IRAM 30–m telescope and the MPIfIR 19–channel bolometer. The influence of the side-lobe pattern and the ¹²CO(2–1) line has been carefully analyzed. Based on this analysis, we conclude that the cold dust does not extend far into the halo as has been previously claimed. The total mass of dust in the inner 3 kpc of the galaxy is 7.5 · 10⁶ M⊙. Assuming a solar gas-to-dust ratio, the inferred total mass of gas is 7.5 · 10⁸ M⊙.

Unlike in any other galaxy we find the CO(2–1) line emission to be clearly more extended than the λ 1.2 mm dust emission. A likely explanation for this exceptional behaviour, seen for the first time in galaxies, is heating of molecular gas by low–energy cosmic rays and soft X–rays in the halo of M 82.

Key words: dust – galaxies: individual: M 82 – galaxies: ISM – galaxies: starburst – radio continuum: galaxies – radio continuum: ISM

1. Introduction

The prototypical starburst galaxy M 82 is the prime example of a galaxy in which the violent star formation activity gives rise to the formation of a bipolar outflow and an associated extended halo, which is visible in various regimes of the electro–magnetic spectrum. Outflowing material was first evident in the Hα light (Lynds & Sandage 1963, McCarthy et al. 1987, Bland & Tully 1988). The kinematics of the outflowing material and the geometry of the cone have been thoroughly worked out by McKeith et al. (1995). The recent detection of Hα emission ∼11 kpc away from the plane of M 82 (Devine & Bally 1999) determines the cap of this outflow. The whole scenario is further corroborated by the existence of vertical magnetic field lines (Reuter et al. 1994), along which relativistic particles participate in the outflow, thus forming a radio halo (Seaquist & Odegard 1991). This halo exhibits a filamentary structure away from the plane (Reuter et al. 1992). Hot gas has been also found in some kind of halo which extends for several arcminutes along the minor axis (Fabbiano 1988, Schaaf et al. 1989, Bregman et al. 1995). This X–ray emission correlates well with the Hα if observed with sufficiently high angular resolution (Watson et al. 1984).

In this context, the search for neutral gas and dust away from the plane of M 82 has seen a number of attempts. Owing to the close interaction between M 81 and M 82, neutral hydrogen is seen enveloping M 82, but whether this gas stems from the M 81 or has been expelled from M 82 is still a matter of debate (Yun et al. 1994). Molecular gas associated with the dusty filaments outside the plane of M 82 has been reported by Stark & Carlson (1984) and has been observed by Sofue et al. (1992) out to a projected distance of ±2 kpc. Clear evidence for the existence of scattering dust away from the plane of M 82 comes from measurements of optical polarization (Bingham et al. 1976, Notni et al. 1981, Neininger et al. 1990).

Owing to its high luminosity in all spectral bands, M 82 has been a prime target for first–light experiments in the mm– and submm–regime (Elias et al. 1978, Jura et al. 1978). With the improvement of bolometric measurements detailed studies of the distribution of the cold dust in this galaxy have become feasible; thus the recent past has seen an increasing number of such investigations (λ2 mm: Kuno & Matsuo 1997; λ1 mm: Thronson et al. 1989, Hughes et al. 1990, Krügel et al. 1990a, Alton et al. 1999; λ0.5 mm: Jaffe et al. 1984, Smith et al. 1990, Alton et al. 1999). Carlstrom & Kronberg (1991) have shown that at λ3 mm thermal free–free emission still dominates the overall spectrum.

Apart from these dedicated bolometric measurements, continuum maps at millimeter wavelengths have been produced as by-products in various observations of spectral lines (e.g. Neininger et al. 1998). As a result of the discoveries of a galactic wind and halo in M 82, the more recent bolometric measurements aimed at detecting a dust halo at mm wavelengths. CO emission away from the plane was reported by Stark & Carlson (1984), Nakai et al. (1986) and by Sofue et al. (1992). An outflow of molecular gas was claimed by Nakai et al. (1987). A dust continuum...
halo was first mentioned by Hughes et al. (1990). Observations with higher resolution (Kuno & Matsuo 1997) suggest emission at 22 mm out to 400 pc from the plane. Recently Alton et al. (1999) reported a dust outflow from the central region of M 82, based on their sub-mm images.

Here we report observations of M 82 in the $\lambda 1.2$ mm continuum performed with the MPIfR 19-channel bolometer at the IRAM 30-m telescope. In Sect. 2 we describe the observations and data analysis, with consideration of the possible influence of the error beam. In Sect. 3 the distribution of the cold dust in M 82 will be presented, with a discussion conducted in Sect. 4, along with a comparison with other published measurements. In Sect. 5 we give a short summary of our results.

2. Observations and data reduction

2.1. Observations

We used the 19-channel bolometer of the MPIfR (Kreysa et al. 1993) in the Nasmyth focus of the IRAM 30-m telescope during the spring session in 1997. The weather conditions were fair during our night-time runs, with rather stable zenith opacities between 0.2 and 0.3 at 230 GHz.

The 19 channels of the bolometer are arranged in a closely packed hexagonal array, with beam sizes of 11″ FWHM and spacings of 20″. The calibration was performed by mapping Uranus every morning. The pointing and focus checks were made at regular intervals during the observations using nearby quasars (in particular 1308+326). The map was centered on the near–infrared peak at $\alpha_{2000} = 09^h51^m43^s, \Delta_{2000} = 69^\circ55'01''$ (Joy et al. 1987). The data were taken in the standard mapping mode where the field is scanned at a constant speed of 4″ per second in azimuth, with subsequent scans being spaced by 4″ in elevation. The map size was chosen large enough ($320'' \times 270''$) to assure a good baseline determination in the presence of extended emission. We thus made sure that the field was mapped sufficiently far out perpendicular to the major axis of M 82, such as to trace the full extent of any dust component in the halo. While scanning the sub-reflector was wobbled at a 2 Hz rate with an amplitude of 45″, which is small enough to ensure a stable beam pattern. Due to the small wobbler throw the OFF position was not necessarily free of emission, but using the algorithm of Emerson et al. (1979) this should have no effect on the resulting map. We also mapped Mars once and the point source 3C 273 twice each in order to obtain a detailed beam pattern. In addition, more maps of Mars and other calibration sources were used to properly check the calibration.

2.2. Standard data reduction

The whole field was covered six times. For each coverage we performed the data reduction separately using NIC (GILDAS software package), starting with the subtraction of a third–order baseline.

The scanning mode described in the previous section leads to maps which contain a superposition of a positive and a negative image of the source (double-beam maps). In principle the deconvolution can be done by dividing the Fourier transform (FT) of the measured intensity distribution by the FT of the wobble function and transforming back to image space. As the FT of the wobble function is a sine wave with zeroes at the origin and at harmonics of the inverse wobbler throw, it would cause problems at these spatial frequencies. To avoid these problems we used the algorithm of Emerson et al. (1979) to restore the double–beam maps into equivalent single–beam maps.

Thereafter we combined the 19 channels and calibrated the resulting map with respect to Mars and Uranus (assuming brightness temperatures of 198.5 K and 97.2 K respectively). In a last step the four best coverages were averaged and regridded onto equatorial (B1950) coordinates. (Two coverages were ignored because of bad S/N ratios.) This final map has a sensitivity of 5 mJy per beam and a angular resolution of 12″ (HPBW).

2.3. Influence of the error beam

In order to check the influence of the error beam on the extended emission we applied a CLEAN algorithm developed for single–dish maps (Klein & Mack 1995) to each coverage using a radially symmetric antenna pattern. This pattern was obtained in the following way: A field of $4.5' \times 3.5'$ size was mapped centred on 3C 273. This antenna pattern was then rotated in small steps ($5^\circ$), and these individual (rotated) maps were averaged to yield a nearly radially symmetric pattern. The subtraction of the CLEANed map from the original one showed that the error beam contributes less than 25% of the rms noise level to the extended emission ($\geq 20''$ away from the central position).

Even the sidelobes can be ignored in our case, because at $\lambda 1.2$ mm they are of the order of 2%, corresponding to roughly 5 mJy/beam in the M 82 maps. Averaging four coverages with different parallactic angles (and accordingly different positions of the sidelobes) the effect of the antenna pattern on the extended emission falls well below the rms noise of our final map.

This extra analysis make sure that the extended emission seen in our map is real and not affected by the error beam.

2.4. Correction for CO emission

Using the 19-channel bolometer, with its central frequency of 240 GHz and its effective bandwidth of $\Delta f_{bol} \approx 80$ GHz, the $^{12}$CO(2–1) line at 230 GHz might noticeably contribute to the total intensity in the bandpass. To get a
Fig. 1. Maps of M 82 at $\lambda$1.2 mm. The upper map shows the continuum emission after standard data reduction. The lower one shows the continuum emission, with the CO line emission subtracted. The contours are the same in both images starting at the 2$\sigma$ (10 mJy/beam) level. The beamsize of the IRAM 30-m telescope is shown in the lower left corner of each image.

Fig. 2 shows the CO-corrected continuum map of M 82 at $\lambda$1.2 mm, superimposed onto an optical image. At $\lambda$1.2 mm M 82 has a more or less oval shape (ellipticity $e \approx 0.6$), with the major axis parallel to the galactic plane (molecular gas). This corresponds to a position angle of approximately 70$^\circ$. The maximum of the continuum emission is located at $\alpha_{50} = 9^h51^m41^s$, $\Delta_{50} = 69^\circ54'55''$. Within the errors this position is identical to the peaks of the distributions at $\lambda800$ $\mu$m and $\lambda1.1$ mm (Hughes et al. 1990). Besides this regular shape there are some spur-like features extending above and below the galactic plane, which might be associated with the outflow seen at optical and IR wavelengths.

Fig. 3 shows the CO-corrected continuum map of M 82 at $\lambda$1.2 mm, superimposed onto an optical image. At $\lambda$1.2 mm M 82 has a more or less oval shape (ellipticity $e \approx 0.6$), with the major axis parallel to the galactic plane (molecular gas). This corresponds to a position angle of approximately 70$^\circ$. The maximum of the continuum emission is located at $\alpha_{50} = 9^h51^m41^s$, $\Delta_{50} = 69^\circ54'55''$. Within the errors this position is identical to the peaks of the distributions at $\lambda800$ $\mu$m and $\lambda1.1$ mm (Hughes et al. 1990). Besides this regular shape there are some spur-like features extending above and below the galactic plane, which might be associated with the outflow seen at optical and IR wavelengths.

3. Results

3.1. Overall distribution of the dust emission

The contours in Fig. 3 indicate some extended emission also along the minor axis of the galaxy, but at first glance...
the extent in this direction is not as large as suggested by the maps of Kuno & Matsuo (1997) and Alton et al. (1999). We have therefore computed the intensity as a function of distance from the galactic center along the minor (major) axis, averaging over some 30″ in the major-axis (minor-axis) direction. These profiles are displayed in Fig. 3. For comparison the $^{12}$CO(2−1) line intensity, the 850 μm (Alton et al. 1999) and 20 cm continuum profiles are shown, too.

The $\lambda$1.2 mm emission shows the most concentrated distribution, significantly smaller than that at 850 μm. Especially the scale height along the minor axis is very small with respect to the other wavelengths and the molecular emission.

Contrary to the expectation the molecular emission is the most extended component. Possible explanations for this phenomenon are discussed in Sect. 4.2.

3.3. Integrated flux density

Integrating over the continuum map we obtain a total flux density of $S_{240} = 1.91 \pm 0.13$ Jy. This is lower than the value measured by Krügel et al. (1990a), but their flux density was much more uncertain, owing to the lower sensitivity of their 1-channel bolometer.

Fig. 4 shows a radio-to-IR spectrum of M 82 with the individual values listed in Tab. 1. Our new 240 GHz measurement is completely consistent with the slope of the spectrum at this frequency (indicated by the dotted line), whereas the value derived by Kuno & Matsuo (1997) at 157 GHz lies much too high with respect to all adjacent data points.

The CO–corrected flux density is significantly lower than the flux density in our original map. This demonstrates that a line correction for continuum measurements in the relevant bands is indispensible.

The total flux can be turned into a gas mass via

$$M_g = \frac{S_{240} \cdot D^2}{B(T_d) \cdot \kappa_{240} \cdot \frac{M_d}{M_g}}$$

With a distance of $D = 3.25$ Mpc, and using the same parameters as Krügel et al. (1990a), i.e. a dust temperature of $T_d = 30$ K (Chini et al. 1989) and a dust absorption coefficient $\kappa_{240} = \kappa_{240}^* \cdot \frac{M_d}{M_g} = 0.003$ cm$^2$g$^{-1}$ (Krügel et al. 1990b), we derive a gas mass of $M_g = 7.5 \cdot 10^8 M_\odot$. If we adopted the Draine & Lee value $\kappa_{240} = 0.005$ cm$^2$g$^{-1}$ (Draine & Lee 1984) the resulting gas mass would be somewhat lower ($M_g = 4.5 \cdot 10^8 M_\odot$).

In this calculation we assumed a gas-to-dust ratio of approximately $M_g/M_d \approx 100$. The corresponding dust mass is $M_d = 7.5 \cdot 10^6 M_\odot$. 
4. Discussion

4.1. A dust halo?

The A2-mm map (Kuno & Matsuo 1997) shows continuum emission with a box–like shape, indicating a dust halo around M 82. Although the emission at λ1.2 mm and λ2 mm should be similar, we do not see any evidence for a significant halo contribution to the cold dust. This difference could be due to the error beam of the Nobeyama 45-m telescope.

Effects of the error beam and the antenna pattern have been investigated and largely removed from our map (see Sect. 2.3), while this is not mentioned in case of the Nobeyama measurements. The total flux density in the Nobeyama map is 1.7 Jy, which is much more than expected at this wavelength (see Fig. 4). This extra flux might be due to emission entering through sidelobes and the error beam.

The 850 μm map made by Alton et al. (1999) with the JCMT shows continuum emission at the 50 mJy level up to 40” above the galactic plane. This translates to 15 mJy at λ1.2 mm, corresponding to the second contour (3σ) in our map. Considering only the overall extent of the emission, the JCMT map is consistent with ours. The different shapes might be due to problems with the baseline subtraction, because the area mapped by Alton et al. is only slightly larger than the extent of the continuum emission.

4.2. Comparison of dust and CO

In non–active galaxies like NGC 4565 (Neininger et al. 1996) and NGC 5907 (Dumke et al. 1997) the molecular line emission is more concentrated towards the central region than the thermal dust emission. As can be seen from Fig. 4 and 5 the galaxy M 82 exhibits the opposite behaviour. The CO emission appears to be much more extended than the continuum. Since the maps in Fig. 4 are made with the same telescope at the same frequency, the difference can not be due to different beam patterns and error beams.

The dust is heated by the UV radiation field, which is concentrated towards the dense central region, because the UV photons can hardly escape without being absorbed. Only a small fraction of the UV photons makes its way out to kpc distances from the galactic plane, where it might contribute to the observed polarized radiation.

The molecular gas can be excited by the radiation field, but also by low–energy cosmic rays and by soft X–ray photons (see e.g. Glassgold & Langer 1973), which have a much larger scale height than the UV photons (Shopbell & Bland-Hawthorn 1998).

Fig. 4 shows that the synchrotron intensity at λ20 cm drops faster with distance from the galaxy plane than the CO and even the dust emission. However, at low radio frequencies there may be a significant radio halo (low–energy cosmic rays have longer lifetimes), which is already indicated by the 327–MHz map of Reuter et al. (1992). Hence, there may be abundant cosmic rays for heating. Such cosmic rays (E ≲ 100 MeV) remain, however, invisible in the radio window, since even in the strong (B ≃ 10 . . . 50 μG) magnetic field of M 82 they produce synchrotron radiation at frequencies below about 10 MHz. Soft X–rays are also seen far out of the plane of M 82 (e.g. Bregman et al. 1995). These circumstances altogether provide the likely
heating sources for any molecular material transported out of the disk of M 82 into the halo, rendering the CO "over-
luminous". This is also indicated by the low conversion 
ratio of CO line intensity to molecular gas column den-
sity, \(X_{\text{CO}} = N_{\text{H}_2}/I_{\text{CO}}\) derived by Smith et al. (1991). The 
existence of a soft X–ray and a low–frequency radio halo 
around M 82 readily explains the larger extent of the CO 
emission as compared to the cold dust.

5. Summary

In this paper we presented a new high–sensitivity map 
of the continuum emission at \(\lambda 1.2\) mm in the starburst 
galaxy M 82. To get a reliable map of the extended thermal 
dust emission we applied a CLEAN algorithm to our 
map (error beam correction) and subsequently subtracted 
the \(^{12}\text{CO}(2-1)\) line emission. Besides this the contribution 
of the sidelobes of the IRAM 30-m telescope has been esti-
minated.

The total mass of dust in the inner 3 kpc of the galaxy 
derived from the integrated \(\lambda 1.2\) mm flux density is \(5.0 \cdot 10^6\) 
\(M_\odot\), the inferred total mass of gas is \(7.5 \cdot 10^8\) \(M_\odot\).

Fig. 5. Comparison of the λ1.2 mm continuum and the CO(2−1) line emission. The upper image shows the CO–corrected λ1.2 mm continuum map of M 82. Contours start at 2σ (10 mJy/beam). The lower image shows the integrated CO(2−1) line intensity. Contours start at 3σ (20 K km s$^{-1}$/beam). The beam size of the IRAM 30-m telescope is given in the lower left corner of each image.

Although the continuum emission is not confined to the galactic disk, our map rules out the existence of any pronounced halo of cold dust around M 82. We find the CO(2−1) line emission to be clearly more extended than the λ1.2 mm dust emission. This unexpected observational result now waits for a conclusive theoretical explanation.

Acknowledgements. We thank Dr. A. Sievers from IRAM (Granada) for his support with additional calibration. We are very grateful to Dr. P.B. Alton for making his JCMT data available to us.
