Abstract

A method is proposed to calculate the confidence level for agreement of data with the Standard Model (SM) by combining information from direct and indirect Higgs Boson searches. Good agreement with the SM is found for $m_H \simeq 120$ GeV using the observables most sensitive to $m_H$: $A_t$ and $m_W$. In particular, quantum corrections, as predicted by the SM, are observed with a statistical significance of forty-four standard deviations. However, apparent deviations from the SM of $3.7\sigma$ and $2.8\sigma$ are found for the $Z\nu\bar{\nu}$ and right-handed $Zb\bar{b}$ couplings respectively. The maximum confidence level for agreement with the SM of the entire data set considered is $\simeq 0.006$ for $m_H \simeq 180$ GeV. The reason why confidence levels about an order of magnitude higher than this have been claimed for global fits to similar data sets is explained.
1 Introduction

It is now almost three decades since the first accelerator [1, 2] and physicists [1, 3] studies, that eventually lead to the construction and operation of the LEP $e^+e^-$ collider at CERN were performed. Now, some roughly twenty man-millenia of work by physicists and engineers later, the almost final results of the LEP and concurrent SLC (Stanford Linear Collider) experimental programs are available [4, 5]. By general consensus, the most scientifically important of these results concern high precision tests of the Standard Electroweak Model (SM) [6, 7, 8]. During the same period, important contributions to this subject (discovery of, and measurement of the mass, $m_t$, of the top quark, measurement of the mass, $m_W$, of the W boson and the NuTeV neutrino-quark scattering results) were also made at the FERMILAB laboratory.

The LEP program consisted of two stages. In the first, ‘Z-pole’, running a total of $\sim 1.7 \times 10^7$ Z decays into pairs of all the fundamental fermions (the matter fields of the SM), except the top quark, were collected by the four LEP detectors, ALEPH, DELPHI, L3 and OPAL. At SLC, the same processes were studied with lower statistics but with precisely controlled electron beam polarisation, allowing experiments of very high sensitivity to be performed, so producing results of comparable statistical accuracy to those of LEP. The final outcome of all this work may be summarised, in what concerns the SM, in only seven numbers, which, for definiteness can be taken to be the right- and left-handed couplings to the Z of the charged lepton, c-quark and b-quark pairs and the (left-handed) coupling of the Z to neutrino pairs. The busy reader, who would like to go straight to the final conclusions, is invited to look directly at Tables 19 and 20 below where the measured values of these coupling constants, together with the corresponding SM predictions are shown. The second, ‘high energy’ phase of LEP operation at collision energies above the threshold for W pair production provided essentially one additional high precision SM parameter, $m_W$. This measurement, in combination with the FERMILAB measurement of comparable accuracy of the same quantity, is also shown in Tables 19 and 20. Other important measurements performed during the second LEP phase were of the triple boson WW$\gamma$ and WWZ couplings, but these have less impact than the fermion couplings as a test of the core physics underlying the SM: a renormalisable quantum field theory incorporating local gauge invariance that is spontaneously broken by the Higgs mechanism$^1$. They are therefore not discussed further in this paper. In the conventionally used on-shell renormalisation scheme [9] where $m_W$ is traded as an input parameter for the much more precisely known Fermi constant, $G_\mu$, derived from the measured muon lifetime, the predictions of the SM depend (apart from other and better known parameters) on three relatively poorly known ones: $m_t$, the electromagnetic couplant at the Z mass scale, $\alpha(m_Z)$, and the mass of the Higgs boson, $m_H$. Because of quantum loop corrections, the right- and left-handed couplings, $g_R^l$ and $g_L^l$, of the Z to charged lepton pairs, as well as $m_W$, are strongly sensitive to the values of $m_t$ and $m_H$. Actually, it is only the ratio $g_R^l/g_L^l$ and $m_W$ which are strongly sensitive to $m_H$, so that the measurements of these

$^1$In fact the now experimentally well verified [4] SM predictions for the WW$\gamma$ and WWZ couplings were already contained in Glashow’s original electroweak paper [6] where they follow at tree level from global SU(2)$_L$ invariance and quantum mechanical mixing of the $W^0$ and $B^0$ fields. Their values then shed little light on the correctness (or otherwise) of either the renormalisability of the theory or the Higgs mechanism. A genuine test of local gauge symmetry would be provided by measurements of the strength of quadrilinear boson couplings. So far this has not been done.
two quantities provide the most stringent limits, from quantum corrections, on the value of \( m_H \).

In the second phase of LEP, an unsuccessful search was performed for directly produced Higgs bosons [10], resulting in the 95\% confidence level (CL) lower limit \( m_H > 114.4 \) GeV. The principle aim of the present paper is to combine, in a transparent way, this direct limit with the indirect information derived from \( \frac{g_R}{g_L} \) (or equivalently \( A_t \), see below) and \( m_W \), to derive combined curves of CL, the confidence level that the \( m_H \)-sensitive data agrees with the SM, as a function of \( m_H \). The reader might then reasonably hope that the result of the paper would be a single curve of CL versus \( m_H \). In fact she (or he) will find eight figures where CL is plotted versus \( m_H \) containing in total 18 different curves. The reason for this complication is that the data, though perfectly consistent experimentally\(^2\), is not consistent with the SM (see Tables 19 and 20) and depending on the assumptions made (SM correct, model-independent analysis, certain data included or excluded) different results are found for the CL curves. I have included a number of different possibilities to demonstrate the inconsistency of the data with SM predictions. The reader may then choose the curve for which the assumptions match best her (or his) own favourite ones.

The structure of the paper is as follows: In the next Section some general remarks concerning the different functions of the science of Statistics in data analysis are made. In particular it is pointed out that the choices made until now for the \( \chi^2 \) estimator in global electroweak analyses give an over-optimistic estimate of the level of agreement of the data with the SM. In Section 3, the heavy quark asymmetry measurements that are \textit{prima facie} inconsistent with charged lepton asymmetries, when both are interpreted within the SM, are discussed. In particular, the internal consistency of the data and systematic error estimates are examined in some detail. The sensitivities of different electroweak observables to \( m_t \) and \( m_H \) are discussed in Section 4. This is the only place in the paper where fit results are shown and discussed. It is demonstrated that the sensitivity to \( m_H \) comes essentially from only the observables \( A_t \) and \( m_W \). Section 5 describes the algorithm used for combining the direct and indirect measurements of \( m_H \). Results for CL derived from \( A_t \) and \( m_W \), assuming the correctness of the SM, but selecting different data, are shown. Also shown in this Section is the sensitivity of CL to the values of the parameters \( m_t \) and \( \alpha(m_Z) \). In Section 6 the alternative interpretations of the result of the NuTeV experiment are explained and it is pointed out that the interpretation, as required in a model-independent analysis, as a measurement of the \( Z \nu \bar{\nu} \) coupling, instead of \( m_W \), is strongly favoured by arguments of statistical consistency. In Section 7 a complete set of model independent observables is extracted and compared with SM predictions. Constraints are set on the coupling of non-b down-type quarks using the precisely measured observable \( \Gamma_{had} \). Quantum corrections are extracted for different fermion flavours and compared with SM predictions. Finally, in Section 7, curves of CL versus \( m_H \) derived from a \( \chi^2 \) estimator using all or selected subsets of the considered observables (including now \( m_H \)-insensitive ones) are shown. In Section 8 values of CL obtained as described in Section 7, are compared with the confidence levels of previously published global fits to similar data. The confidence levels are seen to be very consistent when the purely statistical dilution of the hypothesis testing power of the \( \chi^2 \) estimators of the global fits, as

\(^2\)That is, good agreement is found between different measurements of the same experimental observables. For details see Reference [4]
discussed in Section 2, is taken into account. Section 8 also contains a critical discussion of $m_H$ limits determined from $\Delta\chi^2$ plots. Section 9 contains a summary and conclusions, including the author’s personal choice of three most pertinent $\overline{CL}$ versus $m_H$ plots. The busy reader is encouraged to read this Section first to get a general view of the results and conclusions returning later (if still interested) to the earlier Sections for more information and supporting arguments.

When the first version of the present paper was almost complete a new experimental value of $m_t$, $178 \pm 4.3$ GeV, was announced by the CDF and D0 collaborations [11]. Since the change from the previous value of $174.3 \pm 5.1$ GeV has a dramatic effect on the $\overline{CL}$ curves, especially for large values of $m_H$, all such curves shown, when the contrary is not explicitly stated, use the new value of $m_t$. However no global fits have yet been published by the EWWG and EWPDG using the new value. Therefore, in Section 4 where comparisons with the results of EWWG global fits are made, the old value of $m_t$ is used. The conclusions of Section 8, where the consistency of the confidence levels found in the present paper with those quoted for global fits is discussed, are unaffected by the change in the measured value of $m_t$.

2 Statistics: Data Consistency versus Hypothesis Testing

In the context of the analysis of experimental data, Statistics has three quite distinct roles to play. These are:

(i) To judge whether different measurements of the same physical quantity are consistent with each other, and to derive an unbiased weighted average value of the quantity.

(ii) To test the hypothesis that an ensemble of measurements of the same or different physical quantities are consistent with some theory.

(iii) In the case of positive answers to the questions implicit in (i) and (ii), to determine numerical values of unknown or partially known parameters of a theory from the data.

In previous and current analyses of precision electroweak data performed by the LEP and SLD electroweak working groups (EWWG) [4] and the standard model sub-group of the Particle Data Group (EWPDG) [5], only the functions (i) and (iii) above are systematically performed, with little, if any regard for (ii). In fact tests of data consistency (comparisons of different measurements of the same physical quantity) are performed by the EWWG using the $\chi^2$ estimator, with, in general, very satisfactory results [4]. In the global fit to all data, since the point (ii) is not addressed, all relevant data is used for parameter estimation in the global fit. In the case that all of the data is in agreement with the SM this procedure gives the best, unbiased, estimate of parameter values. However, if certain sub-sets of data do not agree with the SM, biased results may be obtained using this procedure. In particular, as will be discussed below, the fitted value of $m_H$
obtained with the current data set is biased towards higher values by about 50 GeV by just such an effect. The EWPDG also do not investigate the level of agreement of different data sub-sets with the SM and related biases, being concerned only with the function (iii), parameter estimation on the assumption that all data is correctly described by the SM [12]. In this case different measurements of the same physical quantity are included as independent data in the fit without any prior consistency checks such as those performed by the EWWG. In the case that subsets of data do not agree with the SM, fitted parameters may then be biased in just the same way as in the EWWG global fits. It seems to the present writer that seeking the answer to the question posed in (ii) above should be the principle aim of experimental investigations of the SM, but, as a point of fact, this is an avowed goal of neither the EWWG nor the EWPDG.

So what is the answer to the question implicit in (ii) above provided by the current electroweak data set? The nature of the problem is well illustrated by some fit results quoted in a paper devoted to a search for possible evidence of supersymmetry in precision electroweak data [13]. Fitting, as a preamble, the minimal electroweak standard model to only the $\sin^2 \Theta_{\text{eff}}^{\text{lept}}$ values derived from either leptonic or hadronic asymmetry measurements, a $\chi^2$ per degree of freedom ($\chi^2$/d.o.f.) of 18.4/4 was obtained corresponding to a CL of 0.001. A fit by the EWWG to the same data set, but using instead about 20 observables$^3$ reported a $\chi^2$/d.o.f. of 26.0/15, with a CL of 0.04. An analysis of essentially the same year 2000 data set by EWPDG, but fitting the SM to more than 40 observables found, for a global fit, a $\chi^2$/d.o.f. of 42/37 with a CL of 0.27 [14]. The fitted value of $m_H$, was very similar in these three different fits since, as discussed below, almost all the sensitivity to $m_H$ is found in only two observables, $\sin^2 \Theta_{\text{eff}}^{\text{lept}}$ and $m_W$. Thus, for essentially the same fitted value of $m_H$, CLs differing by a factor of up to 270, according to the fit procedure used, were obtained. Which (if any) of the different CLs most truly reflects the agreement between the data and the SM prediction? The principal aims of the present paper are, firstly, to provide an answer to this question, and, secondly, to combine CLs derived from direct and indirect experimental limits on $m_H$ so has to obtain a meaningful overall CL that reflects both the internal consistency of different observables and the global level of agreement with the SM.

The explanation of the poor CL obtained in the fit to only the leptonic and hadronic $\sin^2 \Theta_{\text{eff}}^{\text{lept}}$ values is now well known. As first pointed out in analyses of the 1996 data set [15, 16] The Z-boson b-quark couplings appear to be anomalous at about the three standard deviation level. These couplings are quite insensitive, in the SM, to $m_H$ and $m_t$, but, due to a correlation effect, when heavy quark forward/backward asymmetries are analysed, assuming the correctness of the SM, to extract a value of $\sin^2 \Theta_{\text{eff}}^{\text{lept}}$, the latter is found to correspond to a much larger value of $m_H$ than that derived from purely leptonic measurements [17, 18]. This leads to barely compatible values of $\sin^2 \Theta_{\text{eff}}^{\text{lept}}$ from leptonic and hadronic (essentially b-quark) data and explains the poor CL of the fit to this data to obtain $m_H$ and $m_t$ mentioned above.

More recently, much more precise experimental measurements of $m_W$ have become available. These are found to favour a value of $m_W$ even lower than that suggested by the

$^3$Many of these quantities are actually ‘pseudo-observables’, but for brevity the term ‘observable’ will be used throughout this paper for extracted physical quantities sensitive to parameters of the electroweak theory.
leptonic data, thus resulting in a large discrepancy between the $m_H$ value obtained by combining the leptonic data and $m_{W}$ and that derived from hadronic asymmetries. This problem has been been recently stressed in the literature [19] and is now generally appreciated [20].

The reason for the factor $\simeq 300$ difference in the CLs of different fits is easily understood. The point is that the fit to only the $\sin^2\Theta^{\text{eff}}_{\text{lept}}$ values was essentially performing the function (ii) above, i.e. hypothesis testing, whereas the EWWG and EWPDG fits were combining the functions (i) and (ii) with a large weighting factor in favour of (i). How this happens will now be explained. In addition to this effect, the hypothesis testing ability of the fit $\chi^2$ is further blunted by the inclusion of observables in the fit, that have almost no sensitivity to $m_H$ and $m_t$, in both the EWWG and EWPDG analyses.

Consider a number, $N$, of independent measurements, $Q_i$, of the same quantity, $Q$. The theoretical expectation for $Q$ is $Q_{\text{th}}$ and the weighted average value of the measurements is $\bar{Q}$. With the assumption of uncorrelated experimental errors, three different Pearson $\chi^2$ estimators may be defined, as follows:

$$\chi^2_{\text{data,WA}} = \sum_{i=1}^{N} \frac{(Q_i - \bar{Q})^2}{\sigma_i^2} \quad (2.1)$$

$$\chi^2_{\text{data,th}} = \sum_{i=1}^{N} \frac{(Q_i - Q_{\text{th}})^2}{\sigma_i^2} \quad (2.2)$$

$$\chi^2_{W,A,th} = \frac{(\bar{Q} - Q_{\text{th}})^2}{\bar{\sigma}^2} \quad (2.3)$$

In Eqn(2.3), $\bar{\sigma}$ is the weighted mean error on the quantity $\bar{Q}$. Assuming uncorrelated, Gaussian distributed, errors it is given by the relation:

$$\frac{1}{\bar{\sigma}^2} = \sum_{i=1}^{N} \frac{1}{\sigma_i^2} \quad (2.4)$$

where $\sigma_i$ is the estimated RMS uncertainty on $Q_i$. Noting the identity:

$$Q_i - Q_{\text{th}} \equiv (Q_i - \bar{Q}) + (\bar{Q} - Q_{\text{th}}) \quad (2.5)$$

Eqn(2.2) may be written as:

$$\chi^2_{\text{data,th}} = \sum_{i=1}^{N} \left[ \frac{(Q_i - \bar{Q})^2}{\sigma_i^2} + \frac{(\bar{Q} - Q_{\text{th}})^2}{\sigma_i^2} + 2(Q_i - \bar{Q})(\bar{Q} - Q_{\text{th}}) \right] \sum_{i=1}^{N} \frac{Q_i}{\sigma_i^2} - \bar{Q} \sum_{i=1}^{N} \frac{1}{\sigma_i^2}$$

$$\chi^2_{\text{data,WA}} + \chi^2_{W,A,th} + 2(\bar{Q} - Q_{\text{th}}) \left( \frac{\sum_{i=1}^{N} Q_i}{\sum_{i=1}^{N} \frac{1}{\sigma_i^2}} \right) \left[ \sum_{i=1}^{N} \frac{Q_i}{\sigma_i^2} - \bar{Q} \sum_{i=1}^{N} \frac{1}{\sigma_i^2} \right]$$

$$\chi^2_{\text{data,WA}} + \chi^2_{W,A,th} \quad (2.6)$$

where, in the third line of Eqn(2.6) the definition of $\bar{\sigma}$, (2.4) and Eqn(2.3) have been used, and in the fourth line the definition of $\bar{Q}$:

$$\bar{Q} \equiv \frac{\sum_{i=1}^{N} Q_i}{\sum_{i=1}^{N} \frac{1}{\sigma_i^2}} \quad (2.7)$$
So, in the simple case of uncorrelated Gaussian errors, the $\chi^2$ for consistency of the data with the theory is equal to the simple sum of the $\chi^2$ for consistency of the data with its weighted average plus the $\chi^2$ for consistency of the theory with the weighted average. Clearly $\chi^2_{data,W_A}$ is a measure only of the internal consistency of the data and so the corresponding CL provides an answer only to the question raised in point (i) above. $\chi^2_{W_A,thy}$ gives, providing the CL for $\chi^2_{data,W_A}$ is acceptable, an estimate of probability that the data is correctly described by the theory, and so provides the hypothesis test mentioned in (ii) above, as well as estimating the values of unknown parameters of the theory (for example, $m_H$ if $thy = SM$) in accordance with point (iii) above. However, the value of $\chi^2_{data,thy}$, the statistical estimator universally used by both the EWWG and the EWPDG, reflects both the internal consistency of the data and the level of agreement of the data with the theory. If the number of data is very large, the relative contribution of $\chi^2_{W_A,thy}$ to $\chi^2_{data,thy}$ becomes very small, since the former $\chi^2$ has only one degree of freedom. Under these circumstances, the CL of $\chi^2_{data,thy}$ is not a meaningful indicator of the level of agreement of the data and the theory.

To take a simple example, suppose that there are 40 data and that $\chi^2_{data,W_A} = 30$ and $\chi^2_{W_A,thy} = 16$, so that, on the assumption of uncorrelated Gaussian errors, Eqn(2.6) gives $\chi^2_{data,thy} = 46$. The corresponding confidence levels are: $\chi^2_{data,W_A}$/d.o.f. = 30/39, CL= 0.849; $\chi^2_{W_A,thy}$/d.o.f. = 16/1, CL= $6.3 \times 10^{-5}$; $\chi^2_{data,thy}$/d.o.f. = 46/40, CL= 0.28. Thus the effect of the four standard deviation discrepancy observed in $\chi^2_{W_A,thy}$ is diluted to give an innocuous CL of 0.28 for the statistical estimator $\chi^2_{data,thy}$.

To take properly into account both the internal consistency of different measurements of the same quantity, and the level of agreement of the data with theory, a useful statistical procedure is to combine the confidence levels of the appropriate $\chi^2$ functions. Since $\chi^2_{data,W_A}$ and $\chi^2_{W_A,thy}$ are independent statistical estimators, the corresponding CLs may be combined by use of the formula [21]:

$$CL(\alpha_1, \alpha_2) = \alpha_1\alpha_2[1 - \ln(\alpha_1\alpha_2)] \quad (2.8)$$

where $\alpha_1$ and $\alpha_2$ are the two independent CLs to be combined. It follows that in the simple example considered above the combined CL has the value $5.8 \times 10^{-4}$ so that the data/theory discrepancy is still well in evidence. Note that the combined CL is a factor 493 smaller than the CL of $\chi^2_{data,thy}$ in this case! In the following the combined CL given by Eqn(2.8) will be used to calculate the overall confidence level that the relevant data are consistent and that the data are in agreement with the SM, for different values of $m_H$.

In the above example each datum has the same sensitivity to the parameters of the theory. However, among the $\approx 20$ observables included in the global electroweak fits performed by the EWWG and the $\approx 40$ in the similar EWPDG fits, the majority are only weakly sensitive to the values of $m_H$ and $m_t$. This effect dilutes even further the hypothesis testing power of the statistical estimator $\chi^2_{data,thy}$ beyond that due to the dominant contribution of $\chi^2_{data,W_A}$ discussed above. In the statistical analysis presented below, the separate contributions of $\chi^2_{data,W_A}$ and $\chi^2_{W_A,thy}$ to $\chi^2_{data,thy}$ will be extracted to provide separate answers to the questions posed in points (i) and (ii) above. The overall CL will then be calculated according to Eqn(2.8) above. In the case of a small number of sensitive observables $^4$it will be found that, unlike in the example discussed above, good

$^4$Indeed, for $m_H$, there are only two such observables $A_t$ and $m_W$ as discussed in Section 4 below.
agreement is found between the CL of the total \( \chi^2 \): \( \chi^2_{\text{data,W}A} + \chi^2_{W,A,T} \) and the combined CL calculated using Eqn(2.8). The former CL is then used as a statistical estimator for the indirect Higgs mass analysis.

Previous authors [22, 23] have calculated normalised probability density functions (PDFs) giving the relative probability of different values of \( m_H \), by combining direct and indirect limits. Instead, in the present paper, the combined CL is found by combining the CLs of the direct and indirect measurements in region of overlap using Eqn(2.8). This combined CL gives an absolute rather than a relative probability that the SM is consistent with the data for any value of \( m_H \). In this way the hypothesis testing aspect of the comparison of the data with the SM is addressed. This is not done by the normalised PDFs derived in References [22, 23].

### 3 Heavy Quark Asymmetry Measurements

A discussion of the consistency of the b-quark asymmetry measurements in the data up to 1999 may be found in Reference [24]. The current LEP and SLD heavy flavour asymmetry measurements are collected in Table 1 (b-quarks) [25] and Table 2 (c-quarks) [25]. In Table 1 are reported eight independent measurements of the forward/backward asymmetry \( A^{0,b}_{FB} \) as well as the direct SLD measurement of \( A_b \) from the forward/backward,left/right asymmetry. Table 2 contains seven LEP measurements of \( A^{0,c}_{FB} \) and the direct \( A_c \) measurement from SLD. For each LEP asymmetry measurement the corresponding value of \( A_b \) or \( A_c \) is estimated using the relation:

\[
A_Q = \frac{4A^{0,Q}_{FB}}{3A_l} \quad (Q = b, c)
\]

where \( A_l \) is the LEP+SLD average value of the charged lepton asymmetry parameter extracted by assuming charged lepton universality:\(^5\)

\[
A_l = \frac{2\tau_l \bar{\tau}_l}{\nu_l^2 + \nu_l^2} = \frac{2\tau_l}{1 + \tau_l^2}
\]

where

\[
\tau_l = \frac{\tau_l}{\bar{\tau}_l} = 1 - 4 \sin^2 \Theta_{\text{eff}}^{\text{lept}}
\]

The value used is [4]:

\[
A_l = 0.1501(16)
\]

The values of \( A_b \) and \( A_c \) derived in this manner are presented in the last columns of Tables 1 and 2. The SM predictions for the values of \( A_b \) and \( A_c \) are 0.935 and 0.668 respectively.

---

\(^5\)The notation follows that of Reference [17]

\(^6\)Errors are quoted on the least significant digits. e.g. 4.123(32) means 4.123 ± 0.032. When two errors are quoted, the first is statistical and the second systematic
with a negligible dependence on $m_H$ and $m_t$ at the scale of the present experimental errors. Also shown in Tables 1 and 2 are the LEP average values of $A_{0,b}^{FB}$, $A_b$, $A_{0,c}^{FB}$ and $A_c$ as well as the LEP+SLD combined values of $A_b$ and $A_c$. The uncertainties on the LEP average values of $A_b$ and $A_c$ come mainly from those on $A_{0,b}^{FB}$ and $A_{0,c}^{FB}$ (1.6 % and 5.0 %) rather than that on $A_l$ (1.1 %). The statistical and systematic errors on both the LEP average and the SLD measurements of $A_{0,b}$ and $A_{0,c}$ are of comparable magnitude.

Values of the different $\chi^2$ estimators: $\chi^2_{\text{data,W},A}$, $\chi^2_{W,A,\text{Thy}}$, and $\chi^2_{\text{data,\text{Thy}}}$ introduced above for the quantities $Q = A_b, A_c$ are presented in Table 3. The $\chi^2_{\text{data,W},A}$ CLs of 0.92 and 0.90 for $A_b$ and $A_c$ indicate good internal consistency of the data, but also, possibly, an over-estimate of systematic errors. The $\chi^2_{W,A,\text{Thy}}$ CLs of $1.11 \times 10^{-2}$ and 0.45 for $A_b$ and $A_c$ indicate in the former case a 2.5$\sigma$ discrepancy, and, in the latter, good agreement with the SM prediction. As in the example discussed above, the $A_b$ discrepancy is not evident in the CL of $\chi^2_{\text{data,\text{Thy}}}$, which takes the value 0.21. The combined CLs, according to Eqn(2.8), that the $A_b$ and $A_c$ data are both consistent and in agreement with the SM are 0.057 and 0.77 respectively. This would seem to indicate that it is not unreasonable that the deviation of $A_b$ from the SM prediction could be due to statistical fluctuation.
perhaps in combination with some unknown systematic effect. However, this conclusion requires confidence in the estimation of the systematic errors. As will be discussed below, there is some evidence, from the data itself, that the uncorrelated systematic errors may be somewhat overestimated, thus reducing from its true value the significance of the observed $A_b$ deviation.

It is interesting to note that a goodness-of-fit estimator, independent of the $\chi^2$ test, is provided by the so-called ‘Run Test’ [26]. For the case of the $A_b$ data in Table 1, since all 9 independent measurements constitute a single ‘run’ (they are all less than the SM prediction) the corresponding CL is easily calculated. Since a single run can occur in only two ways (all data higher than or all data lower than the theoretical prediction) the CL is $2/2^9 = 3.9 \times 10^{-3}$. Unlike for the $\chi^2$ test, the CL of the Run Test is insensitive to over- or under-estimation of uncorrelated systematic errors. Since the CLs of the Run Test, of $\chi^2_{\text{data,WA}}$ and of $\chi^2_{\text{WA,thy}}$ are all independent, they may be combined into a single CL using the formula that generalises Eqn(2.8) to the case of three independent CLs: $\alpha_1$, $\alpha_2$ and $\alpha_3$ [21]:

$$ \text{CL}(\alpha_1, \alpha_2, \alpha_3) = \alpha_1 \alpha_2 \alpha_3 [1 - \ln(\alpha_1 \alpha_2 \alpha_3) + \frac{[\ln(\alpha_1 \alpha_2 \alpha_3)]^2}{2}] $$ (3.5)

The combined CL for the $A_b$ data given by Eqn(3.5) is $2.5 \times 10^{-3}$. The single run of the $A_b$ data may be associated with a genuine deviation of the data from the SM prediction or a large correlated systematic effect of unknown origin. It is argued below that the latter explanation is unlikely. The third possible explanation, a statistical fluctuation, is also unlikely, given the small value of the combined confidence level.

As there are $\simeq 10$ independent measurements of both $A_b$ and $A_c$, it is possible to compare errors estimated directly from the data, with the calculated statistical and estimated uncorrelated systematic errors on the weighted average values of $A_b$ and $A_c$ shown in Tables 1 and 2. The estimators for the error on the weighted average, $\bar{\sigma}$ and its RMS uncertainty $\sigma_{\bar{\sigma}}$ are given by the formulae [27]:

$$ \bar{\sigma} = \sqrt{\frac{\sum_i (Q_i - \bar{Q})^2}{N(N-1)}} $$ (3.6)

$$ \sigma_{\bar{\sigma}} = \frac{\bar{\sigma}}{\sqrt{2N(N-1)}} $$ (3.7)

These formulae yield values of $\bar{\sigma}$ of 0.0089(22) for $A_b$, and 0.018(5) for $A_c$, to be compared with the estimated total errors on the WA values of 0.013 and 0.020 respectively in these quantities. The agreement is good for $A_c$, but for $A_b$ there is an indication, at the 1.9$\sigma$ level, that the uncorrelated systematic errors may be overestimated. This is confirmed by

|       | $\chi^2_{\text{data,WA}}/\text{d.o.f.}, \text{CL}$ | $\chi^2_{\text{WA,thy}}/\text{d.o.f.}, \text{CL}$ | $\chi^2_{\text{data,thy}}/\text{d.o.f.}, \text{CL}$ | Comb. CL |
|-------|---------------------------------|---------------------------------|---------------------------------|----------|
| $A_b$ | 3.2/8, 0.92                      | 6.4/1, 0.011                    | 12.0/9, 0.21                    | 0.057    |
| $A_c$ | 3.2/7, 0.90                      | 0.56/1, 0.45                    | 4.1/8, 0.85                     | 0.77     |

Table 3: Different $\chi^2$ estimators and CLs derived from the LEP and SLD measurements of $A_b$ and $A_c$. 
calculation of the WA statistical error on the LEP+SLD weighted average value of $A_b$, which is just 0.0088, in perfect agreement with the value of $\bar{\sigma}$ estimated directly from the data. Using this error to calculate $\chi^2_{WA,\text{Thy}}$ gives $\chi^2/\text{d.o.f.} = 14.0/1$, CL = $1.8 \times 10^{-4}$ a 3.7$\sigma$ effect. Thus, although (see Table 1) the estimated systematic error on the LEP+SLD average value of $A_b$ is by no means the dominant one, the significance of the apparent deviation of $A_b$ from the SM prediction is very sensitive to it. There is some evidence, from the data itself, that the uncorrelated part of this systematic error may be over-estimated.

The dominant source of correlated systematic error on both $A_{FB}^{0,b}$ and $A_{FB}^{0,c}$ arises from the QCD corrections [28] of $(2.96 \pm 0.40)\%$ for $A_{FB}^{0,b}$ and $(3.57 \pm 0.76)\%$ for $A_{FB}^{0,c}$. This source contributes 35% of the total systematic error on the LEP average value of $A_b$, the remaining part being essentially uncorrelated between the different measurements. Thus the observed fractional discrepancy, 0.053, between the LEP average value of $A_b$ and the SM prediction, is about 1.8 times larger than the QCD correction and about 13 times larger than the estimated uncertainty on this correction. The latter would have to have been underestimated by more than an order of magnitude in order to explain the observed discrepancy with the SM prediction. This seems unlikely. Note, however, that the estimate of systematic error from the data itself using Eqns(3.6) and (3.7) gives no information on such a correlated uncertainty.

In conclusion, the different measurements of $A_b$ are in very good agreement with each other, but their average value shows a -2.5$\sigma$ deviation from the SM prediction. There is some evidence, from the data itself, that uncorrelated systematic errors may be over-estimated, thus possibly reducing the observed deviation from its true value. The correlated systematic error must have been underestimated by a large factor if the origin of the $A_b$ deviation is unknown systematics rather than a breakdown of the SM. The measurements of $A_c$, on the other hand are found to be both consistent and in good agreement (within their much larger errors) with the SM prediction. Also however, as will be seen below, all of the hadronic asymmetries show similar fractional deviations from the SM parameters favoured by the purely leptonic data. The possibility of deviations from the SM in the c-quark and light quark sectors as large as that observed in the b-quark sector is therefore not excluded by the asymmetry data.

4 Sensitivities of Electroweak Observables to $m_t$ and $m_H$

To justify the restricted choice of observables used below to calculate the $\chi^2$ estimators for the data/SM comparison this Section presents some results of fits to obtain $m_H$, or $m_H$ and $m_t$. The overall approach used is the ‘model-independent’ one of References [16, 17, 18] All charged lepton and heavy quark measurements from LEP and SLD are combined to obtain the independent observables: $A_l$, $\bar{\sigma}_l$, $A_b$, $\bar{\sigma}_b$, $A_c$ and $\bar{\sigma}_c$. The $A_f$ ($f = l, b, c$) parameters are defined as in Eqn(3.2) above, with small additional correction terms in the case of $A_b$. The quantity, $\bar{\sigma}_f$, is defined as $\bar{\sigma}_f = \pi_f^2 + \pi_f^2$ and so is proportional to the partial width for $Z \to ff$ decays. Again, due to the large mass of the b-quark, small corrections are included in this case [17]. The LEP+SLD average values of these observables used in the fits presented below are shown in Table 1. To take properly into account error
Table 4: Measured values of $A_f$ and $\bar{s}_f$ compared to SM predictions for $m_t = 174$ GeV, $m_H = 100$ GeV. $\text{Dev}(\sigma) = (\text{Meas.}-\text{SM})/\text{Error}$.

| $X$ | $X_{\text{expt}}$ | $\sigma_X$ | $(\Delta X/\sigma_X)_m$ | $(\Delta X/\sigma_X)_H$ |

| $s_{\nu b}$ | 1.3211 | 0.0043 | 0.93 | 0.32 |
| $m_W$ | 80.426 | 0.034 | 3.5 | -3.1 |

Table 5: Sensitivities of different measured quantities to $m_t$ and $m_H$ (see text).

correlations, the directly measured values; $A_b = 0.925(20)$ and $A_c = 0.670(26)$ from SLD are assigned separate terms in the $\chi^2$ estimator. Correlations between $A_t$, $A_b$ and $A_c$ resulting from Eqn(3.1) are included in the $\chi^2$ error matrix. Also shown in Table 4 are the SM predictions for $m_t = 174$ GeV and $m_H = 100$ GeV as well as normalised deviations. This Table has the same format and SM predictions as Table 3 of [17], with which it may be directly compared.

The sensitivity of different observables to $m_t$ and $m_H$ is presented in Table 5. To take into account both the intrinsic sensitivity and the effect of experimental uncertainty, the quantities $(\Delta X/\sigma_X)_m$ and $(\Delta X/\sigma_X)_H$ are shown for each observable, $X$, with experimental uncertainty $\sigma_X$. The quantity $\Delta X$ in $(\Delta X/\sigma_X)_m$ is the change in the value of $X$ for a variation of $m_t$ from 164 GeV to 184 GeV, with $m_H = 120$ GeV and $\Delta X$ in $(\Delta X/\sigma_X)_H$ is the change in the value of $X$ for a variation of $m_H$ from 20 GeV to 200 GeV, with $m_t = 174.3$ GeV. Most of the sensitivity to $m_t$ resides in the observables $A_t$, $\bar{s}_t$ and $m_W$, to $m_H$ in $A_t$ and $m_W$ only. The sensitivity of $\bar{s}_t$ (or $\Gamma_t$) to $m_t$, but not to $m_H$, has also been noted in a recent paper [29].

Also included in Table 5 are the observables: $s_\nu = \bar{s}_\nu + \bar{s}_\nu$ and $s_{\nu b}$ (to be discussed below) which is similarly defined to $s_c$ and $s_b$ but for non-b quarks. Both these observables have a moderate sensitivity to both $m_t$ and $m_H$.

As pointed out above, if $A_{FB}^{0,b}$ is used as observable to estimate, via quantum corrections, $m_H$, a very different value is obtained from that favoured by $A_t$ or $m_W$. This is due to the linear dependence of $A_{FB}^{0,b}$ on $A_t$ (see Eqn(3.1) above) and the 2.5$\sigma$ deviation of $A_b$.

Note that the $(\Delta X/\sigma_X)_m$ entries of $\bar{s}_t$ and $\bar{s}_b$ of the similar table in Reference [17] are incorrect.
from the SM prediction discussed in the previous Section\textsuperscript{8}. Assuming the correctness of the SM, ‘hadronic’ values of \( A_l \) may be extracted from the measurements of \( A_{FB}^{0,b} \) and \( A_{FB}^{0,c} \) by substituting the SM predictions for \( A_b, A_c \) (which are essentially independent of \( m_H \) and \( m_t \)) into Eqn(3.1). Another, independent ‘hadronic’ value of \( A_l \) may be derived from the value of \( \sin^2 \theta_{eff}^{lep} \) obtained from the SM analysis the quark anti-quark charge asymmetry, \( Q_{FB}^{had} \) [4]. These different ‘hadronic’ determinations of \( A_l \), obtained by assuming the correctness of the SM, are presented, together with the ‘leptonic’ value from Table 4, in Table 6. Note that the ‘leptonic’ value of \( A_l \), although derived assuming charged lepton universality does not assume the correctness of the SM, only that the process \( Z \rightarrow \ell \bar{\ell} \) is described by some effective vector and axial vector couplings so that Eqn(3.1) is obeyed.

The ‘leptonic’ value of \( A_l \) in Table 6 is derived from \( e, \mu \) and \( \tau \) forward/backward charge asymmetries and from \( \tau \)-polarisation measurements. The hadronic ones from quark forward/backward charge asymmetries. In fact the \( A_l \) derived uniquely from \( \tau \)-polarisation measurements: \( A_l(\tau-poln) = 0.1465(33) \) lies almost exactly mid-way between the SLD ALR and LEP \( A_{FB}^{0,l} \) weighted average of 0.1513(19) and the value of \( A_l(had) \) quoted in Table 6. It is 1.3\( \sigma \) below the former and 1.1\( \sigma \) above the latter. In the 1996 data set [30] the difference between \( A_l(\tau-poln) \) and the ALR, \( A_{FB}^{0,l} \) average was

\textsuperscript{8}This effect is particularly transparent in Fig.1 of Reference [18] or in Fig 15.1 of Reference [4]

much larger, 2.5σ, so that the inclusion (or not) of the τ-polarisation data had a large effect on the value of $A_t$ extracted using Eqn(3.1). This was discussed in some detail in Reference [16]. In another paper discussing the same 1996 data set [31] it was pointed out that, considering also the τ-polarisation data as ‘hadronic’ (because of the predominantly hadronic final states), the value of $\sin^2 \Theta_{eff}^{lept}$ derived from the leptonic ALR and $A_{FB}^{0.1}$ measurements was found to differ by more than 3σ from that given by the ‘hadronic’ ones, i.e. τ-polarisation and quark asymmetry measurements. The situation is much improved in the current (essentially final) LEP+SLD data. Excluding the τ-polarisation measurements gives a minor change in the WA $A_b$ value: $A_b(\tau - poln\ out) = 0.898(13)$ to be compared with the value quoted in the last row of Table 1. The deviation of $A_b$ from the SM prediction is only increased from 2.5σ to 2.8σ, instead of the $\simeq 1\sigma$ increase found in the 1996 data set [16].

Because of its strong dependence on $m_H$ and $m_t$ then, unlike in the case of $A_b$ and $A_c$, no definite SM prediction exists for $A_t$. However it is of interest to compare the ‘leptonic’ value of $A_t$, $A_t^{(lept)}$ with the different ‘hadronic’ values $A_t^{(had)}$. The following $\chi^2$ values and confidence levels are obtained: $\chi^2_{had,W,A}/d.o.f. = 0.047/2$, CL= 0.977; $\chi^2_{lat,W,A}/d.o.f. = 9.0/3$, CL= 0.029; $\chi^2_{had,lept}/d.o.f. = 9.2/1$, CL= 0.0024. Thus the three hadronic determinations are very consistent with each other, whereas the hadronic and leptonic determinations differ by 3 standard deviations. This poor overall consistency of the different values of $A_t$, extracted assuming the correctness of the SM for the quark couplings, must be taken into account when assessing the overall level of agreement of the data with the SM.  

It is important to stress that this mismatch is not the result of any inconsistency evident in the experimental data themselves, but rather the result of interpreting the data according to the SM prediction.

The following strategy is now followed for fits to obtain limits on $m_H$: In a first step, fits similar to those previously presented in References [17, 18] are performed to the the entire LEP+SLD data set contributing to the six observables of Table 4, as well as LEP+FERMILAB combined direct measurement of $m_W$: $m_W = 80.426(34)$ GeV. Other fits are done including also the indirect determination of $m_W$: $m_W(NuTeV) = 80.136(83)$ GeV by NuTeV [32]. Only $m_H$ is varied in the fits, the other important parameters: $m_Z$, $m_t$, $\alpha(m_Z)$ and $\alpha_s(m_Z)$ being fixed at their measured values of 91.1875 GeV, 174.3 GeV, 0.007755 and 0.118 respectively. The effect of variation of the second and third of these parameters, within their experimental uncertainties, on the CL for agreement of the data with the SM, will be discussed in Section 5 below. The values of other fixed parameters are specified in References [16, 17, 18].

In the fits, a numerical parameterisation, accurate at the per mil level, of the effective weak mixing angle given the two-loop ZFITTER 5.10 program [33] was used:

$$\sin^2 \Theta_{eff}^{lept} = 0.233657 - 8.42 \times 10^{-8} m_t^2 - 3.86 \times 10^{-8} \ln m_t + 5.00 \times 10^{-4} \ln m_H$$

(4.1)

where $m_t$ and $m_H$ are expressed in GeV units. The overall normalisation factors $\rho_f$ ($f = l, \nu, u, d, b$) for fermionic widths of the Z are given by a numerical parametrisation similar

\footnote{Indeed, the consistency of the three different ‘hadronic’ estimates of $A_t$ is much better than expected. Because of the large statistical uncertainties of the b- and c-quark data this is most likely due to a chance co-incidence rather than any over-estimation of systematic errors.}

\footnote{The formula is valid at the quoted accuracy for $m_H \geq 40$ GeV. For lower values of $m_H$, small corrections are made to the constant term and the coefficient of $\ln m_H$.}
to Eqn(4.1) of the entries in Table 2 of Reference [34]. For $m_W$, the parameterisation of Reference [35] was used.

The fits for $m_H$ are then repeated using only the $m_H$-sensitive observables $A_l(\text{all})$ and $m_W$ where $A_l(\text{all})$ is the weighted average of the leptonic and hadronic values of $A_l$ given in the last column of Table 6. Similar fits are performed including also $m_W$(NuTeV). The results of this comparison are shown in the first four rows of Table 7. In can be seen that essentially the same range of Higgs masses is obtained whether fits are made to the complete set of electroweak observables or only to the $m_H$-sensitive ones $A_l$ and $m_W$. The fit results presented in the fifth and sixth rows of Table 7 demonstrate that very low values of $m_H$, with best fit values incompatible with the 95% direct lower limit of 114.4 GeV, are found when fitting only the $m_H$-sensitive observables $A_l(\text{lept})$ and $m_W$. As shown in the last two rows of Table 7, much higher values of $m_H$ are found when $A_l(\text{lept})$ is replaced by $A_l(\text{had})$ in the fits. This is a consequence of the deviation of the measured value of $A_b$ from the SM expectation, and the strong correlation between $A_l$ and $A_b$ resulting from Eqn(3.1), when $A_{FB}^0$ is measured. In all cases inclusion of the NuTeV $m_W$ measurement results in slightly higher fitted values for $m_H$ and reduces all confidence levels, by about an order of magnitude, to values less than 0.01.

As another cross-check of both the fitting procedure and the $m_H$, $m_t$ sensitivity of different observables, simultaneous fits to $m_H$ and $m_t$ were performed including also in the $\chi^2$ estimator the directly measured value of $m_t$ from FERMILAB: $m_t = 174.3(5.1)$ GeV. The results of these fits, both including and excluding the indirect NuTeV $m_W$ measurement, are presented in Table 8, where they may be compared with the results of similar fits from the most recent EWWG report [4]. Slightly lower fitted values of $m_H$ are found in the latter, probably due to the inclusion of other observables such as $\Gamma_Z$, and $Q_W(\text{Cs})$ from atomic parity-violating experiments, that have some sensitivity to $m_H$, in the EWWG fits. The uncertainties on both $m_H$ and $m_t$ found in the two sets of fits are very similar. In fact slightly more precise values of $m_H$ are obtained in the fits of the present paper. This, in combination with the results shown in the first four rows of Table 7, shows that the restriction to $A_l$ and $m_W$ entails no significant loss of sensitivity in the indirect determination of $m_H$. The dilution effect discussed in Section 1 of the hypothesis-testing power of the $\chi^2$ estimator, due to the inclusion of unaveraged equivalent observables, or additional ‘noise’ observables, that are insensitive to $m_H$ and $m_t$, is evident in the $\chi^2$/d.o.fs and CLs of the fits that are also presented in Table 8. The EWWG fits have a CL that is a factor of 8(4) times larger than those of the present paper for the fits including(excluding) the NuTeV $m_W$ measurement. A more detailed discussion of the global EWWG fits is found in Section 8 below.

5 Combining Confidence Levels of Direct and Indirect Limits on $m_H$

The combined result of the direct searches for the Standard Model Higgs Boson by the LEP Collaborations ALEPH, DELPHI, L3 and OPAL is given in Fig.9 of Reference [10]. This shows the confidence level ratio: $\text{CL}_s \equiv \text{CL}_{s+b}/\text{CL}_b$ as a function of $m_H$. $\text{CL}_{s+b}$ is the confidence level of the signal-plus-background hypothesis and $\text{CL}_b$ that of the background-
Figure 1: Illustration of the combination of direct (CL_{s+b}) and indirect CL(\chi^2_{SM} + \chi^2_{WA}) m_H confidence levels using Eqn(2.8). The observables used to calculate CL(\chi^2_{SM} + \chi^2_{WA}) are A_t(all) and m_W.

Figure 2: Combined m_H confidence levels. The observables used to calculate CL(\chi^2_{SM} + \chi^2_{WA}) are A_t and m_W.
Figure 3: Combined $m_H$ confidence levels. The observables used to calculate $\text{CL}(\chi^2_{\text{SM}} + \chi^2_{\text{WA}})$ are $A_l$, $m_W$ and $m_W$(NuTeV).

Table 9: Confidence levels as a function of $m_H$ for different sets of observables. The values of $\chi^2_{WA}$/d.o.f. and CL refer to $A_l$. 

### Table 10: Confidence levels as a function of $m_H$ for different sets of observables.

| Observables          | $m_H$ [GeV] | 120  | 160  | 200  | 240  | 280  |
|----------------------|-------------|------|------|------|------|------|
| $A_l$(all), $m_W$, $m_W$(NuTeV) | CL($\chi^2_{SM}$) | 0.012 | 0.015 | 0.0089 | 0.0036 | 0.0012 |
|                      | CL($\chi^2_{SM} + \chi^2_{WA}$) | 0.0027 | 0.0033 | 0.0021 | 0.00096 | 0.00036 |
|                      | CL(Comb)    | 0.0030 | 0.0037 | 0.0024 | 0.00107 | 0.00039 |
| $A_l$(lept), $m_W$, $m_W$(NuTeV) | CL($\chi^2_{SM}$) | 0.0071 | 0.0025 | 0.00066 | 0.00013 | 3.3 x 10^{-5} |
|                      | CL($\chi^2_{SM} + \chi^2_{WA}$) | 0.018 | 0.0072 | 0.0022 | 0.00056 | 0.00014 |
|                      | CL(Comb)    | 0.022 | 0.0089 | 0.0027 | 0.00065 | 0.00018 |
| $A_l$(had), $m_W$, $m_W$(NuTeV) | CL($\chi^2_{SM}$) | 0.00031 | 0.0012 | 0.0022 | 0.0029 | 0.0029 |
|                      | CL($\chi^2_{SM} + \chi^2_{WA}$) | 0.0021 | 0.007 | 0.012 | 0.015 | 0.015 |
|                      | CL(Comb)    | 0.0028 | 0.0091 | 0.016 | 0.020 | 0.019 |

Table 11: Combined confidence levels $CL$ for consistency with the SM as a function of $m_H$. Observables used in the $\chi^2$ estimator: $A_l$ and $m_W$.

| $m_H$ (GeV) | $A_l$(All) | $A_l$(lept) | $A_l$(had) |
|------------|------------|-------------|------------|
| 111        | 8.4 x 10^{-7} | 6.3 x 10^{-6} | 6.6 x 10^{-7} |
| 113        | 3.2 x 10^{-4} | 2.1 x 10^{-3} | 2.6 x 10^{-4} |
| 115        | 0.047 | 0.23 | 0.041 |
| 140        | 0.062 | 0.23 | 0.088 |
| 180        | 0.034 | 0.054 | 0.13 |
| 220        | 0.013 | 0.010 | 0.13 |
| 260        | 3.9 x 10^{-3} | 1.9 x 10^{-3} | 0.11 |
| 300        | 1.1 x 10^{-3} | 3.3 x 10^{-4} | 0.077 |

Table 12: Combined confidence levels $CL$ for consistency with the SM as a function of $m_H$. Observables used in the $\chi^2$ estimator: $A_l$, $m_W$ and $m_W$(NuTeV).
only hypothesis. Inspection of the figure shows that, at percent level accuracy: CLs = 10^{-6}, 0.05, 0.08 for \( m_H = 111, 114.4, 120 \) GeV, respectively. For the present study it is preferred to work directly with CL\(_{s+b}\), which is similar to the \( \chi^2 \) confidence level given by comparing the SM to Z-decay data, to obtain indirect \( m_H \) limits. As shown in Fig.7 of Reference [10], the value of CL\(_b\) is about 0.8 in the region \( 110 \) GeV < \( m_H < 120 \) GeV, of interest for the present study. This gives the estimates: CL\(_{s+b}\) = 10^{-7}, 0.04, 0.64 for \( m_H = 111, 114.4, 120 \) GeV, respectively.

The following numerical parameterisation of CL\(_{s+b}\) is used:

\[
\begin{align*}
111 \text{ GeV} &< m_H < 114.4 \text{ GeV} \\
\log \text{CL}_{s+b} & = 1.382 m_H(\text{GeV}) - 159.51 \\
114.4 \text{ GeV} & \leq m_H < 120 \text{ GeV} \\
\log \text{CL}_{s+b} & = -0.1938 - \left( \frac{120 - m_H(\text{GeV})}{5.3945} \right)^{4.968}
\end{align*}
\]  

(5.1) (5.2)

As shown in Fig.1, the function of Eqn(5.2) has the same value and first derivative as that of Eqn(5.1), at the matching point \( m_H = 114.4 \) GeV, and vanishing first derivative at \( m_H = 120 \) GeV, where CL\(_{s+b}\) = 0.64. Allowing for the overall scale factor of 0.8, the parameterisation of Eqns(5.1) and (5.2) describes well the experimentally determined curve of CL\(_{s+b}/\text{CL}_b\) in Fig.9 of Reference [10]. It should be noted, however, that the precise shape of CL\(_{s+b}\) has only a small effect on the final confidence level curves to be presented below. The direct search excludes, with a CL of \( \leq 10^{-3} \), the possibility that the SM Higgs boson exists with mass of less than 113 GeV, and gives essentially no information for \( m_H > 115 \) GeV. Thus the region where it is of interest to combine CL\(_{s+b}\) with indirect confidence levels covers only a narrow range of \( m_H \).

In order to define the confidence level for agreement of Z-decay data with the SM, the \( \chi^2 \) of the data/SM comparison is simply calculated as a function of \( m_H \), setting \( m_t \) and \( \alpha(m_Z) \) to the measured values given above. Therefore no fit to the data is necessary. The sensitivity of the CL curves to the assumed values of \( m_t \) and \( \alpha(m_Z) \) is discussed below. In this Section only the '\( m_H \)-sensitive' observables \( A_l \) and \( m_W \) are included in the \( \chi^2 \) estimator, where the W mass is either the directly measured value from LEP and FERMILAB or the indirectly determined NuTeV value. \( A_l \) is determined either by using all asymmetry data (\( A_l(\text{all}) \)), lepton data only (\( A_l(\text{lept}) \)) or only hadronic data (\( A_l(\text{had}) \)). The corresponding values are presented in Table 6 above. To take into account the internal consistency of the different data sets the values of \( \chi^2_{\text{all,WA}}, \chi^2_{\text{lept,WA}}, \text{or } \chi^2_{\text{had,WA}} \) are added to the \( \chi^2 \) of the SM comparison: \( \chi^2_{\text{W,SM}} \) in each case. As shown below, almost identical CLs are found using either \( \chi^2_{\text{X,WA}} + \chi^2_{\text{W,SM}} \) (\( X = \text{all, lept, had} \)) or by combining the CLs of \( \chi^2_{\text{X,WA}} \) and \( \chi^2_{\text{W,SM}} \) using Eqn(2.8). The former CL is then combined with CL\(_{s+b}\) using Eqn(2.8) to yield the direct plus indirect confidence level curves shown below. The values of \( \chi^2/\text{d.o.f.} \) for \( \chi_{\text{had,WA}}^2 \) and \( \chi_{\text{all,WA}}^2 \) are given above; that for the leptonic data: \( \chi_{\text{lept,WA}}^2/\text{d.o.f.} = 1.6/2, \text{CL} = 0.45 \) given by combining the \( A_l \) values obtained from lepton forward/backward asymmetries and tau polarisation measurements from LEP and the \( A_{LR} \) measurement from SLD, is taken from Reference [4].

Some typical CLs for the indirect \( m_H \) analysis, obtained as described above, are presented in Table 9 (observables considered: \( A_l, m_W \)) and Table 10 (observables considered: \( A_l, m_W, m_W(\text{NuTeV}) \)). In all cases good agreement is found between CL(\( \chi_{\text{SM}}^2 + \chi_{\text{WA}}^2 \)) and
CL(Comb) calculated using Eqn(2.8), where the abbreviations $\chi^2_{SM} \equiv \chi^2_{W,A,SM}$, $\chi^2_{W,A} \equiv \chi^2_{X,W,A}$ have been introduced.

The combination of CL($\chi^2_{SM} + \chi^2_{W,A}$) (indirect measurements) and CL$_{s+b}$ (direct measurements) for different values of $m_H$ is illustrated in Fig.1. Since CL$_{s+b}$ provides little information on $m_H$ for $m_H > 114.4$ GeV (the 95\% CL lower limit of the direct search), CL($\chi^2_{SM} + \chi^2_{W,A}$) is combined with CL$_{s+b}$ provided that CL(Comb) is less than CL($\chi^2_{SM} + \chi^2_{W,A}$). In the contrary case CL($\chi^2_{SM} + \chi^2_{W,A}$) alone is used. Thus the algorithm used to obtain the combined confidence level, CL, is:

- Calculate $\alpha_3$ from $\alpha_1 = \text{CL}(\chi^2_{SM} + \chi^2_{W,A})$ and $\alpha_2 = \text{CL}_{s+b}$ according to Eqn(2.8).
- If $\alpha_3 < \text{CL}(\chi^2_{SM} + \chi^2_{W,A})$, set $\overline{\text{CL}} = \text{CL}(\alpha_1 \alpha_2)$.
- If $\alpha_3 \geq \text{CL}(\chi^2_{SM} + \chi^2_{W,A})$, set $\overline{\text{CL}} = \text{CL}(\chi^2_{SM} + \chi^2_{W,A})$.

In Fig.1 the dotted curve shows CL$_{s+b}$, the dashed curve CL($\chi^2_{SM} + \chi^2_{W,A}$) and the solid curve CL.

Curves of $\overline{\text{CL}}$ calculated in this manner are shown in Figs.2 and 3. When $A_l$(lept) and $A_l$(all) are used, the general shape, with a sharp peak above, but close to, the direct lower limit and a rapid fall-off for higher values of $m_H$ is similar to that of the PDFs presented in References [22, 23]. However $\overline{\text{CL}}$, unlike the PDFs, gives an estimate of the absolute probability that the data is consistent with the SM for a given value of $m_H$. An exception to this behaviour is provided by the data sets $A_l$(had), $m_W$ and $A_l$(had), $m_W$, $m_W$(NuTeV) where the maximum of CL occurs at much higher values of $m_H$ and on average much larger values of CL are obtained. The confidence level curves in Figs.2 and 3 are presented in numerical form in Tables 11 and 12, in the same format as the similar curves considered in Section 7 below. The latter use all precision observables, rather than only the $m_H$-sensitive ones as in Figs. 2 and 3. Comparison of the two sets of curves then shows the effect of ‘non $m_H$-sensitive’ observables on the level of agreement with the SM prediction.

The effect on the $\overline{\text{CL}}$ curves of variation of the value of $m_t$ by plus or minus the experimental error around the measured value is shown in Fig.4 and Table 13. The effect of a similar variation of $\alpha(m_Z)$ is shown in Fig.5 and Table 13. For large values of $m_H$ this variation of $m_t$ changes the values of $\overline{\text{CL}}$ by many orders of magnitude. Even so, in the case of the data set $A_l$(lept), $m_W$, shown in Figs.4 and 5, which can be argued (see below) to be likely to give the most reliable estimate of $m_H$, $\overline{\text{CL}}$ is still only, at best, 0.01, at $m_H = 300$ GeV. Change of $\alpha(m_Z)$ within the current experimental errors can change CL by up to an order of magnitude, but the effect is much less dramatic than for $m_t$. Clearly a much improved measurement of $m_t$ is needed to significantly improve the indirect limits on $m_H$.

The analysis presented in this Section has many similarities with that of Reference [19] where confidence levels taking into account both direct and indirect information on $m_H$ were derived. However, the present writer has doubts about the mathematical correctness of the method used in Reference [19]. It consists of combining the confidence level given by the $\chi^2_{min}$ and d.o.f. of a fit with that derived from $\Delta \chi^2 = \chi^2(m_H = 114 \text{ GeV}) - \chi^2_{min}$ of
Figure 4: Dependence of combined $m_H$ confidence levels on the value of $m_t$. The observables used to calculate $\text{CL}(\chi^2_{\text{SM}} + \chi^2_{\text{WA}})$ are $A_l(\text{lept})$ and $m_W$. $\alpha(m_Z) = 0.007755$ is assumed.

| $m_H$ GeV | $m_t = 173.8$ GeV | 182.2 GeV | $\alpha(m_Z) = 0.007752$ | 0.007758 |
|-----------|------------------|-----------|------------------------|---------|
| 111       | $2.1 \times 10^{-6}$ | $9.4 \times 10^{-6}$ | $8.6 \times 10^{-6}$ | $3.5 \times 10^{-6}$ |
| 113       | $6.9 \times 10^{-4}$ | $3.2 \times 10^{-3}$ | $2.9 \times 10^{-3}$ | $1.1 \times 10^{-3}$ |
| 115       | 0.085             | 0.33       | 0.30                   | 0.13    |
| 140       | 0.032             | 0.61       | 0.46                   | 0.073   |
| 180       | $3.4 \times 10^{-3}$ | 0.30       | 0.18                   | 0.010   |
| 220       | $3.5 \times 10^{-4}$ | 0.11       | 0.051                  | $1.3 \times 10^{-3}$ |
| 260       | $3.6 \times 10^{-5}$ | 0.036      | 0.013                  | $1.7 \times 10^{-4}$ |
| 300       | $4.0 \times 10^{-6}$ | 0.010      | $3.1 \times 10^{-3}$ | $2.3 \times 10^{-5}$ |

Table 13: Combined confidence level curves $\text{CL}$ for variation of $m_t$ and $\alpha(m_Z)$ by plus or minus one standard deviation around their measured values. Observables used in the $\chi^2$ estimator: $A_l(\text{lept})$ and $m_W$. 

20
Figure 5: Dependence of combined $m_H$ confidence levels on the value of $\alpha(m_Z)$. The observables used to calculate $\text{CL}(\chi_{SM}^2 + \chi_{WA}^2)$ are $A_l(\text{lept})$ and $m_W$. $m_t = 178$ GeV is assumed.

The same fit, assuming them to be independent. Certainly, the formula used to combine the confidence levels, simple multiplication instead of Eqn (2.8) above, is incorrect. The approach used is essentially to replace the measured CL$_{a+b}$ curve by a $\theta$-function at $m_H = 114$ GeV. As can be seen in Fig.1, this is quite a good approximation. The global fits used in Reference [19] took no account of the dilution of the hypothesis testing power of the $\chi^2$ estimator resulting from the use of unaveraged and insensitive observables, as discussed in Section 2 above and, in more detail, in Section 8 below. For instance there is the statement: 'The global SM fit was excellent in 1998 and has now (2002) become poor'. This is not at all true of the contribution to the $\chi^2$ of the $m_H$-sensitive observables, which is similarly high for both data sets. In fact, the high confidence level for the 1998 global fit is a consequence of an anomalously low contribution from the non $m_H$-sensitive observables [18]. Also, although the NuTeV measurement was discussed, together with $A_b$, as a possible source of anomaly relative to the SM prediction, only the published interpretation as a measure of $\sin^2 \theta_W^{m-shell}$ or $m_W$ was considered. Also the correctness of the SM prediction for the quark couplings to the Z was assumed to define different values of $\sin^2 \Theta_{eff}^{\text{lept}}$ (equivalent to $A_l$ in the present paper). The same two assumptions have been made in the analysis presented in this Section. In the analysis of model-independent observables presented in Section 7 below the alternative interpretation of the NuTeV result, discussed in the following Section, as a measurement of the $Z\nu\nu$ coupling is also used, where no a priori assumptions are made concerning the couplings of the Z to fermion pairs.

11The present author made the same mistake in Reference [16]
An important point stressed in Reference [19], first pointed out in Reference [18], is that, regardless of how the $A_b$ anomaly is interpreted (statistical fluctuation, unknown systematic effect or new physics) the most reliable estimate of $m_H$ must be that derived from the charged lepton asymmetries and $m_W$ that give consistent predictions for this quantity. Inclusion of the $A_{FB}^{0.1}$ measurements in the fit results in a positive $\sim 50$ GeV bias on the 95% CL upper limit on $m_H$, due to the $A_t-A_b$ correlation resulting from Eqn(3.1). Although fits with and without the ‘anomalous’ NuTeV measurement are routinely presented by the EWWG, fits excluding the (equally ‘anomalous’) hadron asymmetry data that would provide the most reliable estimate of $m_H$, have (to my best knowledge) never been shown in the periodical updates of the status of electroweak measurements, such as Reference [4], produced by this working group. I agree with almost all of the general conclusions of Reference [19], in particular, that if the lepton asymmetry data is correct then, regardless of the status of the hadronic asymmetry data, the SM provides only a poor global description of the data. I would also remark that the confidence levels of the global fits quoted, although small, will become even smaller when corrected for the dilution effects discussed in Section 2 above. Use of the correct formula for combining confidence levels will, on the other hand, give higher combined confidence levels. The analysis of Reference [19] gives, however, no hint of the very low values of $\bar{\text{CL}}$ for large values of $m_H$ apparent in Figs.2 and 3 and Tables 11 and 12. Finally, in connection with Reference [19], as discussed in Section 8 below, the use of $\Delta \chi^2$ to provide confidence levels for parameter estimation is of doubtful validity when, as is the case for the current electroweak data, the absolute confidence level derived from $\chi^2_{min}$ shows that the model containing the parameter of interest does not adequately describe the data.

6 Alternative Interpretations of the NuTeV Experiment

The publication of the results of the NuTeV experiment [32] gives an estimation of the value of the on-shell weak mixing angle:

$$\sin^2 \theta_{W}^{on-shell} = 0.2277(13)(9) \quad (6.1)$$

that may be translated directly into a W-mass measurement via the defining relation of the on-shell renormalisation scheme:

$$\sin^2 \theta_{W}^{on-shell} \equiv 1 - \frac{m_W^2}{m_Z^2} \quad (6.2)$$

This interpretation however requires that the $Z\nu\nu$ coupling is assigned its standard model value. As discussed in Reference [36] and shown, for example, in Fig.1 of Reference [38], the experiment actually measures a quantity that is sensitive both to $\sin^2 \theta_{W}^{on-shell}$ and the strength of the $Z\nu\nu$ coupling, which may be specified by a parameter $\rho_0$ such that:

$$\bar{s}_\nu = \bar{s}_\nu^2 + \bar{s}_\nu^2 = \rho_0 \bar{s}_\nu^{\text{SM}} \quad (6.3)$$
Assuming the SM value \( (\rho_0 = 1) \) gives a prediction for \( \sin^2 \theta^\text{on-shell}_W \):

\[
\sin^2 \theta^\text{on-shell}_W = \frac{0.22733(135)(93) - 8.8 \times 10^{-8} (m_t \text{[GeV]}^2 - 175^2) + 3.2 \times 10^{-4} \ln(m_H \text{[GeV]}/150)}{\rho_0} \tag{6.4}
\]

Assuming instead the SM value of \( \sin^2 \theta^\text{on-shell}_W \) the experiment provides a measurement of \( \rho_0 \) [36]:

\[
\rho_0 = 0.9942(13)(16) + 2.4 \times 10^{-8} (m_t \text{[GeV]}^2 - 175^2) - 1.6 \times 10^{-4} \ln(m_H \text{[GeV]}/150) \tag{6.5}
\]

Choosing the values \( m_t = 175 \text{ GeV} \) and \( m_H = 150 \text{ GeV} \) consistent with the measured value of \( m_W \), (6.5) gives a measurement of the model-independent parameter \( \bar{s}_\nu \):

\[
\bar{s}_\nu(\text{NuTeV}) = 0.4992(21) \tag{6.6}
\]

which may be compared with the LEP measurement quoted in Table 5:

\[
\bar{s}_\nu(\text{LEP}) = 0.5014(15) \tag{6.7}
\]

Since:

\[
\bar{s}_\nu(\text{LEP}) - \bar{s}_\nu(\text{NuTeV}) = 0.0022(26) \tag{6.8}
\]

the two measurements are quite consistent \((\chi^2_{\nu, A, \text{d.o.f.}} = 0.78/1, \text{CL} = 0.38)\) and yield the weighted average value:

\[
\bar{s}_\nu(\text{LEP + NuTeV}) = 0.5006(12) \tag{6.9}
\]

Alternatively assuming that \( \rho_0 = 1 \) and using Eqns(6.2) and (6.4) to obtain \( m_W \) gives:

\[
\bar{s}_\nu(\text{NuTeV}) = \bar{s}_\nu(\text{SM}) = 0.5050 \tag{6.10}
\]

\[
m_W(\text{NuTeV}) = 80.136(83) \text{ GeV} \tag{6.11}
\]

In this case the assumed, SM, value of \( \bar{s}_\nu \) differs from the LEP measurement by \( 2.4\sigma \) \((\chi^2/\text{d.o.f.} = 5.76/1, \text{CL} = 0.016)\) and also

\[
m_W(\text{LEP + FERMILAB}) - m_W(\text{NuTeV}) = 0.290(90) \tag{6.12}
\]

the \( 3.2\sigma \) discrepancy \((\chi^2/\text{d.o.f.} = 10.4/1, \text{CL} = 0.0013)\) mentioned in Reference [32]. Using Eqn(2.8) to combine the data consistency CLs for \( \bar{s}_\nu \) and \( m_W \) yields an overall CL of \( 2.5 \times 10^{-4} \). Thus on the assumption that the NuTeV measurement is correct, the alternative interpretation of the experiment is strongly favoured statistically as the ratio of data consistency CLs of the two interpretations is \( \simeq 1.5 \times 10^3 \).

For both interpretations the SM prediction is unfavoured. For the standard one \((m_W \text{ measurement and } \rho_0 = 1)\) the CL of the SM comparison is that just quoted: \( 2.5 \times 10^{-4} \).

For the alternative interpretation \((\rho_0 \neq 1)\) it is found that:

\[
\bar{s}_\nu(\text{LEP + NuTeV}) - \bar{s}_\nu(\text{SM}) = -0.0044(12) \tag{6.13}
\]

or a \( 3.7\sigma \) \((\chi^2/\text{d.o.f.} = 13.4/1, \text{CL} = 2.5 \times 10^{-4})\) deviation from the SM prediction. The alternative interpretation thus shows exactly the same deviation from the SM as the one proposed in Reference [32].
A number of theoretical assumptions must be made in order to derive Eqns (6.4) and (6.5) from the experimental quantities:

\[ R_{\nu}^{\text{exp}} = \frac{\sigma(\nu Fe \rightarrow \nu X)}{\sigma(\nu Fe \rightarrow \mu^{-}X)}, \quad R_{\bar{\nu}}^{\text{exp}} = \frac{\sigma(\bar{\nu} Fe \rightarrow \bar{\nu} X)}{\sigma(\bar{\nu} Fe \rightarrow \mu^{+}X)} \]

actually measured by the NuTeV experiment. A recent concise review of the situation may be found in Reference [20] in which citations of related work can be found. The most important and extensively discussed assumption concerns the supposed symmetry of the strange sea momentum distribution in a nucleon. A recent analysis by the CTEQ Collaboration [37] presented in Reference [20] finds some evidence for a positive asymmetry of the strange quark sea:

\[ s^{-} = \int_{0}^{1} x(s(x) - \bar{s}(x))dx = 0.002(1) \quad (6.14) \]

It is pointed out in Reference [20] that an asymmetry of 0.002 has the effect of reducing by 42% the discrepancy between the measured value of \( \sin^{2}\theta_{W}^{\text{on-shell}} \) derived from the direct \( m_{W} \) measurements, and the value of the same quantity found from Eqn (6.4). The alternative, and statistically favoured, interpretation of the NuTeV experiment as a measurement of \( \rho^{0} \), was not considered in Reference [20], but in view of the linear correlation between \( \sin^{2}\theta_{W}^{\text{on-shell}} \) and \( \rho^{0} \) provided by the measurement\(^{12}\), it is reasonable to suppose that, in the alternative interpretation, the strange quark sea asymmetry will reduce the deviation of \( \rho^{0} \) (or, equivalently \( \pi_{\nu} \)) from the SM expectation by the same fraction. Thus the estimated value of \( \pi_{\nu} \), correcting for the effect of the asymmetry of Eqn(6.14) is 0.5015(21), which agrees perfectly with LEP measurement in Eqn(6.7). The LEP+NuTeV weighted average becomes 0.5014(12), which still lies 3.0\( \sigma \) below the SM expectation. The apparent anomaly in the \( Z\nu\bar{\nu} \) coupling is therefore reduced, but not removed, by the estimated effect of a strange quark sea asymmetry on the NuTeV results.

It remains true however that because of the many systematic effects, detailed in Reference [20], the results of the NuTeV experiments are less ‘sure’ than the measurement of the related quantity \( \Gamma_{\text{inv}} \) at LEP. Because of this some authors [43] prefer to adopt a conservative position and exclude the NuTeV results completely from global electroweak analyses. In contrast, the present paper takes a strictly neutral position on the question of the reliability, or otherwise, of the NuTeV results. In the following Section then, CLs as a function of \( m_{H} \) will be calculated using all available LEP and SLD data on the assumption of either of the two possible interpretations of the NuTeV experiment, or by excluding the experiment. The CLs obtained are later compared in Section 8 below with those obtained from the global EWWG and EWPDG fits.

7 Model-Independent Observables Compared to SM Predictions

Following the model-independent approach of References [16, 17, 18] essentially all precision information on the SM provided, to date, by the LEP, SLC and FERMILAB...
experimental programs, as well as by the NuTeV experiment, is contained in the values of the nine observables listed in Table 14. The other important quantities \( m_t \) and \( \alpha(m_Z) \) are not included as they are here considered as input parameters for the SM prediction rather than measurements which provide a test of the SM. All information from leptonic forward/backward charge asymmetry and \( \tau \)-polarisation measurements as well as the SLC ALR measurement is condensed into the single parameter \( A_L(\text{lept}) \), equivalent to \( \sin^2 \Theta_{\text{eff}}^{\text{lept}} \). The quantity \( \tilde{\sigma}_c \) is derived from the width of the Z for decay into charged leptons on the assumption of charged-lepton universality. The quantities \( A_c \) and \( A_b \) are derived using Eqn(3.1) from the c- and b-quark forward/backward charge asymmetries measured at LEP as well as from the SLC measurement of forward/backward-left/right asymmetries of c and b quarks. \( \tilde{\sigma}_c \) and \( \tilde{\sigma}_b \) are obtained from the Z decay widths into c and b quarks, more conventionally expressed in terms of the ratios: \( R_Q = \Gamma_Q/\Gamma_{\text{had}} \), \( (Q = c, b) \), using the relation:

\[
\tilde{\sigma}_Q = \sqrt{\frac{2\pi}{3}} \frac{R_Q \Gamma_Z}{G_\mu M_Z^2} \frac{\sqrt{R_i \sigma_i^0}}{C_Q^{\text{QED}} C_Q^{\text{QCD}}} \quad (Q = c, b),
\]

(7.1)

The QED and QCD correction factors are given in Reference [16]. The observable \( \tilde{\sigma}_\nu \) is given by the invisible width, \( \Gamma_{\text{inv}} \), of the Z boson, determined from the Z-boson total width, \( \Gamma_Z \), the hadronic width, \( \Gamma_{\text{had}} \), and the leptonic width, \( \Gamma_l \) via the relation:

\[
\Gamma_{\text{inv}} = \Gamma_Z - \Gamma_{\text{had}} - 3\Gamma_l
\]

(7.2)

Since the hadronic width of the Z is quite precisely measured: \( \Gamma_{\text{had}} = 1.7444(20) \) GeV, the measurements of \( R_b \) or \( \tilde{\sigma}_b \) can be used, in combination with the former, to extract the quantity:

\[
\tilde{\sigma}_{\text{nb}} = \sum_{q=u,c} [(\overline{\tau}_q)^2 + (\overline{\tau}_q)^2] C_u^{\text{QED}} + \sum_{q=d,s} [(\overline{\tau}_q)^2 + (\overline{\tau}_q)^2] C_d^{\text{QED}}
\]

(7.3)

The subscript ‘nb’ here stands for ‘non-b’ quarks. As will be discussed below, the measurements of \( \tilde{\sigma}_{\text{had}} \) and \( \tilde{\sigma}_{\text{nb}} \) provide much more stringent constraints on the possible values of the couplings of non-b down-type quarks to the Z than the existing direct measurements of these couplings, which have large experimental errors.

The experimental errors on the observables listed in Table 14 are largely uncorrelated between the observables, which facilitates calculation of a \( \chi^2 \) estimator for global SM comparisons. Correlations exist between: \( A_t \), \( A_c(\text{LEP}) \) and \( A_b(\text{LEP}) \) due to the use of Eqn(3.1) to obtain \( A_c(\text{LEP}) \) and \( A_b(\text{LEP}) \). Because of the small uncertainty on \( \Gamma_{\text{had}} \) the errors on \( \tilde{\sigma}_b \) and \( \tilde{\sigma}_{\text{nb}} \) are strongly anticorrelated. Weaker correlations exist between \( \tilde{\sigma}_c \) and \( \tilde{\sigma}_{\text{had}} \). In view of the relatively poor precision of the \( \tilde{\sigma}_c \) measurement in comparison with those of \( \tilde{\sigma}_b \) and \( \tilde{\sigma}_{\text{nb}} \), and the correlations between these three observables, the contribution of the former is omitted from the \( \chi^2 \) estimator used in the global comparisons with the SM shown below. As previously mentioned, to take properly into account correlations, the direct SLC measurements of \( A_c \) and \( A_b \) are assigned separate terms from the LEP measurements in the \( \chi^2 \) estimator. In Table 14, however, the weighted average LEP+SLC values of \( A_c \) and \( A_b \) are quoted.

The value of \( \tilde{\sigma}_\nu \) given in Table 14 is the LEP+NuTeV weighted average, i.e. the ‘alternative’ interpretation of the NuTeV experiment is taken. This is mandatory in a model-independent analysis where no \textit{a priori} assumptions concerning the couplings of the leptons or quarks to the Z (with the exception of charged lepton universality, well
Table 14: Model-independent electroweak observables. The SM predictions correspond to $m_t = 178$ GeV, $m_H = 120$ GeV and $\alpha(m_Z) = 0.007755$.

| Coupling | Expt value | SM | (Exp-SM)/\sigma |
|----------|------------|----|----------------|
| $v_\ell$ | -0.03783(41) | -0.03734 | -1.2 |
| $v_{3\ell}$ | -0.50125(26) | -0.50137 | 0.46 |
| $v_{\nu}$ | 0.5003(6) | 0.50251 | -3.7 |

| $v_{b}$ | 0.5045(50) | 0.5015 | 0.60 |
| $v_{t}$ | -0.3232(78) | -0.3435 | 2.6 |
| $v_{b}$ | -0.5133(50) | -0.4983 | -3.0 |

Table 15: Effective vector and axial-vector coupling constants of the Z boson to lepton neutrino and heavy quark pairs. The SM predictions correspond to $m_t = 178$ GeV, $m_H = 120$ GeV and $\alpha(m_Z) = 0.007755$.

The experimental values of the observables in Table 14 are compared with the SM prediction for $m_t = 178$ GeV, $m_H = 120$ GeV and $\alpha(m_Z) = 0.007755$. This choice of $m_H$ (just above the experimental lower limit) is near to the maxima of the $A_l(\text{lept})$ and $A_l(\text{all})$ curves of log $\mathcal{C}$ plotted in Figs.2 and 3. Note that the model-independent analysis corresponds to only the $A_l(\text{lept})$ curves in Figs.2-6. Only by making the stronger assumption of the SM values of the Z couplings to quarks, is it possible to derive $A_l(\text{had})$ and $A_l(\text{all})$.

The agreement with the SM predictions shown in Table 14 is not completely satisfactory. The largest deviations are for $\bar{\sigma}_\nu$ (-0.84% and 3.7\sigma) and $A_b$ (-3.5% and 2.5\sigma). The positive 1.05\sigma and 0.94\sigma deviations of both $A_l$ and $m_W$ respectively reflect the fact that

the central values of $m_H$ preferred by these observables\textsuperscript{13}:

\begin{align*}
  m_H &= 72.5^{+36.4}_{-24.2} \quad \text{fit of } A_l(\text{lept}) \text{ only} \\
  m_H &= 65.3^{+59.9}_{-37.8} \quad \text{fit of } m_W \text{ only}
\end{align*}

are incompatible with the direct lower limit of $m_H = 114.4$ GeV.

The effective vector and axial vector couplings of charged leptons, neutrinos, c quarks and b quarks, that may be directly derived from the observables $\bar{\tau}_f$ and $A_f$ ($f = l, \nu, Q$) are presented in Table 15, in comparison with SM predictions. The agreement with the SM is satisfactory for the charged leptons and c quarks, but the neutrino couplings show a $3.7\sigma$, $\bar{\tau}_b$ a $2.5\sigma$ and $\bar{\alpha}_b$ a $2.9\sigma$ deviation. As previously pointed out [16, 17] the apparently anomalous behaviour of the b-quark couplings is essentially found in the right-handed effective coupling, $\bar{g}_b^R$ rather than the left-handed one, $\bar{g}_b^L$ where:

\begin{equation}
  \bar{g}_b^R = \frac{\bar{\tau}_b - \bar{\alpha}_b}{2}
\end{equation}

\begin{equation}
  \bar{g}_b^L = \frac{\bar{\tau}_b - \bar{\alpha}_b}{2}
\end{equation}

It is interesting to consider the history of this apparent anomaly, which is illustrated in Table 16. The most significant deviation (42\% and 3.2$\sigma$) was seen in the 1996 data set [30]. In the current, essentially final, data set the size of the effect is reduced to 32\% but still has a significance of 2.8$\sigma$. The left-handed coupling is now slightly more consistent with the SM (1.7$\sigma$ deviation) as compared to 1998 (2.1$\sigma$ deviation) and 1996 (1.8$\sigma$ deviation). The experimental error on $\bar{g}_b^R$ is reduced by $\approx 40\%$ in the current data set as compared to that of 1996. The sources of these changes are made clear by the entries of Table 17 in which are presented the model-independent observables used to calculate the b-quark couplings, as derived from the 1996 and 2003 data sets. Also shown are the shifts of the observables in units of the 2003 experimental errors. It can be seen that the most important change occurs in the direct measurement of $A_b$ from SLC. The value of $A_l$(LEP+SLC) used to extract $A_b$(LEP) from $A_{FB}^{0b}$ is the same for the two data sets.

To date, only a few authors [40, 41, 42] have proposed new physics interpretations of the measured b-quark couplings. Other authors [13, 43] have argued that there is unlikely to be a new physics interpretation of the observed anomaly. The present writer finds all the reasons given for this conclusion to be either simply wrong, or unconvincing. It was argued that: ‘the sensitivity of $A_{FB}^{0b}$ to $A_b$ is small, because $A_l$ is small’. In fact, the size of $A_l$ is irrelevant. What are important are the relative precisions with which it and $A_{FB}^{0b}$ are known. Since the errors on $A_l$ and $A_{FB}^{0b}$ are uncorrelated it follows from Eqn(3.1) that:

\begin{equation}
  \frac{\sigma(A_b)}{A_b} = \sqrt{\left(\frac{\sigma(A_l)}{A_l}\right)^2 + \left(\frac{\sigma(A_{FB}^{0b})}{A_{FB}^{0b}}\right)^2}
\end{equation}

where $\sigma(X)$ is the experimental error on $X$. As shown in Tables 1 and 6, $A_l$ and $A_{FB}^{0b}$ have relative uncertainties of 1.2\% and 1.6\% respectively. Since the observed deviation from the SM is 3.6\%, the contribution to the uncertainty on $A_b$ due to that on $A_l$ is essentially

\textsuperscript{13}These fitted values of $m_H$ are for $\alpha(m_Z) = 0.007755$ and $m_t = 178$ GeV
negligible in comparison with the observed deviation from the SM prediction. It is further argued in Reference [13] that a new physics interpretation is disfavoured because a significant deviation is seen only in $A_{FB}^{0,b}$ from LEP and not in $R_b$ (equivalent to $\tau_b$) or $A_b$(SLC). But, in the case of a deviation from the SM only in the right-handed coupling, no significant change is expected in $R_b$. Also the measured value of $A_b$(SLC) lies $1.5\sigma$ above $A_b$(LEP) and $0.5\sigma$ below the SM prediction. Furthermore $\chi^2_{A_b,W_A}/d.o.f. = 2.32/1$, CL=0.13. There is therefore no strong evidence for any inconsistency between the measured values of $A_b$(SLC) and $A_b$(LEP). Both values are included in the weighted average that differs by $2.5\sigma$ from the SM prediction. In Reference [13] it is stated that: ‘One concludes that most probably the observed discrepancy is due to a large statistical fluctuation and/or an experimental problem’. The discussion in Section 3 above reaches just the opposite conclusion. In fact the statement just quoted tacitly implies (without any justification) that all the LEP experiments have seriously underestimated the systematic errors of their $A_{FB}^{0,b}$ measurements; indeed, as discussed in Section 3 above, by at least an order of magnitude. This may be possible, but hardly seems likely. The total estimated experimental error on the LEP value of $A_{FB}^{0,b}$ is largely statistical. In contrast the $R_b$ measurement has a statistical error of $0.20\%$ to be compared with a systematic one of $0.22\%$, so that the estimated systematic contribution is much more important than that for $A_{FB}^{0,b}$. Indeed from general experimental considerations, asymmetries such as $A_{FB}^{0,b}$ are expected to have smaller systematic uncertainties than quantities such as $R_b$ where absolute experimental detection efficiencies play a role. Contrary to what is implied in Reference [13] then, there is no objective reason to suppose that the $A_{FB}^{0,b}$ measurement should be less reliable than the $R_b$ one. As discussed in Section 3, the hypothesis that the $A_b$ deviation is a purely statistical effect has a CL of $\simeq 10^{-3}$ and so, though not completely excluded, is very unlikely. It remains true however that a correlated systematic error of unknown origin in the LEP $A_{FB}^{0,b}$ measurements is expected to produce an anomaly predominantly in the right-handed effective coupling. Assuming SM values for the couplings and that the $-3.5\%$ discrepancy in $A_b$ is of systematic origin, the derived values of the couplings: $g_6^R = 0.09486$ and $g_6^L = -0.4187$ are in good agreement with the measured values in Table 16. Another argument [17] in favour of an unknown systematic origin for the $A_b$ discrepancy is to note the good agreement of the measured value of $\tau_b$ with the SM prediction shown in Table 14. This agreement requires the presence of of large, $m_t^2$ dependent, quantum corrections originating in the strong breaking of quark flavour symmetry in the third generation of SM fermions. Neglect of these corrections gives a prediction of $0.3707$ for $\tau_b$, differing from the measured value by $3.7\sigma$. In the case of a new physics explanation of the $A_b$ discrepancy, the appearence of the expected quantum corrections from the SM for $\tau_b$ must be regarded as fortuitous. Thus, although there are no objective experimental reasons to doubt the correctness of the $A_b$ measurement, a systematic effect of unknown origin cannot be excluded. The good agreement of $\tau_b$ with the SM prediction and the large observed deviation in the right-handed coupling are consistent with this hypothesis. A purely statistical fluctuation is very unlikely. The effect could also be explained by new physics. There are no good reasons for the statement in Reference [13] that: ‘It is well known that this ($A_b$) discrepancy is not likely to be explained by some new physics effect in the $b\bar{b}Z$ vertex’. In fact all the explanations mentioned above (including new physics)
| \( \Gamma_{\text{had}}(\text{thy}) \) definition | \( \Gamma_{\text{had}} \) [GeV] | \( [\Gamma_{\text{had}}(\text{thy}) - \Gamma_{\text{had}}(\text{expt})] / \sigma(\text{expt}) \) |
|----------------|----------------|----------------------------------|
| SM             | 1.7439         | -0.4                             |
| \( b \to b(\text{meas}) \) | 1.7451         | 0.35                             |
| \( b,d \to b(\text{meas}) \) | 1.7414         | -1.50                            |
| \( b,d,s \to b(\text{meas}) \) | 1.7377         | -3.4                             |
| \( \Gamma_{\text{had}}(\text{expt}) \) | 1.7444(20)     | -                                |

Table 18: Constraints on the Z couplings to d-type quarks from the LEP average measurement of \( \Gamma_{\text{had}} \).

remains open possibilities. Only better experimental data can decide between them.

The next question that obviously arises is whether there is any evidence that the couplings of non-b quarks may also deviate from the SM predictions. Direct measurements of the light quark couplings have been performed by the DELPHI \[44\] and OPAL \[45\] Collaborations. For example, OPAL found:

\[
\overline{g}_{d,s}^L = -0.44^{+0.13}_{-0.09}, \quad \overline{g}_{d,s}^R = 0.13^{+0.15}_{-0.17}
\]

in good agreement with the SM predictions of -0.424 and 0.077 respectively. However, the very large uncertainties on the measurements preclude obtaining any useful information concerning deviations at the few % level, such as that observed for the parameter \( A_b \). In fact the observed deviations of \( A_b \) and \( A_c \) from the SM predictions by factors of 1.036 and 1.023 are of comparable size. Since the relative error on \( A_c \) is two times larger than that on \( A_b \), only for the latter is a possibly significant deviation from the SM observed. The similar qualitative behaviour of \( A_b \) and \( A_c \) with respect to the SM prediction can be seen in Fig.15.1 of Reference \[4\]. The LEP measurement of \( Q_{FB}^{\text{had}} \) can be used to extract an average value of \( A_{\tau} \) (averaged over all quark flavours) that is 1.07(7) times the SM prediction for this quantity. Thus, as previously mentioned, the different quark charge asymmetry measurements do not exclude deviations of \( A_q \) \((q = u, d, s, c)\) as large as that observed for \( A_b \). The present data are not, however, sufficiently precise to give any positive evidence for such an effect.

As pointed out in Reference \[46\], much stronger constraints on the non-b quark couplings are provided by the LEP average value of the hadronic width, \( \Gamma_{\text{had}} \), of the Z boson \[4\]:

\[
\Gamma_{\text{had}} = 1.7444(20) \text{ GeV}
\]

This value is in excellent agreement with the SM prediction\[15\] of 1.7439 GeV (0.03 %, 0.25\(\sigma\) deviation). One may also note in Table 14 the almost perfect agreement of the \( \overline{\sigma}_{\text{nb}} \) measurement with the SM prediction. The small relative uncertainty of 0.11% on \( \Gamma_{\text{had}} \) allows significant constraints to be placed on different hypotheses concerning the size of the \( Zq\overline{q} \) couplings. Using the relation:

\[
\Gamma_{\text{had}} = \frac{\sqrt{2}G_F m_Z^3}{4\pi} \sum_{q} \overline{\sigma}_q C_q^{\text{QED}} C_q^{\text{QCD}}
\]  

\[14\] Since \( \overline{\sigma}_{b} \approx 2[(\overline{g}_{b}^L)^2 + (\overline{g}_{b}^R)^2] \) and, with the SM values of the couplings: \( (\overline{g}_{b}^L)^2 = 0.005, (\overline{g}_{b}^R)^2 = 0.18 \), a 100% deviation of \( \overline{g}_{b}^R \) from the SM prediction changes \( \overline{\sigma}_{b} \) (or \( R_b \)) by only 8%.

\[15\] Unless otherwise stated, all SM predictions are for \( m_t = 178 \text{ GeV}, m_H = 120 \text{ GeV} \) and \( \alpha(m_Z) = 0.007755 \).
the SM predictions for the $d$ and $s$ quarks may be replaced by the central values of the measured $b$-quark couplings from Table 14. The results given by replacing, in Eqn(7.7), the SM predictions for (i) $b$ quarks, (ii) $b$ and $d$ quarks and (iii) $b$, $d$ and $s$ quarks by the measured $b$-quark couplings from Table 14 are presented in Table 18, in comparison with the measured value of $\Gamma_{\text{had}}$. It can be seen that, although the prediction is little changed for case (i), case (iii) is excluded by the measured value of $\Gamma_{\text{had}}$ at the 3.4$\sigma$ level.

Since (see Table 14) the measured value of $\bar{\pi}_c$ agrees well with the SM prediction, the measured value of $\Gamma_{\text{had}}$ will provide no useful constraints if the procedure used in Table 18 is repeated for $u$-type quarks. The effective coupling constants $\pi_c$ and $\pi_c$ also agree well with the SM predictions.

The experimental situation concerning measurements of right-handed and left-handed $Z$-fermion pair couplings and the $W$ boson mass is summarised in Tables 19 and 20. In Table 19 the couplings of charged leptons, $c$ quarks, $b$ quarks and neutrinos are compared with SM predictions. Similar comparisons are made in Table 20, varying the values of $m_t$ and $m_H$ in the SM predictions. In this case, for clarity, only deviations from the SM predictions are tabulated. Tables 19 and 20 contain, in concise form, essentially all the precision information on the SM derived from the experimental programmes of LEP and SLD as well as the main contributions of FERMILAB to the same subject (essentially measurements of $m_t$, $m_W$ and the $Z\nu\nu$ coupling) during the same period.

Looking at this comparison, it is difficult to conclude that the level of agreement with the SM is good. For $m_H = 120$ GeV, i.e. around the maximum value of $\overline{\text{CL}}_\ell$, as in Table 19, $\overline{\pi}_b^R$ and $\overline{\pi}_\nu^L$ show deviations of 2.8 and -3.7 standard deviations respectively. All of $\overline{\pi}_l^R$, $\overline{\pi}_l^L$ and $m_W$ show negative deviations around the one standard deviation level as a consequence of the low values of $m_H$ (inconsistent with the experimental direct lower limit) favoured by the measured values of these quantities. For $m_H = 300$ GeV (see Table 20) five out of the eight EW parameters show deviations around three standard deviations. Those associated with $\overline{\pi}_b^R$ and $\overline{\pi}_\nu^L$ are almost independent of $m_H$ and vary only weakly with $m_t$. Another feature is that increasing (decreasing) the value of $m_t$ improves (worsens) the agreement for $\overline{\pi}_b^R$ and $\overline{\pi}_\nu^L$ ($m_W$) for all values of $m_H$. In any case, the SM still fares badly for $m_H = 300$ GeV and above. This is already apparent in Figs.2 and 3, and will also be evident in the combined confidence level curves based on all precision data to be discussed below.

Perhaps the most important aspect of the SM that has been tested by recent precision measurements is the renormalisability of the theory. This enables quantum loop corrections involving fermions, weak bosons and the Higgs boson to be calculated and compared to experiment, just as precise measurements of similar effects in QED, such as the Lamb shift of Hydrogen and the anomalous magnetic moments of the electron and muon, were important to establish the essential correctness of the theory for the description of such quantities. The model-independent observables shown in Table 14 can be used to isolate the effect of quantum corrections in the coupling of charged leptons, $c$ quarks, $b$ quarks and neutrinos to the $Z$ boson. For this only the values of $A_l(\text{lept})$, $A_c$, and $A_b$ are required for charged leptons and heavy quarks, and that of $\pi_\nu$ for neutrinos. The $A$ parameters are all simple mappings (see Eqn(3.2)) of the ratio: $r = v/a$ of the vector and axial-vector
coupling constants. At tree-level in the SM the following relations hold:

\begin{align*}
    r_l &= 1 - 4s^2_W & (7.8) \\
    r_c &= 1 - \frac{8}{3}s^2_W & (7.9) \\
    r_b &= 1 - \frac{4}{3}s^2_W & (7.10) \\
    g^L_\nu &= \frac{1}{2} & (7.11)
\end{align*}

where \(s^2_W = \sin^2 \theta^\text{on-shell}_W\) as defined in Eqn(6.2). In the presence of quantum corrections \(r_f \to \tau_f\), and \(s^2_W \to (s^2_W)^f\) (\(f = l, c, b\)) in Eqns(7.8)-(7.10) and \(g^L_\nu \to \overline{g}^L_\nu\) in Eqn(7.11).

Thus parameters, \(\delta^f_{\text{Quant}}\), that measure directly the effect of quantum corrections can be introduced according to the definitions:

\begin{align*}
    \delta^l_{\text{Quant}} &= \frac{(s^2_W)^l - s^2_W}{s^2_W} = \frac{1 - \tau_i}{4s^2_W} - 1 & (7.12) \\
    \delta^c_{\text{Quant}} &= \frac{(s^2_W)^c - s^2_W}{s^2_W} = \frac{3(1 - \tau_c)}{8s^2_W} - 1 & (7.13) \\
    \delta^b_{\text{Quant}} &= \frac{(s^2_W)^b - s^2_W}{s^2_W} = \frac{3(1 - \tau_b)}{4s^2_W} - 1 & (7.14) \\
    \delta^\nu_{\text{Quant}} &= \overline{g}^L_\nu - \frac{1}{2}/(\frac{1}{2}) = 2\overline{g}^L_\nu - 1 & (7.15)
\end{align*}

In the absence of quantum corrections all the \(\delta^f_{\text{Quant}}\) parameters vanish. The experimental values of these parameters derived from the entries of Table 14, as well as the corresponding SM predictions, are presented in Table 21.

It can be seen from this table that the expected size of the corrections in the SM is \(\simeq 4 - 5\%\) for \(l\, c\) and \(b\), and an order of magnitude lower for \(\nu\). By far the most significant measurement of quantum corrections (44 standard deviations from zero!) is that of \(\delta^l_{\text{Quant}}\). Good agreement with the SM prediction (1.2\(\sigma\) deviation) is found, at least for \(m_H = 120\) GeV, as used in the SM predictions in Table 21. As discussed previously, in connection with \(\overline{g}^R_\nu\) and \(\overline{g}^L_\nu\) (see Table 20), the agreement worsens considerably for higher values of \(m_H\). For example, for \(m_H = 300\) GeV, \(\delta^l_{\text{Quant}}(\text{SM}) = 0.04385\), a deviation of 3.5\(\sigma\) from the measured value. For \(c\) quarks the expected quantum correction is only a 1.7\(\sigma\) effect. Good agreement with the SM prediction is found in this case.

For \(b\) quarks the expected quantum correction is unmeasurable with present data (expected effect 0.64\(\sigma\) from zero) whereas a 3.4\(\sigma\) effect is actually observed, differing by 2.7\(\sigma\) from the SM prediction. This is indicative, as discussed previously, of either a large and unknown correlated systematic effect (perhaps in combination with a statistical fluctuation) in the LEP \(A^{b,b}_{FB}\) measurements, or of new physics at tree-level, or, indeed some combination of the two. A purely statistical fluctuation is very unlikely. The situation is exactly the opposite for the neutrino couplings. The SM predicts a large (4.2\(\sigma\)) quantum correction, while in the data only a 0.5\(\sigma\) effect is seen. The discrepancy with the SM amounts to -3.7\(\sigma\) in this case. Rather than a tree-level effect giving a large apparent quantum correction, as for the \(b\) quarks, it seems that the SM quantum corrections are effectively ‘turned off’ in the case of the the \(Z\nu\bar{\nu}\) couplings! Theoretical interpretations of this apparent coupling suppression have been made in References [47, 48].

Table 20: Values of deviations (Expt-SM)/\(\sigma\) for precision electroweak parameters. SM predictions with \(\alpha(m_Z) = 0.007755\).

The main conclusion to be drawn from the results presented in Table 21 is that only for the charged leptons and c quarks is the present data reasonably consistent with the SM. This implies that since the c-quark couplings are almost completely insensitive to the values of \(m_t\) and \(m_H\) (see Table 5) information on these parameters, via quantum corrections, can only be reliably obtained from the charged lepton couplings. This further implies (see Tables 11 and 12) that the maximum values of \(\bar{C}\) of 23% or 1.7% are obtained at \(m_H = 115\) GeV when the NuTeV \(m_W\) measurement is excluded or included respectively. Much lower confidence levels of 0.054 and 0.0011 are obtained, under the same conditions, for \(m_H = 220\) GeV, the presently quoted 95% CL upper limit on \(m_H\) from the EWWG [4]. In fact, even lower CLs will be found for a global analysis based on all model-independent observables shown in Table 14, which will now be discussed.

In order to test the overall level of agreement of the precision data with the SM, \(\chi^2\) estimators are calculated from the observables shown in Table 14. The corresponding confidence level \(\text{CL}(\chi^2_{SM})\) is then combined with that, \(\text{CL}_{s+b}\), of the direct Higgs search using Eqn(2.8) to give \(m_H\) confidence level curves, \(\text{CL}\). Since all equivalent and statistically compatible measurements are combined in order to extract the model-independent observables, there is, in this case, no contribution of the type \(\chi^2_{X,W,A}\) to take into account the degree of statistical compatibility of different measurements of the same quantity \(X\). In view of the possibility of new physics or poorly understood systematic effects for the

Combined $m_H$ confidence levels. $\text{CL}_{a+b}$ is combined with $\text{CL}(\chi^2_{SM})$ using Eqn(2.8). $\chi^2_{SM}$ is calculated from all model-independent variables: $A_l(\text{lept})$, $\bar{\tau}_l$, $A_c$, $A_b$, $\bar{\tau}_b$, $\bar{\tau}_{nb}$, $\bar{\tau}_\nu$, $m_W$ and $m_W(\text{NuTeV})$.

$Zb\bar{b}$ couplings, and of the overall status, as well as the different possible interpretations of the NuTeV experiment, the above procedure is repeated for different selections and interpretations of the data: the results are presented in Tables 22 and 23 and Figs.6 and 7.

In Table 22 and Fig.6, all the observables in Table 14, except $\bar{\tau}_c$, are included in the $\chi^2$ estimator. In the case that the NuTeV result is excluded, $\bar{\tau}_\nu$ is assigned the LEP-only value of Table 5 and Eqn(6.7). The ‘NuTeV $\bar{\tau}_\nu$ meas.’ curves use the $\bar{\tau}_\nu$ value quoted in Table 14 and Eqn(6.9) (LEP+ NuTeV average). For the interpretation of the NuTeV result as an $m_W$ measurement, $m_W(\text{NuTeV})$ is included in $\chi^2$ and $\bar{\tau}_\nu$ is set to the LEP-only value. The number of degrees of freedom of the ‘NuTeV out’, ‘NuTeV $\bar{\tau}_\nu$ meas.’ and ‘NuTeV $m_W$ meas.’ estimators are 10, 10 and 11 respectively.

In the case of new physics, or unknown systematic effects, in the $A_b$ measurement, it is clearly of interest to test only the level of agreement of the leptonic sector with the SM. For this, combined $m_H$ confidence level curves are also derived using only the leptonic observables: $A_l(\text{lept})$, $\bar{\tau}_l$ and $\bar{\tau}_\nu$ as well as $m_W$ and, possibly $m_W(\text{NuTeV})$. The ‘NuTeV out’, ‘NuTeV $\bar{\tau}_\nu$ meas.’ and ‘NuTeV $m_W$ meas.’ cases are considered as previously, giving now 4, 4 and 5 degrees of freedom, respectively, for $\chi^2_{SM}$. The results for the ‘Lepton data only’ case are presented in Table 23 and Fig.7.

It can be seen from Table 22 and Fig.6 that, when all data is included, the maximum of $\log \text{CL}$ occurs around $m_H = 180$ GeV, and has a value $\simeq 0.05$ in the case that the
Combined $m_H$ confidence levels. $CL_{s+b}$ is combined with $CL(\chi^2_{SM})$ using Eqn(2.8). $\chi^2_{SM}$ is calculated from the leptonic model-independent variables: $A_l$(lept), $\bar{s}_l$, $\bar{s}_\nu$, as well as $m_W$ and $m_W$(NuTeV).

NuTeV experiment is excluded and $\simeq 0.0065$ when it is included, independently of the interpretation ($\bar{s}_\nu$ or $m_W$ measurement) of the experiment. For $m_H = 300$ GeV, the CLs are much lower, being 0.015, 0.0016 and 0.0034 for the ‘NuTeV out’, ‘NuTeV $\bar{s}_\nu$ meas.’ and ‘NuTeV $m_W$ meas.’ cases respectively. In the case that only the leptonic Z-decay data is considered, the maximum value of $\overline{CL}$ occurs just above the direct lower limit with the values $\simeq 0.06$ (NuTeV out) and $\simeq 0.004$ (NuTeV included). For $m_H = 300$ GeV, very low values of $\overline{CL}$ are found: $6.0 \times 10^{-5}$, $3.4 \times 10^{-6}$ and $1.2 \times 10^{-5}$ for the three cases considered previously.

8 Comparison with the EWWG and EWPDG Global Fits

The conclusions presented above concerning the global level of agreement with the SM, and the possible value of $m_H$ may seem somewhat at variance with those drawn from the global fits of the EWWG [4] and EWPDG [5]. Indeed, the quoted $\chi^2$ confidence levels of the latter are much higher. The EWWG quotes confidence levels of 4.5% for ‘all data’ and 28% when NuTeV is excluded. These fits obtain (see Table 2) $m_H = 96^{+60}_{-35}$ GeV and $m_H = 91^{+55}_{-36}$ GeV respectively. These central fit values are completely inconsistent with the experimental direct lower limit on $m_H$. Already for $m_H = 111$ GeV, $CL_{s+b} = 10^{-6}$. In addition the fitted values of $m_H$ are strongly biased towards higher values, as discussed
above, due to the inclusion of the ‘anomalous’ quark asymmetry data in the fits. The latest global EWPDG fit, which did not include the NuTeV datum, found \( m_H = 98^{+51}_{-35} \) GeV and \( \chi^2/d.o.f. = 47.3/38 \), CL = 14%. Some reasons for the higher confidence levels found for the global EWWG and EWPDG fits have been put forward in Section 2 above, so it is interesting, in the light of that discussion, to examine in detail the contributions of different types of observables to the \( \chi^2 \) of these fits.

The 20 observables included in the EWWG fit may be classified as follows:

- **Measured:** \( \Delta_{had}(m_Z^2), m_Z, m_t \).
- **\( m_H \)-sensitive:** \( A_{FB}^{0,l}, A_t(P), \sin^2 \Theta_{eff}(Q_{FB}^{had}), A_t(SLD), A_{FB}^{0,b}, A_{FB}^{0,c}, m_W, \sin^2 \Theta_W(\nu N) \).
- **Others:** \( \sigma_h^0, \Gamma_Z, R_t^0, R_b^0, R_e^0, A_b, A_c, \Gamma_W, Q_W(Cs) \).

The relative contributions to the total \( \chi^2 \) of the different types of observable are summarised in the first three rows of Table 24. The quantities \( \sum \Delta(\chi')^2 \) are calculated from the squares of the ‘pulls’ given in the last column of Table 16.1 of Reference [4]. Also shown in Table 18 are the ‘pseudo-confidence levels’, \( \text{CL}' \), for each of the different types of observable assuming that the effective number of degrees of freedom, \( d.o.f.' \), is equal to the number of observables of each type. Since there are five fitted parameters: \( m_Z, m_t, \log(m_H), \alpha(m_Z) \) and \( \alpha_s(m_Z) \), the true total number of degrees of freedom is 15 rather than 20, so that the quoted values of \( \text{CL}' \) should be considered as upper limits on the true CL to be associated with each type of observable. This procedure neglects correlations between the fitted parameters, but is adequate to show the very different contributions of the different observable types to the overall \( \chi^2 \). The ‘Measured’ observables, i.e. those that are identical to the fitted parameters, are seen to provide an essentially vanishing contribution to \( \chi^2 \), since the fitted parameters are completely determined by the corresponding observables. Thus three extra degrees of freedom are obtained, free of charge, which considerably improve the CL of the SM comparison16. The Measured parameters should be fixed in the fit, not treated as observables to be fitted. The effective confidence level, \( \text{CL}' \) of the 8 ‘\( m_H \)-sensitive’ observables is a factor of 21 smaller than the \( \text{CL}' \) of all observables (see Table 24) and a factor 6.4 smaller than the EWWG global fit CL. The value of \( \text{CL}' \) for the \( m_H \)-sensitive observables is similar to the maximum value 0.0064 of \( \overline{\text{CL}} \) for the analysis of all model-independent observables in the last column of Table 22 and Fig.6. The ‘Other’ observables give a rather low contribution to the total \( (\chi')^2 \), as compared to the expectation from the number of degrees of freedom, which give a further improvement to the CL of the global fit beyond that expected from the inclusion of observables that are only weakly sensitive to \( m_t \) and \( m_H \). Excluding the NuTeV datum \( \sin^2 \Theta_W(\nu N) \) from the group of \( m_H \)-sensitive observables gives \( \sum \Delta(\chi')^2 = 12.6, d.o.f.' = 7, \text{CL}' = 0.08 \) which is similar to the maximum value of \( \overline{\text{CL}} \) of 0.053 for the corresponding analysis of model-independent observables in Fig 6 and the first column of Table 22.17 Thus the difference

16 For example, calculating \( \text{CL}' \) by summing the values of \( \sum \Delta(\chi')^2 \) corresponding to each observable type gives \( (\chi')^2/d.o.f.' = 26.64/20, \text{CL}' = 0.15 \) when the Measured observables are included (see Table 24) and \( (\chi')^2/d.o.f.' = 26.60/17, \text{CL}' = 0.064 \) when they are excluded.

17 Actually the EWWG and EWPDG fits use the old \( m_t \) value 174.3(5.2) GeV rather than 178.0(4.3) GeV as used in Tables 22 and 23. This, however, has only a minor effect on the maximum values of \( \overline{\text{CL}} \). Using the old value of \( m_t \) maximum values of \( \overline{\text{CL}} \) of 0.0080 [0.057] are found when the NuTeV experiment is included [excluded], to be compared with the corresponding numbers 0.0064 [0.053] quoted above using
between the confidence levels found in the present paper and those of the global EWWG fits can be largely understood as a consequence of the extra degrees of freedom associated with the ‘Measured’ and ‘Other’ observables which are only weakly sensitive to the crucial unknown parameter, \(m_H\), of the SM.

Classifying the 42 observables used in the latest global EWPDG fit [5] in the same fashion as done above for the EWWG fit gives:

Measured: \(m_Z, m_t\).

\(m_H\)-sensitive: \(A_{FB}^0, A_{FB}^\mu, A_{FB}^\tau, A_{FB}^b, A_{FB}^s, \sin^2 \theta_{eff}^{lep}(Q_{FB}^{had}), A_e(1), A_e(2), A_e(3), A_\mu, A_t(1), A_t(2), m_W(FERMILAB), m_W(LEP)\)

Others: \(\Gamma_Z, \Gamma_{had}, \Gamma_{inv}, \Gamma_{t+\tau-}, \sigma_h^0, R^0_e, R^0_\mu, R^0_\tau, R^0_b, R^0_c, R^0_A, A_b, A_c, A_t, R_+, R^-, R^{0+}, R^{0-}(1), R^{0-}(2), g^{\nu e}_V(1), g^{\nu e}_V(2), g^{\nu e}_A(1), g^{\nu e}_A(2), Q_W(CS), Q_W(Tl), \Gamma(b \to s\gamma)/\Gamma(c \to e\nu), (g_\mu - 2 - \alpha/\pi)/2\)

The difference with respect to the EWWG fit is that a wider range of observables are included as well as several different measurements of the same quantity, indicated, for example, as \(A_e(1), A_e(2)\), and that charged lepton universality has not been used to reduce the number of observables. It could be argued that some of the ‘Other’ observables such as \(\Gamma_Z, \Gamma_{had}\) and \(\Gamma_{inv}\) are actually quite ‘\(m_H\)-sensitive’, but the choice of the latter type of observable has been restricted, for purposes of comparison, to correspond as closely as possible to that made above for the EWWG fit. The values of \(\sum \Delta (\chi)^2\), \(d.o.f.'\) and CL’ for the three classes of observables in the EWPDG fit are presented in the fifth, sixth and seventh rows of Table 24. There are only two Measured observables, \(m_t\) and \(m_Z\), since the fitted parameters are: \(m_t, m_Z, m_H\) and \(\alpha(m_Z)\). Unlike for the EWWG fit \(\alpha_s(m_Z)\) is treated as a fixed rather than a fitted parameter. The high value of CL’ for the Measured observables shows that, as in the case of the EWWG fit, it is more appropriate to treat \(m_t\) and \(m_Z\) as fixed parameters in the fit. As for the EWWG fit, the value of CL’ for the \(m_H\)-sensitive observables is much less than the global fit confidence level. The value of CL’ for the ‘Other’ observables gives no indication for a possible overestimation of systematic errors as in the EWWG fit. However, the observables \(\Gamma_{inv}\) and \(g_\mu - 2 - \alpha/\pi)/2\) not included in the EWWG fit show quite large deviations from the SM prediction. Removing these observables from the ‘Others’ set gives: \(\sum \Delta (\chi')^2 = 14.4, d.o.f.' = 23, CL = 0.91\), again indicating a possible overestimation of systematic errors for the remaining observables, leading to a confidence level for the global fit that gives an optimistic estimate of the level of agreement with the SM. The lower confidence level of the global EWPDG fit compared to the EWWG one, in spite of the inclusion of many unaveraged observables, is also explained by the inclusion of these ‘discrepant’ observables in the former fit. Excluding them gives \(\chi^2/d.o.f. = 37.7/36, CL = 0.39\) which is larger than that of the EWWG fit (0.28), as expected.

Thus the lower confidence levels found in the global analysis of the present paper as compared to those quoted by the EWWG and EWPDG are fully explained in terms of the dilution of the hypothesis testing power of the latter fits due to the inclusion of unaveraged or insensitive observables in the \(\chi^2\) estimator.

---
the new \(m_t\) measurement.
Table 24: Contributions of different types of observables to the $\chi^2$ of the latest global EWWG [4] and EWPDG [5] fits. See text for definitions of the quantities shown.

A final remark concerning the CLs quoted for the EWWG and EWPDG fits is that, as previously mentioned, these numbers correspond to central fitted values of $m_H$ that are grossly inconsistent with direct the experimental lower limit of 114.4 GeV. Replacing the fitted values by this limit will evidently yield lower CLs. Because of the relatively large uncertainy on the fitted value of $m_H$, the expected reduction in the CL will be less than that due to correcting for the statistical dilution effects discussed above. It still remains however a meaningless exercise to quote CLs for fits with $m_H \approx 90 - 100$ GeV, values that are excluded by the direct search result with a CL (see Fig.1) very much less than $10^{-7}$.

The latest EWWG report [4], quotes a 95% confidence level upper limit on $m_H$ of 219 GeV. This estimate is based on the famous ‘blue band’ plot (Fig 16.5 of Reference [4]) which shows the quantity: $\Delta \chi^2 = \chi^2 - \chi^2_{\text{min}}$ for the global fit as a function of $m_H$. Choosing an appropriate fixed value of $\Delta \chi^2$ to define a confidence limit for $m_H$ is a valid procedure only in the case that the confidence level derived from the value of $\chi^2$ of the fit to the $m_H$-sensitive variables is sufficiently high. Inspection of Figs 2 and 3 and Tables 11 and 12 shows that this is hardly the case for the actual electroweak data set. It was argued in the previous Section that most reliable estimate of $m_H$ is that derived using only charged lepton asymmetry data and $m_W$. In this case the maximum value of CL is 0.017 when the NuTeV $m_W$ measurement is included, 0.23, if it is excluded. Thus the $\Delta \chi^2$ estimator for $m_H$ is acceptable only for the case of a fit to $A_\ell$($lep$) and $m_W$ excluding the NuTeV measurement. However, at the 95% confidence level EWWG upper limit of $m_H = 220$ GeV, the corresponding values of CL are $1.1 \times 10^{-3}$ and 0.054 with the implication that if a Higgs boson existed with this mass, and including, as in the final EWWG fit, the NuTeV measurement, the SM would be excluded by the data with a confidence level only slightly larger than $10^{-3}$! This is not at all the message that one might naively draw from the corresponding EWWG numbers. A confidence level of 4.5% for a global fit gives the impression that the data is, in general, not too badly described by the SM. In fact as a brief inspection of Tables 19-23, which contain all relevant information, show, this is hardly the case, so that a meaningful estimate of $m_H$ cannot be derived from a $\Delta \chi^2$ plot based on such a global fit. In the model-independent analysis of all precision data in the previous Section, the level of the discrepancy with the SM may be even larger.

---

18 So-called because of the coloured version shown in dozens of electroweak review talks over the last decade.
than if only the $m_H$-sensitive observables $A_l$ and $m_W$ are considered. Referring to Figs 6 and 7 and Tables 22 and 23 and taking the 'NuTeV $\bar{\nu}_l$ meas.' curves, mandatory in a model-independent analysis, gives values of $\overline{CL}$ of 0.0038 (0.0056) for $m_H = 115$ (220) GeV for the 'All data' case and 0.0047 ($1.0 \times 10^{-4}$) for the most reliable 'Lepton only' data. The reader must judge for herself (or himself) whether, in these circumstances, the SM does, or does not, provide an adequate description of the current data. Only in the case that it does, the 'blue band' plot, derived from a global fit to this data, provides a meaningful upper limit on $m_H$.

9 Summary and Conclusions

It has been demonstrated in this paper that the statistical estimator, $\chi^2_{data,SM}$ universally employed by the EWWG and EWPDG to judge the level of overall agreement of precision electroweak data with the SM predictions typically yields a confidence level an order of magnitude higher than estimators chosen to test specifically this level of agreement rather than the internal consistency of different measurements. The reasons for this are discussed in Section 2. While, as shown in Section 4, the number of independent observables sensitive to the most important poorly known parameters $m_t$ and $m_H$ is very small, large numbers of observables (20 for EWWG, 42 for EWPDG) are used to construct $\chi^2_{data,SM}$. In these circumstances the corresponding $CL$ reflects more the internal consistency of measurements of different observables than the level of agreement of the essential 'refined' parameters with the SM. Further dilution of the hypothesis testing power of $\chi^2_{data,SM}$ results from the inclusion of many observables only weakly sensitive to $m_t$ and $m_H$ as well as fit parameters identical to measured quantities that give anomalously low contributions to the global $\chi^2$.

In Section 3 the internal consistency of different heavy quark asymmetry measurements is discussed in detail. It is found to be very good. There is a hint, from the data itself, that uncorrelated systematic errors may be overestimated. Thus the observed 2.5σ deviation of the LEP+SLD average value of $A_b$ may be an underestimation. Combination of the statistically independent $\chi^2$ and Run Tests for the LEP and SLD measurements of $A_b$ yields a $CL$ of $2.1 \times 10^{-3}$ for a pure statistical fluctuation, which therefore seems unlikely. Attributing the $A_b$ deviation to a correlated systematic error of unknown origin in the LEP $A^{a,b}_{FB}$ measurements would require an effect that is 1.8 times larger than the estimated QCD correction, which is the dominant source of correlated systematic uncertainty on this quantity, and 13 times larger than the estimated uncertainty on this correction. Even given the inevitable theoretical uncertainties associated with QCD effects this again seems unlikely. Thus there is no sound experimental reason to doubt, as suggested by some authors [13, 43], the validity of the b-quark asymmetry measurements and the possible evidence they provide for new physics beyond the SM.

It is shown in Section 4 that essentially all information from quantum loop effects on the values of $m_t$ and $m_H$ is provided by only three observables: $A_l(lept)$, $\overline{\nu}_l$ and $m_W$ (see Table 5). For $m_H$ there are only two strongly sensitive observables: $A_l(lept)$ and $m_W$. It is demonstrated by fitting only the $m_H$-sensitive observables and also complete sets of model-
independent observables that indeed the fitted value of $m_H$ is essentially determined by
the former set only. In an approach similar to that followed in Reference [19] it is assumed,
in Section 4, that the SM is valid so that different values of $A_t$ may be extracted from
purely leptonic data ($A_t(\text{lept})$) and from quark forward/backward asymmetries ($A_t(\text{had})$).
As previously noted [19], for the case of the equivalent observable $\sin^2 \Theta_{eff}^{\text{lep}}$, these two
estimates differ by $3.0\sigma$ showing that the SM interpretation of the data is also inconsistent
at this level. This is a simple consequence of the observed anomalous behaviour of $A_b$
and the possibly similar behaviour of other $Z_{q\bar{q}}$ couplings. Also, as previously noticed,
much larger values of $m_H$ are favoured by $A_t(\text{had})$ than by $A_t(\text{lept})$. This is because
(see Table 5) in the SM only $A_t$, not $A_b$, is sensitive to $m_H$ and the measured forward
backward asymmetry $A_{FB}^{0,b}$ is, as shown in Eqn(3.1), proportional to $A_t A_b$. Whatever the
explanation of the $A_b$ anomaly, the most reliable estimate of $m_H$ that can be derived from
the present data is therefore that provided by $A_t(\text{lept})$. Inclusion of $A_t(\text{had})$, assuming
the correctness of the SM, gives a calculable bias towards higher values of $m_H$ resulting
from the $A_t$-$A_b$ correlation in the quark forward/backward asymmetry.

In Section 5 a combined confidence level, $\overline{\mathrm{CL}}$, as a function of $m_H$ is derived from the
directly measured [10] confidence level curve $\overline{\mathrm{CL}}_{2+b}$ and the CL curve derived from the
$\chi^2$ estimator using the $m_H$-sensitive observables $A_t$ and $m_W$ (see Fig.1). As in Section 4
the correctness of the SM is assumed and different $\overline{\mathrm{CL}}$ curves are calculated for $A_t(\text{lept})$,
$A_t(\text{had})$ and $A_t(\text{all})$, where the latter is the weighted average of the former two observables.
The above mentioned inconsistency between $A_t(\text{lept})$ and $A_t(\text{had})$ is taken into account
when calculating the $\overline{\mathrm{CL}}$ curve for $A_t(\text{all})$. Consistent results for $\overline{\mathrm{CL}}$ (see Tables 9
and 10) are found using either $\chi^2_{\text{data,W}} + \chi^2_{W,SM}$ directly or combining the CLs of $\chi^2_{\text{data,W}}$
and $\chi^2_{W,SM}$ using Eqn(2.8). Only the standard interpretation of the NuTeV experiment,
as a measurement of $m_W$, is considered in Section 4, and the $\overline{\mathrm{CL}}$ curves are calculated
both including and excluding this datum. The results for $\overline{\mathrm{CL}}$ are shown in Tables 9-12
and Figs. 2 and 3. The inconsistency of the SM interpretation is evident on inspection
of these figures. For $m_H = 300$ GeV values of $\overline{\mathrm{CL}}$ differing by two orders of magnitude are obtained from $A_t(\text{lept})$ and $A_t(\text{had})$. Also studied in Section 5 is the dependence
of the $\overline{\mathrm{CL}}$ curves on the assumed values of $m_t$ and $\alpha(m_Z)$ (Table 13 and Figs.4 and 5).
Variation of $m_t$ by plus or minus the experimental uncertainty changes the value of $\overline{\mathrm{CL}}$ by
more than three orders of magnitude for $m_H \approx 300$ GeV; somewhat smaller changes are
given by a similar variation of $\alpha(m_Z)$. This demonstrates the importance of more precise
measurements of these parameters in order to obtain well defined SM predictions.

In Section 6 the alternative interpretation of the result of the NuTeV experiment as a
measurement of the $Z_{\nu\nu}$ coupling, rather than $m_W$, is considered. It is pointed out that
the former interpretation, mandatory in a model-independent analysis where no a priori
assumptions are made concerning the strengths of the $Z/\nu$ couplings, is highly favoured by
an argument based on the internal consistency of LEP and NuTeV data. In this case
the model-independent observable $\overline{\sigma}$, derived from the LEP and NuTeV data differs from
the SM prediction by $3.7\sigma$ and so is the largest single deviation observed from a SM
prediction. The combined CL, taking into account both agreement with the SM and data
consistency, is very similar for either interpretation of the NuTeV result.

An analysis in terms of model-independent observables similar to those previously
published for earlier electroweak data sets [16, 17, 18, 46] is presented in Section 7. Results
are presented in terms of the ‘maximally uncorrelated’ observables presented in Table 14. Vector and axial vector couplings of the Z to fermion pairs (Table 15), and the equivalent right-handed and left-handed couplings (Table 19) are also presented and compared with SM predictions. The history of, and the different possible physical interpretations of, the $A_b$ anomaly are also discussed. Although there are no purely experimental reasons for doubting the correctness of the fully compatible LEP and SLD measurements of $A_b$ it is pointed out that the good agreement between the measured values of $\tau_b$ and the SM prediction (which requires the presence of large $m_t$ dependent quantum corrections) must be fortuitous if the $A_b$ anomaly is to be explained by new physics. This is an argument suggesting an unknown systematic bias as the cause of the effect. It is also pointed out that such a systematic bias would result in an anomaly predominantly in the right handed coupling ($2.8\,\sigma$ effect observed) rather than in the left-handed one ($1.7\,\sigma$ effect observed). This implies that only new, more precise, experiments can discriminate between new physics and unknown systematic bias as the cause of the observed anomaly in the right handed b-quark coupling. It is shown that the measured value of $\Gamma_{\text{had}}$ renders unlikely the possibility that the couplings of the other d-type quarks differ from the SM prediction in the same way as observed for the b-quark couplings. The existing direct measurements of these couplings are insufficiently precise to provide any useful constraints.

In Section 7 the observed and expected quantum loop corrections are also discussed (see Table 21). The most significant and the most precisely measured effect, $\delta_{\text{Quant}}$, defined in Eqn(7.12) is a 4% effect measured with a relative precision of 2.2% (measured effect $44\,\sigma$ from zero). For a value of $m_H$ of 120 GeV, the agreement of $\delta_{\text{Quant}}$ with the SM prediction is quite satisfactory (1.2$\sigma$ deviation) but, as shown in Table 20, for higher values of $m_H$ the level of agreement of the charged lepton couplings that determine $\delta_{\text{Quant}}$ deteriorates rapidly. $\delta_{\text{Quant}}$ (Eqn(7.13) is also predicted to be $\simeq 0.04$ in good agreement with the measurement ($0.7\sigma$ deviation) but here the fractional precision of the measurement is only 42%. $\delta_{\text{Quant}}$ is predicted to be $\simeq 0.05$ with an expected relative accuracy of 151%, so that no significant measurement is to be expected in this case. In fact the measured value of $\delta_{\text{Quant}}$ is much larger, 0.249(74), and so requires new physics at the tree level ($2.7\sigma$ deviation from the SM) if the data is correct. In contrast the experimental value of $\delta_{\text{Quant}}$ (Eqn(7.15) is 0.00502 with an expected relative experimental uncertainty of 24% ($4.2\,\sigma$ deviation from zero) whereas the measured value is 0.0006(12) ($0.5\,\sigma$ deviation from zero). In this case the expected quantum corrections are not observed, leading to a $-3.7\,\sigma$ deviation from SM prediction. Some theoretical interpretations of this effect have already been proposed [47, 48].

Finally, in Section 7, combined confidence level curves $C_L$ are derived including in the $\chi^2$ estimator not only the $m_H$-sensitive observables, as in Section 5, but all, or chosen subsets of, other model-independent observables. In order to see the impact of the NuTeV experiment, $C_L$ curves are are presented excluding the NuTeV data or for the two alternative interpretations: $\bar{s}_\nu$ or $m_W$ measurements. The same set of $C_L$ curves is also obtained using only the leptonic observables: $A_{l\text{(lept)}}, \bar{s}_l$ and $\bar{s}_\nu$, in addition to $m_W$. The results are shown in Tables 6 and 7 and Tables 22 and 23. The curves where NuTeV is included lie about an order of magnitude below those where it is excluded. The $C_L$ curves for the two different interpretations of the NuTeV experiment are similar, except that those corresponding to an $\bar{s}_\nu$ measurement lie significantly lower for large values of $m_H$ of $\geq 300$ GeV.
In Section 8 a comparison is made between the CLs found previously in the present paper and those quoted for the latest published EWWG and EWPDG global fits. They are shown to be quite consistent when the various dilution effects of the $\chi^2$ estimators used in the global fits are taken into account. The maximum value of CL using all data and choosing the $s_{\nu}$ measurement interpretation of the NuTeV experiment of 0.0059, at $m_H = 180$ GeV, is about an order of magnitude lower than the CL of 4.5% quoted for the ‘all data’ EWWG fit. The CLs of the global EWWG and EWPDG fits correspond to central fitted values of $m_H$ completely excluded by the direct experimental lower limit of 114.4 GeV at 95% CL. Replacing the fitted values of $m_H$ by this lower limit, to give the largest possible CL consistent with all experimental data, will result in lower CLs than those quoted for the fits.

Finally are shown, in Fig.8, the author’s personal choice of the three most pertinent CL curves among the 18 different ones previously presented in this paper. The ‘$A_i$(lept) and $m_W$ only’ curve (dotted) gives the most reliable estimate of $m_H$. The value of CL of $\simeq 0.2 - 0.3$ for values of $m_H$ just above the direct lower limit of 114.4 GeV is quite acceptable. However for $m_H = 300$ GeV, CL is $< 10^{-3}$ implying that, if the SM describes correctly the charged lepton sector and the Higgs boson exists, it must be very light indeed: $\leq 180$ GeV if CL $\geq 0.05$. Higher values of $m_H$ are favoured by the ‘All data NuTeV out’ curve (dashed). This is mainly due to the $A_i - A_b$ correlation following from Eqn(3,1) in the $A_{FB}^{0b}$ measurement, as discussed above. The maximum value of CL is $\simeq 0.05$ at about $m_H = 140$ GeV. Including the NuTeV measurement gives the ‘All data NuTeV $s_{\nu}$ meas.’ curve (solid line) with a similar shape but lying roughly an order of magnitude lower. The maximum value of CL is $\simeq 0.006$ at $m_H \simeq 180$ GeV. This accurately reflects the best possible level of agreement, with the SM prediction, of the entire electroweak
data set. It is an order of magnitude, or more, lower than the CLs quoted by the EWWG and EWPDG groups for their global fits to similar data sets.

Acknowledgements

I thank B.Roe for teaching me the correct way to combine confidence levels and W.Metzger for several illuminating conversations on statistical matters. I especially thank M.Dittmar and S.Meie for their detailed criticisms that have enabled me to improve the clarity of the presentation in several places. Comments on the manuscript from G.D’Agostini, T.Aziz, M.Chanowitz, J.Erler, P.Gambino and P.Renton are also gratefully acknowledged.
