Abstract

Objective: Pectus excavatum (PE) and pectus carinatum (PC) are two common chest deformities. We investigated the prevalence of chest wall deformities including PE and PC in Iranian population.

Methods: 25587 children and adolescents aged 7-14 years consisting of 13586 (53.1%) males and 12001 (46.9%) females were studied using cluster-stratified sampling method. Screening was clinical and based on descriptive findings. Suspected subjects with chest wall deformity were referred to the expert surgeon to confirm the diagnosis.

Findings: The prevalence of chest deformities in our population was 204 (1.03%). The mean age of subjects was 10.2±3.0 years. Of these subjects 124 (0.49%) [74 (54%) males and 50 (42%) females] had PE and 80 (0.31%) [58 (72.5%) males and 22 (17.5%) females] had PC.

Conclusion: The prevalence of PE seems to be very high in Iran. Special attention must be paid to diagnose and treat this problem in our population.

Key Words: Pectus excavatum; Pectus carinatum; Chest wall; Deformity; Iran

Introduction

Abnormalities of the thorax often result in cosmetic complaints, but some chest wall deformities result in functional limitations such as activity intolerance related to cardiac or respiratory impairment. Reported symptoms include mild to moderate exercise limitation, respiratory infections, and asthmatic conditions[1,2]. Pectus excavatum (PE) is by far...
the most common major congenital chest deformity, occurring in approximately 23 in every 10000 births in United States[3]. It occurs in males more frequently than in females[4]. PE with sternal depression is approximately six times more common than pectus carinatum (PC) with sternal protrusion[5]. PC consists of a spectrum of deformities, most frequently with anterior displacement of the mid and lower sternum and adjacent costal cartilages. To our knowledge, there has not been any previous report on the prevalence of chest wall deformities including PE and PC in Iran. Therefore, in the present study the prevalence of chest wall deformities was investigated in a population of about 25600 students from Mashhad, Iran.

**Subjects and Methods**

**Subjects:** 25587 children and adolescents consisting of 13586 (53.1%) males and 12001 (46.9%) females were studied using cluster-stratified sampling method during 1998 and 2001.

Recruited individuals were aged 7 to 14 years and were primary or guidance school students in Mashhad, Iran.

**Screening Procedure:** A group of especially trained general practitioners and health teachers of the schools screened all students of each cluster for chest deformity. Doubtful cases of chest deformity were examined by at least two trained general practitioners. Screening was clinical and based on descriptive findings identified in physical inspection of the chest. The hallmark of PE is the caved-in appearance of the anterior chest. As mentioned above, the severity of the defect and the asymmetry of the chest widely vary. Patients may present with a very mild form of PE or their sternum may be almost touching the spine.

Typically, the lower third of the sternum is more involved, and the upper third may appear fairly normal. A compensatory anterior flaring of the lower ribs at each costal margin is also common.

Each patient gave informed written consent to participate in the study, which was approved by the Mashhad University of Medical Sciences Ethics Committee.

**Findings**

The prevalence of chest deformities in our population was 204 (1.03%). The mean age of subjects was 10.2±3.0 years. Of these subjects 178 (0.69%) [74 (54%) males and 58 (72.5%) females] had PE and 80 (0.31%) [58 (72.5%) males and 22 (17.5%) females] had PC. The average age of subjects with PE was 9.5±5.6 and with PC 9.9±4.6 years.

**Discussion**

The prevalence of PE in Iranian population is approximately two times higher than that in a previous report[3]. In a study of 1332 students from the northern region of Brazil (mean age 11.7 yr), the prevalence of pectus abnormalities was found to be 1.95% (PE 1.275% and PC 0.675%)[6] which is higher than that in the present study (1.03%). However, as stated in the

| Gender | Number (%) | Pectus excavatum | Pectus carinatum | Other chest deformities | Total |
|--------|------------|------------------|------------------|------------------------|-------|
| Male   | 13586 (53.1%) | 74 (54%) | 58 (72.5%) | 46 (76.7%) | 178 (0.69%) |
| Female | 12001 (46.9%) | 50 (42%) | 22 (17.5%) | 14 (12.3%) | 86 (0.34%) |
| Total  | 25587 (100%) | 124 (0.49%) | 80 (0.31%) | 60 (0.23%) | 264 (1.03%) |
In the aforementioned study, the observed prevalence was lower than previously reported figures for the southeastern (4.9%) and central-west (3.6%) regions of Brazil\[6-8\]. In regard to the general population, the prevalence of chest deformities is approximately 1%[9]. In the current study, we observed a higher prevalence of PE (54%), PC (72.5%) and overall chest deformities (67%) in males compared with the females, and thus is consistent with previous reports. As stated by Westphal and colleagues, the prevalence of chest deformities among students or preschool children from different regions of Brazil was higher in males (69.2%, 57% and 63.4% for northern, southeastern and central-west regions of Brazil, respectively)\[6\].

Besides, males were also predominant among subjects from United States (78%) and Europe (76%) who were referred for the surgery of chest abnormalities\[10,11\]. In relation to the type of chest deformity, PE is considered to constitute more than 87% of all chest deformities\[9\], therefore being more frequent than PC in most of the studied populations\[6,7,10-12\]. However, there are also some exceptions in which PC was found to be more common than PE such as in Argentina\[9\]. Moreover, PE has been reported to be very rare in African populations\[9\]. As a limitation of the present study it is worth noting that due to the large number of study population, we did not have access to the full demographic data of participants especially their anthropometric indices. These data could have enabled us to assess the association between different biochemical and anthropometric parameters with the incidence of pectus deformities. Furthermore, it would be more helpful to determine the prevalence of cardiovascular and respiratory diseases among subjects with chest deformities as well as the impact of positive family history on the incidence of deformities. Finally, it is recommended to follow up those subjects who are candidates of surgical treatment in a future study and evaluate the impact of surgical repair on the improvement of symptoms such as respiratory problems, exercise tolerance, endurance, etc.

**Conclusion**

In our investigation we were able to show that PE is very prevalent in Iranian population and
more attention must be paid to diagnose chest deformities in Iran.
