Abstract

We study the forms of the orbits in a symmetric configuration of a realistic model of the H$_2$O molecule with particular emphasis on the periodic orbits. We use an appropriate Poincaré surface of section (PSS) and study the distribution of the orbits on this PSS for various energies. We find both ordered and chaotic orbits. The proportion of ordered orbits is almost 100% for small energies, but decreases abruptly beyond a critical energy. When the energy exceeds the escape energy there are still non-escaping orbits around stable periodic orbits. We study in detail the forms of the various periodic orbits, and their connections, by providing appropriate stability and bifurcation diagrams.

1Accepted for publication in Chaos © American Institute of Physics
Small molecules are quantum systems, but their classical study reveals their most important features. The method of the Poincaré surface of section plays a prominent role in such a study. A difficulty that appears often in realistic systems is that one can not always choose a flat Poincaré surface of section that intersects all periodic orbits. In this paper we use a curved Poincaré surface of section in order to study a realistic model of the H$_2$O molecule. We find the phase plots for different values of the energy of the molecule. Then we find all the periodic orbits of period 1 and 2 and compute their stability and bifurcation diagrams.

1 Introduction

Two dimensional Hamiltonian systems are often studied using the technique of the Poincaré map, where one reduces the four dimensional, continuous time flow of the system to an associated two dimensional discrete map, by choosing an appropriate surface of section. Usually a flat surface of section is chosen and the orbits that cross this surface with a particular direction are the consequents of the Poincaré map.

For many systems a flat PSS is not suitable since there are orbits of these systems that do not cross the surface of section. In these cases another choice must be made. In this paper we study a symmetric model of the H$_2$O molecule where we have chosen a curved PSS. This choice for the PSS permits us to study all the periodic orbits of the system for all the values of energy.

The study of periodic orbits and phase plots in realistic models of simple molecules, such as the model we are studying in this paper, gives interesting information that can be compared with the behavior of the corresponding quantum system and with experiments. In particular the relation between classical periodic orbits and quantum mechanical eigenfunctions was emphasized by several authors, starting with the work of Gutzwiller. The most surprising result was that in many cases one simple periodic orbit determines the basic form of the eigenfunction. Further details can be found by using more periodic orbits and the asymptotic structures around unstable periodic orbits.

A partial study of periodic orbits in the H$_2$O molecule has been done by Lawton and Child, Jaffé and Brumer and by Kellman, who emphasize the bifurcation of the local stretching modes from the normal stretching vibrational mode. These papers contain references to previous work on orbits in the H$_2$O molecule.

We describe the model of the H$_2$O molecule in section 2, and use a convenient set of coordinates in defining the Hamiltonian. We calculate the equipotential surfaces for the symmetric molecule (section 3) and in section 4 we define an appropriate Poincaré surface of section and discuss its properties.

Then we study in detail the phase plots on such a Poincaré surface of section and find the main islands of stability and the chaotic zones (section 5). We
calculate the main periodic orbits and their bifurcations and stability in section 6. Finally we summarize our conclusions in section 7.

2 A model for the H$_2$O molecule

For the study of the H$_2$O molecule we have chosen a simple model that is well suited for classical calculations [14]. The potential energy has the form

$$ V_{HHO} = V^{(1)}_O \cdot f(R_1, R_2, R_3) + V^{(2)}_{OH}(R_1) + V^{(2)}_{OH}(R_2) + V^{(2)}_{HH}(R_3) + V^{(3)}_{HHO}(R_1, R_2, R_3) $$

(1)

where $R_1$, $R_2$ and $R_3$ are the O–H$_1$, O–H$_2$ and H$_1$–H$_2$ distances respectively. Distances are measured in Angstroms and energies in eV. The single-body term in equation (1) is given by

$$ V^{(1)}_O \cdot f(R_1, R_2, R_3) = 1.958 \cdot \frac{1}{2} \left(1 - \tanh \left(\frac{3\rho_1 - \rho_1 - \rho_2 + \alpha}{2}\right)\right) $$

(2)

where $\alpha = 1.9018$, $\rho_1 = R_1 - 0.9572$, $\rho_2 = R_2 - 0.9572$ and $\rho_3 = R_3 - 1.5139$. The two-body terms are given by the equations

$$ V^{(2)}_{OH}(R_i) = -D_1(1 + a_1 r_i + a_2 r_i^2 + a_3 r_i^3) \exp \{-a_1 r_i\}, \quad i = 1, 2 $$

(3)

where $r_i = R_i - 0.9696$, $a_1 = 4.507$, $a_2 = 4.884$, $a_3 = 3.795$ and $D_1 = 4.6211$

$$ V^{(2)}_{HH}(R_3) = -D_2(1 + a_4 r_3 + a_5 r_3^2 + a_6 r_3^3) \exp \{-a_4 r_3\} $$

(4)

where $r_3 = R_3 - 0.7414$, $a_4 = 3.961$, $a_5 = 4.064$, $a_6 = 3.574$ and $D_2 = 4.7472$. Finally the three-body term is given by

$$ V^{(3)}_{HHO}(R_1, R_2, R_3) = 0.01892 \cdot P(\rho_1, \rho_2, \rho_3) \prod_{i=1}^{3}(1 - \tanh(\gamma_i \rho_i/2)) $$

(5)

where $\gamma_1 = \gamma_2 = 2.6$, $\gamma_3 = 1.5$ and $P(\rho_1, \rho_2, \rho_3)$ is the polynomial

$$ P(\rho_1, \rho_2, \rho_3) = 1 + \sum_{i=1}^{3} C_i \rho_i + \sum_{i=1}^{3} \sum_{j=i}^{3} C_{ij} \rho_i \rho_j $$

$$ + \sum_{i=1}^{3} \sum_{j=i}^{3} \sum_{k=j}^{3} C_{ijk} \rho_i \rho_j \rho_k + \sum_{i=1}^{3} \sum_{j=i}^{3} \sum_{k=j}^{3} \sum_{l=k}^{3} C_{ijkl} \rho_i \rho_j \rho_k \rho_l $$

(6)

The coefficients $C_i, C_{ij}, C_{ijk}$ and $C_{ijkl}$ are defined in the paper by Murrell and Carter [14].
Instead of the original coordinates $R_1$, $R_2$, $R_3$ we will use the scaled Jacobi coordinates (SJC) $SR$, $Sr$, $\theta$ (figure 1) that are defined by the equations

\begin{align*}
SR &= \frac{1}{2\alpha} \sqrt{2R_1^2 + 2R_2^2 - R_3^2} \\
Sr &= \alpha R_3 \\
\cos \theta &= \frac{R_2^2 - R_1^2}{2\alpha SR R_3}
\end{align*}

(7)

where $\alpha$ is given by the relation

\[
\alpha = \left( \frac{m_O + 2m_H}{4m_O} \right)^{\frac{1}{4}}
\]

(8)

The inverse relations are

\begin{align*}
R_1 &= \sqrt{\left( \frac{Sr}{2\alpha} \right)^2 + (\alpha SR)^2 - SR \ Sr \ \cos \theta} \\
R_2 &= \sqrt{\left( \frac{Sr}{2\alpha} \right)^2 + (\alpha SR)^2 + SR \ Sr \ \cos \theta} \\
R_3 &= \frac{Sr}{\alpha}
\end{align*}

(9)

The potential function given by equations (1-6) can be written in scaled Jacobi coordinates using equations (9).
The kinetic energy of the H$_2$O molecule has the form
\[
T = \frac{1}{2\mu} \left[ P_{SR}^2 + P_{Sr}^2 + \left( \frac{1}{SR^2} + \frac{1}{Sr^2} \right) P_{\theta}^2 \right]
\] (10)
where $P_{SR}$, $P_{Sr}$ and $P_{\theta}$ are the conjugate momenta of $SR$, $Sr$ and $\theta$ respectively. The parameter $\mu$ is defined by the relation
\[
\mu = \sqrt{\frac{m_0 m_H^2}{m_0 + 2m_H}} = \frac{m_H}{2\alpha^2}
\] (11)

The Hamiltonian can now be written as the sum of the kinetic and potential energies
\[
H(P_{SR}, P_{Sr}, \theta, SR, Sr) = T(P_{SR}, P_{Sr}, 0, SR, Sr) + V_{HHO}(SR, Sr, \theta)
\] (12)

### 3 Equiopotential surfaces

If we consider initial conditions with
\[
\theta = \pi/2 \text{ and } P_{\theta} = 0
\] (13)
we can easily see that $\dot{\theta} = 0$ and $\dot{P}_{\theta} = 0$, meaning that the sub manifold of the phase space determined by equations (13) is invariant under the Hamiltonian flow and hence we can perform a standard type reduction in order to get a two degrees of freedom Hamiltonian system on this sub manifold.

The reduced Hamiltonian $\tilde{H}$ is related to the original Hamiltonian through the relation
\[
\tilde{H}(P_{SR}, P_{Sr}, SR, Sr) = H(P_{SR}, P_{Sr}, 0, SR, Sr, \pi/2) = E
\] (14)
and its numerical value is the energy $E$ of the molecule. This Hamiltonian describes the symmetric water molecule, where the distances O–H$_1$ and O–H$_2$ are equal.

The equipotential surfaces for the symmetric molecule are shown in figure 2. The potential has two minima at $SR = \pm 0.676065$, $Sr = 1.31082$ where it takes the value $E_0 = -10.047$. Between the two minima there is a saddle point at $SR = 0$, $Sr = 1.6057$ where the potential takes the value $E_1 = -8.993$. For $E < E_1$ orbits are confined inside the potential well around a minimum of the potential. For $E > E_1$ the two wells join and orbits can pass from one well to the other.

For values of energy greater than $E_2 = -2.7892$ orbits can escape to infinity following the two horizontal channels at the left and the right of figure 3. Escape through these channels corresponds to a configuration of the molecule where the oxygen atom has become unbounded and the two hydrogen atoms form an H$_2$ molecule. Although for $E > E_2$ most orbits escape there are still bounded orbits as one can see in figure 6(c) below.
A Poincaré surface of section

A Poincaré surface of section (PSS) should intersect almost all the orbits. Such intersections occur naturally if the potential has a plane of symmetry. However this does not happen in the present case. On the other hand many orbits have a tendency to pass through a local minimum of the potential (although this is not always the case). Thus in order to find a suitable Poincaré surface of section we calculated numerically for each value of $SR$ the corresponding value of $Sr$ where the potential function has a minimum. Then we fitted the numerically determined function $Sr = f_{\text{num}}(SR)$ by the analytic form

$$Sr = f(SR) = \alpha \tilde{f}(\alpha \, SR)$$

(15)

where

$$\tilde{f}(x) = 0.740350 + 0.482392 \exp(-3.34209 \, x^2) + 0.631258 \exp(-0.112678 \, x^4)$$

(16)

and $\alpha$ is given by equation (8).

This curve is given in figure 2. We checked that the difference between the numerically determined curve $Sr = f_{\text{num}}(SR)$ and the fitted analytic form is very small. For our computations we used the fitted form, given by equations (15) and (16).

Contrary to the textbook approach we have not chosen $SR$ and $PSR$ as the two coordinates on the Poincaré surface of section (PSS). If we had made such a choice we would have the following problem. Consider the orbits of figure 3. Both orbits cross the PSS at the same point with coordinates $SR, Sr$ with

Figure 2: Equipotential surfaces for the symmetric H$_2$O molecule. The solid line is the Poincaré surface of section.
the same momentum $P_{SR}$ and they both have the same energy $E$. Then we solve equation (14) in order to determine $P_{Sr}$, and we get two solutions $\pm P_{Sr}$. From figure 3 we can see that both solutions are valid, but they correspond to different orbits. This in turn means that on such a PSS different orbits would overlap and this is not permissible.

In order to solve this problem we have chosen as coordinates on the PSS, $SR$ and the component $P_t$ of the momentum vector $P = (P_{SR}, P_{Sr})$ tangential to the curve (15). Thus the Poincaré surface of section is determined by the coordinate $SR$ along the curve of figure 2 and the component $P_t$ of the momentum. Some typical orbits on the plane ($SR, Sr$) are shown in figure 4.

A variable that is canonically conjugate to $P_t$ is

$$Q_t = \int_0^{SR} \sqrt{1 + f'(x)}dx$$

In fact the symplectic form in the variables $Q_t, P_t$ is

$$\Omega = (dQ_t) \wedge (dP_t)$$

and it can be shown that this is preserved. The form (18) in the variables $SR, P_t$ is written

$$\Omega = (1 + f'(SR))^{1/2}(dSR) \wedge (dP_t)$$

Thus the two-form $dSR \wedge dP_t$ is not preserved in general. In our study we use the variable $SR$ instead of $Q_t$ because it is not practical to compute $Q_t$ numerically.

Although the coordinates $SR$ and $P_t$ are not canonically conjugate, this does not cause any problems in the study of the system. In fact the integration is performed in the canonical coordinates $SR, Sr, P_{SR}, P_{Sr}$ and the coordinates $SR$ and $P_t$ are used only on the PSS. The result is that the phase plots on the PSS are only slightly distorted relative to the phase plots that we would get if we had chosen canonically conjugate coordinates on the PSS.
Figure 4: The orbits a and c belong in the islands of 1a and 1c respectively. The orbit b lies between these two islands. The thick line represents the PSS.

5 Phase plots on the Poincaré surface of section

In figures 5-6 we give the distribution of the orbits on the Poincaré surface of section for various values of the energy $E$.

The energy of figure 5(a) is close to the minimum of the potential. In this plot practically all the orbits are ordered, defining closed invariant curves. Many invariant curves form two sets around two stable periodic orbits. The upper one is the orbit 1a and the lower one the orbit 1c (see next section). However there are also invariant curves between these two sets, that start on the left or upper side of the boundary, and terminate on the right side of the boundary. In figure 4 we can see why this is happening. In this figure we see three orbits for this value of the energy in configuration space. The orbits labeled as ‘a’ and ‘c’ belong to the islands of the periodic orbits 1a and 1c respectively. We see that the PSS crosses the outline of these orbits at two non-adjacent sides. When this is happening we get closed invariant curves on the PSS. But for the orbit labeled as ‘b’, that lies between the two islands of figure 5(a), the PSS crosses the outline of this orbit at two adjacent sides (figure 4), and on the PSS we get an open invariant curve.

Figures 5(b), 5(c) and 5(d) refer to larger energies and are given in a larger scale than figure 5(a). The orbit 1c is continued as the double period orbit 2c in figure 5(b), the second point being near the left limit of the figure. The islands around both points 2c are now larger. In this case also the chaotic orbits are insignificant.

In figure 5(c) the orbit 2c is unstable (and is represented by two points at the centers of two dark regions) and it has produced by bifurcation four stable points that correspond to a stable orbit 4c of period 4, surrounded by islands
Figure 5: Phase plots for small values of the energy. (a) $E = -9.9$ (b) $E = -9.3$ (c) $E = -9.1$ (d) $E = -8.99$. 
of stability above and below each point of the orbit 2c. In this case there are some small chaotic zones around each unstable orbit.

The chaotic zones have grown considerably in figure 5(d). In this case there are still 4 islands of stability 4c, as in figure 5(c), but very small. All the rest of the area previously occupied by bifurcations of the orbit 2c and their corresponding islands are now chaotic. This case is just above the limiting value of the energy $E_1 = -8.993$ at which the two potential wells join into one. Thus there is one symmetric figure for $SR < 0$ that joins the figure 5(d) at the small throat near the point $(0,0)$. The point $(0,0)$ represents the orbit 1b, which is unstable and produces a large chaotic region around it.

In figure 5(a) we give the phase plot for a larger value of the energy ($E = -8$) when the two potential wells are well connected at $SR = 0$ (see the equipotentials of figure 2). Figure 5(a) is symmetric with respect to the axis $SR = 0$. The apparent asymmetries in the islands of this figure are due to the use of non-symmetric initial conditions on both sides of the axis $SR = 0$. In this case the orbit 1a is unstable and has generated by bifurcation the orbit 2a, surrounded by two islands of stability on the right half of figure 5(a). A symmetric orbit 1a’ and its bifurcations 2a’ appear on the left side of the figure. The orbits 1a, 1a’ have generated two chaotic domains, that surround the islands 2a (respectively 2a’). At the lower left and upper right sides of this figure there are two elongated islands that belong to the family 2b. The center of the figure $(0,0)$ represents again the unstable orbit 1b, that generates a large chaotic domain.

Most of figure 6(a) is covered by one chaotic orbit for which we have calculated $6 \cdot 10^4$ points. We see that the points of the chaotic orbit are not distributed uniformly on the PSS. This is a transient phenomenon and is due to stickiness of the orbits near cantori surrounding the islands 2a, or the islands 2a’. These cantori form partial barriers. Orbits need a long time in order to cross the cantori and for considerable times the regions inside and outside the cantori seem separated. This causes the apparent non uniformity of the distribution of points on the PSS. But after a larger number of iterations the distribution of the points becomes uniform.

The phase plots for larger values of $E$ have some similarity with figure 6(a) but there are also differences. For example in figure 6(b) we see that there are two symmetric islands, one on each side of the axis $SR = 0$. These islands belong to the irregular family 2b, which is symmetric with respect to the point $(0,0)$ (see next section), and not to two different families like the families 1a and 1a’ of figure 5(a). The chaotic domain in this case is again very large.

For $E$ above the energy $E = E_2$ orbits can escape. In figure 6(c) we can see the islands around an orbit that belongs in the family 2b. The orbits that are outside these islands escape and this is why the area between the islands is empty.

The percentage of the area of the PSS covered by organized orbits as a function of the energy is presented in figure 7. We see that for values of energy close to $E_1 = -10.047$ (the minimum value of the potential) almost all orbits are organized. An abrupt change happens at values of energy around $E = -9$. For $E > -9$ most of the PSS is filled by chaotic orbits. There are islands of
Figure 6: Phase plots for energies: (a) $E = -8.0$ (b) $E = -3.0$ (c) $E = -2.5$. 
stability for even larger values of the energy, and we notice that for values of
the energy close to $E = -3$ the percentage of the organized orbits increases,
although it remains below 0.2 (or 20%). This increase is due to the increase of
the size of the island around the family 2b. The islands continue to increase in
size even when $E$ becomes larger than the escape energy $E_2 = -2.79$, but for
still larger $E$ they become smaller.

6 Periodic orbits

We have computed the most important families of periodic orbits for the sym-
metric water molecule. The stability diagram of the period-1 families as a func-
tion of the energy of the molecule can be seen in figure 8(a). Such a diagram
gives the Hénon stability parameter [16] $\alpha$ of each family as a function of $E$. For
a period-$k$ orbit of an area-preserving map $\sigma$, the Hénon stability parameter is
declared by the relation

$$\alpha = \frac{1}{2} \text{Trace}(D[\sigma^k](x_0))$$

where $x_0$ is a point of the periodic orbit and $D[\sigma^k](x_0)$ is the Jacobian matrix of
$\sigma \circ \cdots \circ \sigma$ ($k$ times) evaluated at $x_0$. When the stability parameter of a periodic
orbit lies in the interval from $-1$ to $1$ the orbit is stable, otherwise it is unstable.

Since the Poincaré map is not symplectic, as we have explained in section 4,
the determinant of the Jacobian matrix $D\sigma(x)$ is not equal to 1 for arbitrary points $x$ on the PSS. However for a periodic orbit with period $k$ the determinant
det $D[\sigma^k]$ is exactly equal to 1. In fact, using equation (19) it can be proven that
the determinant of the Jacobian matrix of $\sigma^k$ at a point $x_0 = (SR_0, P_{t0})$ is given

Figure 7: Proportion of regular orbits, as a function of the energy $E$
Figure 8: Stability diagrams: (a) Families 1a, 1b, 1c (b) Families 1a, 1c, 2c (continuation of 1c) (c) Family 1a and its period 2 bifurcations (d) Families 2b, 2r, 2z.
Figure 9: Periodic orbits 1a and 1c for $E = -10.04664$ in configuration space. The line (a) represents the numerically determined minima of the potential and the line (b) represents the selected PSS.

by the relation

$$\det D[\sigma^k](x_0) = \sqrt{\frac{1 + f'(SR_0)}{1 + f'(SR_k)}}$$

(21)

where $x_k = \sigma^k(x_0) = (SR_k, P_k)$ is the k-th image of $x_0$. If an orbit is periodic with period $k$, then $SR_0 = SR_k$ hence $\det D[\sigma^k](x_0) = 1$.

For values of energy close to the minimum value of the potential ($E = E_1 = -10.047$) there exist two period-1 families. We call these families 1a and 1c. They correspond to the two normal modes of the water molecule. In figure 8 we can see the corresponding periodic orbits at $E = -10.04664$ in configuration space.

The family 1c has a peculiar behaviour that is the result of our choice of the PSS. This family is born at $E = -10.047$, but beyond the energy $E = -9.331$ it appears as a period-2 family, that we call 2c (figure 8(b)). We note that no bifurcation appears here. In order to understand what is happening, we should see figure 10. In this figure we see one orbit of the family 1c that intersects the PSS only at one point, as expected for small energies. An orbit of the same family for a larger value of the energy intersects the PSS at two points and thus it appears as a period-2 orbit. We will call the change of the apparent period of a family that is not related to a bifurcation, a transition. We note here that there would be a transition even if we had chosen, as the PSS, the numerically determined curve of the minima of the potential, instead of the fitted function. Family 2c becomes unstable at $E = -9.164$ and generates by bifurcation two stable period 4 families.
For values of the energy between \( E = E_1 = -10.047 \) and \( E = -7.2 \) the largest islands on the PSS are around the family 1a and the family 2a that bifurcates from 1a (figures [3] and [3](a)). The family 1a is created at the minimum energy of the system \( E = E_1 = -10.047 \) as a stable family and becomes unstable at \( E = -8.95 \) (figure [3](a)). At this value of \( E \) it generates by bifurcation the period-2 family 2a (figure [3](c)). Notice that when the stability parameter \( \alpha \) of a period-1 orbit is equal to \(-1\) the same orbit described twice has a stability parameter \(+1\). The family 2a starts at \( E = -8.95 \) with stability parameter \( \alpha = 1 \), and exists for larger values of \( E \). The family 1a remains unstable until \( E = -2.47 \), where the period-2 family 2e is generated by bifurcation from the family 1a, existing for smaller values of \( E \) (figure [3](c)).

The family 2a for \( E = -6.82 \) becomes unstable by crossing the line \( \alpha = -1 \) and becomes stable again for \( E = -5.62 \). The stability parameter of the family 2a takes the value \( \alpha = 1 \) at \( E = -5.568 \). At this energy an unstable period-2 family, that we call 2f is created. The family 2e becomes unstable (going from larger to smaller values of the energy) for \( E = -2.987 \) and becomes stable again for \( E = -5.661 \). The stability parameter of the family 2e takes the value \( \alpha = 1 \) at \( E = -5.675 \). At this energy the unstable family 2f, that was created at a larger energy from 2a, joins 2e (figure [3](c)). The bifurcation diagram of the families 1a, 2a, 2e, 2f and 1b is shown in figure [3]. This figure gives the value of \( SR \) for each energy. We see that the family 2f exists only in a small interval of values of \( E \) and joins the family 1a at its maximum \( E \) and the family 2e at its minimum \( E \). This explains why the families 2a, 2e and 2f form a loop in figure [3](c).

Between \( E = -2.47 \) and \( E = -2.00 \) the family 1a remains stable. At
$E = -2.00$ the family 1a joins the family 1b, and for larger values of energy the family 1a does not exist. We may thus say that the family 1a is a bifurcation of the family 1b. The family 1b is represented by the point $(0, 0)$ on the surface of section. It is created at the energy $E_2 = -8.993$ (figure 8(a)), at the saddle point of the potential (figure 2), with coordinates $SR = 0, Sr = 1.6057$. For energies somewhat larger than $E_2$ the family 1b is unstable ($\alpha = 9.73$). As $E$ increases, the stability parameter of the family 1b becomes larger, but later (for larger $E$) it becomes smaller. At $E = -2.00$ this family becomes stable. It becomes again unstable at $E = -1.50$ with stability parameter $\alpha = -1$. For larger $E$ the family 1b is unstable, but at $E = -0.0205$ it becomes stable again until $E = -0.0110$, where it becomes unstable, by crossing the line $\alpha = 1$ and thus generating another period-1 family. As the energy approaches the energy $E = 0$ the stability parameter of the family 1b tends to infinity, and the return time (period) of the periodic orbit also tends to infinity.

In figure 12 we can see that periodic orbits of the family 1b appear as straight lines in configuration space with $SR = 0$ and varying $Sr$. In physical space this corresponds to a colinear configuration of the molecule with the oxygen atom in the middle and the two hydrogen atoms oscillating symmetrically at each side of the oxygen atom. For large intervals of the energy this configuration is unstable. In figure 12 we can also see how the periodic orbits of the family 1a appear in configuration space for different values of the energy. We note that there is also a family 1a’ that is symmetric to the family 1a with respect to the axis $SR = 0$. As the energy increases the families 1a and 1a’ approach the family 1b, and join 1b for $E = -2.00$.

At energy $E = -8.06$ two irregular period-2 families are created (figure 8(d)). Irregular families are created in pairs (one stable and one unstable) by a tangent bifurcation. This means that irregular orbits are not created by the
bifurcation of an existing periodic orbit, but from each other. The stable family is called 2b and the unstable one is called 2r. The stability parameter of the family 2r grows from $\alpha = 1$ to $\alpha = 17.12$ as the energy increases and then decreases, until it reaches the value $\alpha = 2.77$ at $E = -6.454$. For this energy the family 2r appears as a period-4 family and we have a transition, as in the case of the transition 1c$\rightarrow$2c.

The stable family 2b plays an important role in the structure of the phase space. The stability diagram of the family 2b and the period-2 families that bifurcate from 2b can be seen in figure 8(d). The diagram is very complex, much more than the stability diagram of the family 1a. Here we consider only the family 2b and its equal period bifurcations. The stability parameter of the family 2b crosses (or just reaches) the horizontal line $\alpha = 1$ eight times. Each time this happens a family of period-2 orbits bifurcates from the family 2b. For $E = 0.27$ the family 2b joins a new unstable family 2z and they both disappear there, i.e. they do not exist for larger $E$.

The families 2b, 2r and 2z are symmetric with respect to the point $(0, 0)$. The families that bifurcate from 2b are not symmetric but they come in symmetric pairs. In figure 8(d) some families that have bifurcated from the family 2b suddenly terminate because they are going through transitions. Some orbits of the family 2b can be seen in figure 13. In physical space these orbits correspond to oscillations of the oxygen atom between the two symmetric minima of the potential.

The island around the orbits of the family 2b is the largest island for values of energy close to $E = -3$. Generally, from $E = -8$ to $E = -3$ the island around 2b occupies a significant measure of the PSS.

In the present paper we studied the stability (and instability) of the various

types of orbits on the plane of symmetry $\theta = \pi/2$ and $P_\theta = 0$. However orbits that are stable on this plane may be unstable in a direction perpendicular to this plane. An example is shown in figure 14, where we have calculated two stability parameters for the family 2a. One is the usual stability parameter $\alpha$, as in figure 8(c), and the other is the stability parameter $\alpha_\theta$ for deviations out of the symmetry plane. We see that while the family 2a is stable with respect to deviation on the symmetry plane it becomes unstable with respect to perpendicular deviations for $E = -8$. At the transition to instability there is a bifurcation of a new period 2 family, which extends out of the symmetry plane and is initially stable.

The study of the stability of orbits in a direction out of the symmetry plane is important in many cases. Such studies in galactic dynamics have been made since a long time [17]. A detailed study of the stability and the bifurcations of periodic orbits with respect to the third dimension in the H$_2$O molecule will be given in a future paper.

7 Summary and conclusions

We have made a systematic study of the classical orbits for the symmetric configuration of a realistic model of the H$_2$O molecule.

In order to study the distribution of the ordered and the chaotic orbits for this system, we had to choose an appropriate Poincaré surface of section (PSS). The usual choice for the PSS is a plane surface in phase space, but for the particular system under study here, this would not be convenient, because for any choice of a plane PSS there would be important periodic orbits that would not cross it.

The PSS we chose is a surface passing approximately through the minima of the potential. Most non-escaping orbits cross this PSS. Choosing appropriate coordinates on this PSS, we were able to reduce the study of the dynamics of the symmetric H$_2$O molecule to the study of a two-dimensional map. With this particular choice of the PSS we ensure that the Poincaré map describes the complete dynamics of the molecule. A minor problem with this particular choice for the PSS is that some periodic families appear to change period without a bifurcation, due to an extra intersection of a periodic orbit with the PSS.

We found the distribution of the orbits on this PSS, distinguishing between ordered and chaotic orbits. The ordered orbits are represented by isolated points if they are periodic and by invariant curves if they are quasi-periodic. Most orbits are ordered for small energies. But as the energy increases beyond a critical value the proportion of ordered orbits decreases abruptly. When the energy increases beyond the escape energy ($E_2 = -2.7892$), most orbits escape to infinity, but there are still orbits trapped around stable periodic orbits. This remains true even when the energy increases above $E_3 = 0$, but for positive energies the regions of ordered motion are very small, and practically insignificant.

We studied the main periodic orbits of period 1 and 2 for negative values of the energy. We constructed stability diagrams and bifurcation diagrams for the
various families of periodic orbits. These diagrams are essential in understanding the role of various stable orbits in trapping non-periodic orbits around them. In fact for different energies the trapping takes place around different orbits and we can separate the interval between the critical energy and the escape energy into two regions. In the first region (lower energies) the ordered orbits are trapped mainly around the families 2a and 2a'. In the second region, close to the escape energy the ordered orbits are trapped mainly around the irregular family 2b.

Acknowledgments

This research was supported by the Research Committee of the Academy of Athens (Grant No. 200/419). We thank Prof. S. Farantos for his suggestion to use the particular model studied here. We also thank Dr. C. Skokos for useful discussions. KE has been supported in part by the Greek Foundation of State Scholarships (IKY). We thank also the (anonymous) referees for their remarks and for providing useful references.
