Symbiotic Growth of a Thermophilic Sulfide-Oxidizing Photoautotroph and an Elemental Sulfur-Disproportionating Chemolithoautotroph and Cooperative Dissimilatory Oxidation of Sulfide to Sulfate

Shigeru Kawai, Naoki Kamiya, Katsumi Matsuura and Shin Haruta*

Department of Biological Sciences, Tokyo Metropolitan University, Hachioji, Japan

A thermophilic filamentous anoxygenic photosynthetic bacterium, *Chloroflexus aggregans*, is widely distributed in neutral to slightly alkaline hot springs. Sulfide has been suggested as an electron donor for autotrophic growth in microbial mats dominated with *C. aggregans*, but remarkable photoautotrophic growth of isolated *C. aggregans* has not been observed with sulfide as the sole electron source. From the idea that sulfide is oxidized to elemental sulfur by *C. aggregans* and the accumulation of elemental sulfur may have an inhibitory effect for the growth, the effects of an elemental sulfur-disproportionating bacterium that consumes elemental sulfur was examined on the autotrophic growth of *C. aggregans*, strain NA9-6, isolated from Nakabusa hot spring. A sulfur-disproportionating bacterium, *Caldimicrobium thiodismutans* strain TF1, also isolated from Nakabusa hot spring was co-cultured with *C. aggregans*. *C. aggregans* and *C. thiodismutans* were successfully co-cultured in a medium containing thiosulfate as the sole electron source and bicarbonate as the sole carbon source. Quantitative conversion of thiosulfate to sulfate and a small transient accumulation of sulfide was observed in the co-culture. Then the electron source of the established co-culture was changed from thiosulfate to sulfide, and the growth of *C. aggregans* and *C. thiodismutans* was successfully observed with sulfide as the sole electron donor for the autotrophic growth of the co-culture. During the cultivation in the light, simultaneous consumption and accumulation of sulfide and sulfate, respectively, were observed, accompanied with the increase of cellular DNAs of both species. *C. thiodismutans* likely works as an elemental sulfur scavenger for *C. aggregans*, and *C. aggregans* seems to work as a sulfide scavenger for *C. thiodismutans*. These results suggest that *C. aggregans* grows autotrophically with sulfide as the electron donor in the co-culture with *C. thiodismutans*, and the consumption of elemental sulfur by...
Communities dominated by C. aggregans (Meer et al., 2005). In sulfidic hot springs, however, Chloroflexus grow on organic compounds produced by cyanobacteria (van der C. aggregans Matsuura, and S. Haruta, manuscript in preparation). However, some grew photoautotrophically and chemolithotrophically from Nakabusa hot springs in Nagano, Japan, and found that C. aggregans et al., 2014). Recently, we isolated new strains of Chloroflexus C. aggregans Holo and Sirevag, 1986) and Chloroflexus in the genus Chloroflexus, Chloroflexus aurantiacus OK-70-fl (Holo and Sirevag, 1986) and Chloroflexus sp. strain MS-G (Thiel et al., 2014). Recently, we isolated new strains of C. aggregans from Nakabusa hot springs in Nagano, Japan, and found that some grew photoautotrophically and chemolithotrophically with H₂ as an electron source (S. Kawai, A. Nishihara, K. Matsuura, and S. Haruta, manuscript in preparation). However, no strains of C. aggregans showed marked photoautotrophic growth with sulfide.

Chloroflexus spp. are generally thought to heterotrophically grow on organic compounds produced by cyanobacteria (van der Meer et al., 2005). In sulfidic hot springs, however, Chloroflexus spp. including C. aggregans are found to form microbial mats in the absence of cyanobacteria (Giovannoni et al., 1987; Kubo et al., 2011; Everroad et al., 2012; Otaki et al., 2012). Microbial communities dominated by C. aggregans form well-developed microbial mats in sulfidic hot spring water (∼0.1 mmol L⁻¹ sulfide) at Nakabusa hot springs (Kubo et al., 2011; Everroad et al., 2012; Otaki et al., 2012). Since organic compounds and H₂ in the hot spring water are scarce (Nakagawa and Fukui, 2002), it has been the presumption that C. aggregans grows photoautotrophically using sulfide as the major electron source in the hot springs. A previous study showed bicarbonate-dependent sulfide-oxidation in the C. aggregans-dominated microbial mats under anaerobic conditions in the light (Kubo et al., 2011). In addition, the C. aggregans genome contains the sulfide:quinone oxidoreductase gene for sulfide oxidation, but lacks dissimilatory sulfite reductase genes (Holkenbrink et al., 2011) and a gene set for the SOX pathway (Klatt et al., 2007). These observations suggest that C. aggregans can grow photoautotrophically through oxidation of sulfide to elemental sulfur under anaerobic conditions.

C. thiodismutans enabled the continuous growth of the C. aggregans in the symbiotic system. This study shows a novel symbiotic relationship between a sulfide-oxidizing photoautotroph and an elemental sulfur-disproportionating chemolithoautotroph via cooperative dissimilatory sulfide oxidation to sulfate.

**Keywords:** anoxygenic photosynthesis, sulfur-disproportionation, hot spring microbial mats, sulfide, elemental sulfur

**INTRODUCTION**

The thermophilic filamentous anoxygenic photosynthetic bacterium, Chloroflexus aggregans, in the phylum Chloroflexi, is widely distributed in neutral to slightly alkaline hot springs (Hanada, 2003). This bacterium grows optimally at temperatures from 50 to 60°C. It is capable of growing photoheterotrophically under anaerobic conditions in the light and chemoheterotrophically under aerobic conditions in the dark (Hanada et al., 1995). Genome analysis of C. aggregans MD-66T found a gene set for carbon fixation pathway suggesting that C. aggregans can grow autotrophically (Klatt et al., 2007). However, no photoautotrophic growth has been reported in C. aggregans, despite that photoautotrophic growth with sulfide or H₂ as the electron source has been reported in other species in the genus Chloroflexus, Chloroflexus aurantiacus OK-70-fl (Holo and Sirevag, 1986) and Chloroflexus sp. strain MS-G (Thiel et al., 2014). Concerning the difficulty of the observation of photoautotrophic growth on sulfide in C. aggregans, we hypothesized that accumulation of the oxidized product of sulfide, i.e., elemental sulfur, may suppress autotrophic growth of C. aggregans, and the removal of the elemental sulfur by other bacterial species may be required to stimulate autotrophic growth. Antibacterial effects of elemental sulfur have been known in various species of bacteria (Libenson et al., 1953; Pestana and Sols, 1970). One possible consumer of elemental sulfur, the sulfur-disproportionating bacterium, Caldificrum thiodismutans TF1, has been isolated by Kojima et al. (2016) from Nakabusa hot spring. C. thiodismutans TF1 grows autotrophically on elemental sulfur and thiosulfate to produce sulfide and sulfate under anaerobic conditions in the dark when ferrihydrite is added as a sulfide scavenger to support the growth. Identical 16S rRNA sequences to that of C. thiodismutans TF1 have been detected from the microbial communities with C. aggregans (Everroad et al., 2012).

In this study, we established a co-culture of C. aggregans and C. thiodismutans with sulfide as the sole electron source under autotrophic conditions. We evaluated the growth of C. aggregans when supported by the growth of C. thiodismutans consuming elemental sulfur, which would be produced by photo-anaerobic oxidation of sulfide by C. aggregans. Before the establishment of the co-culture on sulfide, co-cultivation on thiosulfate was conducted to start a co-culture without ferrihydrite, a sulfide scavenger, that was required for the growth of C. thiodismutans in axenic culture.

**MATERIALS AND METHODS**

**Bacterial Strains and Cultivation Conditions**

C. aggregans strain NA9-6 was isolated from Nakabusa hot spring, Japan (S. Kawai, A. Nishihara, K. Matsuura, and S. Haruta, manuscript in preparation). This strain shows good photoautotrophic growth with H₂ as the electron donor and 98.7% identity of 16S rRNA gene sequence with the type strain of C. aggregans (MD-66 = DSM 9485T). C. aggregans NA9-6 was cultivated in a medium lacking an organic carbon source. The autotrophic medium was composed of (L⁻¹) 0.38 g KH₂PO₄, 0.39 g K₂HPO₄, 0.5 g NH₄Cl, 4.2 g NaHCO₃, and 0.5 g Na₂S₂O₃·5H₂O, buffered to pH 7.5. 5 ml of basal salt solution and 1 ml of vitamin mixture (Hanada et al., 1995) were added. Bacteria were cultivated at 55°C in the light (incandescent lamp; 2~3 µmol
m$^{-2}$·s$^{-1}$) under an H$_2$-N$_2$:CO$_2$ (24:56:20, v:v:v) atmosphere. C. thiiodismutans strain TF1 (Kojima et al., 2016), kindly provided by Dr. Fukui and Dr. Kojima, was cultivated in the dark at 70°C in the same autotrophic medium with added 2 mmol L$^{-1}$ ferrihydrite under N$_2$CO$_2$ (80:20) atmosphere. Ferrihydrite was prepared as previously described (Straub et al., 2005).

Effects of Sulfide and Elemental Sulfur on the Growth of C. aggregans NA9-6

C. aggregans cells, cultivated in the autotrophic medium containing thiosulfate and H$_2$ as described above, were collected by centrifugation, washed three times with the autotrophic medium and inoculated into 10 ml of the autotrophic medium in 30 ml test tubes. The gas phase of these culture tubes was H$_2$:N$_2$:CO$_2$ (24:56:20, v:v:v). The initial optical density (OD) at 610 nm was adjusted to be 0.03. 0.05 g of sublimed sulfur (Wako, Osaka, Japan) sterilized at 110°C for 1 h three times or 1 mmol L$^{-1}$ of sulfide was aseptically added into the medium to evaluate the effect of each compound on the growth. The inoculated tubes were cultivated at 60°C in the light (incandescent lamp; 2−3 µmol m$^{-2}$·s$^{-1}$). OD at 610 nm of the culture tube was periodically measured during cultivation. Measurements were made after allowing tubes to stand at 60°C for 5 min in the dark to precipitate sulfur globules.

Co-cultivation of C. aggregans and C. thiiodismutans With Thiosulfate

C. aggregans NA9-6 and C. thiiodismutans TF1 were separately cultivated under autotrophic conditions as described above. The two cultures were inoculated together into 5 ml of the autotrophic medium containing thiosulfate as a sole electron source under an N$_2$:CO$_2$ (80:20) atmosphere in 30 ml glass test tubes, capped with butyl rubber stoppers and screw caps. The tubes were cultivated at 60°C in the light (incandescent lamp; 2−3 µmol m$^{-2}$·s$^{-1}$) for 7−20 days. 1 ml of the culture was repetitively subcultured in 5 ml of fresh medium under the same conditions to remove residual ferrihydrite from the original culture of C. thiiodismutans. OD of the cultures was measured with a photometer (Colorimeter ANA18$^+$, Tokyo photoelectric, Tokyo, Japan). 0.3 ml of the culture solution was sampled during cultivation for measurements of the amount of sulfur compounds in the culture.

Co-cultivation of C. aggregans and C. thiiodismutans With Sulfide

After repetitive subcultures of the co-culture of C. aggregans NA9-6 and C. thiiodismutans TF1 in the medium containing thiosulfate, 1 ml of the co-culture solution was inoculated into 5 ml of the autotrophic medium containing 1 mmol L$^{-1}$ of Na$_2$S instead of thiosulfate in 30 ml glass test tubes, capped with butyl rubber stoppers and screw caps. The gas phase of the tube was N$_2$:CO$_2$ (80:20). The initial OD at 610 nm was adjusted to 0.03. The tubes were cultivated at 60°C in the light (incandescent lamp; 2−3 µmol m$^{-2}$·s$^{-1}$). 0.3 ml of the culture solution was sampled during cultivation for measurements of the amount of sulfur compounds in the culture and extraction of DNAs from the cells.

Measurements of Sulfur Compounds

Sulfide concentration in culture solution was measured using a methylene blue formation method as described previously (Cline, 1969) with some modifications. 50 µl of culture solution was mixed with 250 µl of 0.1 mmol L$^{-1}$ carbonate-bicarbonate buffer (pH 10.0) immediately after collecting from the culture tube to prevent the loss of hydrogen sulfide. The mixture was centrifuged at 19,600 × g for 2 min at 4°C to remove bacterial cells. 200 µl of the supernatant was transferred to 400 µl of solution A (18 mmol L$^{-1}$ zinc acetate, 0.2% v/v acetic acid) and stored at 4°C until measurements were made. The solution was alkalinized by adding 400 µl of 40 mmol L$^{-1}$ NaOH. After centrifugation of the mixture at 19,600 × g for 2 min, the precipitate was solubilized in 552 µl of solution A. Finally, 48 µl of Cline reagent (16 g of N,N-dimethyl-p-phenylenediamine sulfate, 24 g of FeCl$_3$·6H$_2$O in 1 L of 50% HCl) was added and mixed well. After 20 min incubation at room temperature, the absorbance at 665 nm was measured with a spectrophotometer (Infinite 200 PRO, Tecan, Seestrasse, Switzerland).

Thiosulfate and sulfate concentrations were determined by ion chromatography. 100 µl of culture was diluted with 900 µl of MilliQ water and centrifuged at 19,600 × g for 2 min. The supernatant was filtrated with a 0.45-µm pore-size membrane filter. The solution was analyzed with a suppressed anion-exchange chromatography system (Shimadzu, Kyoto, Japan) equipped with a LC-20AD liquid chromatography, a DGU-20A3 degasser, a SIL-10AF auto sampler, a CT-20AC SP column oven, a CDD-10A SP conductivity detector, and a SCL-10A VP system controller. A Shim-pack IC-SA2 (250 mm × 4.0 mm; Shimadzu) was employed for separation of anions. The conditions of analyses were as follows; column temperature, 30°C; injection volume, 50 µl; eluent, 12 mmol L$^{-1}$ NaHCO$_3$ + 0.6 mmol L$^{-1}$ Na$_2$CO$_3$; flow rate, 1.0 ml min$^{-1}$. Data were collected and analyzed using Smart Chrome (KYA Technologies, Tokyo, Japan).

DNA Extraction From Bacterial Cells

DNA was extracted using the benzyl chloride method (Zhu et al., 1993) combined with bead-beating. In brief, bacterial cells collected from culture by centrifugation were mixed with DNA extraction buffer (125 mmol L$^{-1}$ Tris-HCl, 50 mmol L$^{-1}$ EDTA, pH 8.0), SDS, and benzyl chloride. Culture cell suspensions were prepared in 2 ml tubes and incubated at 50°C for 2 h with mixing at 5 min intervals. Next, approximately 0.1 g of 0.1 mm diameter zirconia-silica beads (Biospec Products, Bartlesville, OK, United States) were added and the beating treatment was performed twice for 1 min at 2,500 rpm using a Mini-beadbeater (Biospec Products). DNA was recovered by phenol and chloroform extraction followed by alcohol precipitation with Ethachinmate (Nippon Gene, Tokyo, Japan). Finally, DNA was solubilized in TE buffer (10 mmol L$^{-1}$ Tris-HCl, 1 mmol L$^{-1}$ EDTA, pH 8.0) and stored at −20°C until use.
Quantitative PCR Analysis

PCR primer sets were designed to distinguish 16S rRNA genes of *C. aggregans* and *C. thioidismutans*: agg-F (5′-CAACGTGGCTCAGTGCGATCGG-3′) and agg-R (5′-TACGACGCTAGCTAAGCATTAG-3′) for *C. aggregans*; C-CmicF (5′-TACAATGGGGGTACAGAGG-3′) and C-CmicR (5′-TGATGACGACTTCGGGTG-3′) for *C. thioidismutans*. Specific amplification using each primer set was confirmed by DNA sequence analyses of the PCR fragments obtained using a mixture of both genomic DNAs. StepOne Real-Time PCR system (Applied Biosystems, Foster City, CA, United States) was used with FastStart Universal SYBR Green Master (Roche, Mannheim, Germany). The reaction mixture was composed of 10 µl of FastStart SYBR Green Master, 1 µl of 10 µM primers, 7 µl of water and 1 µl of DNA solution. Real-time PCR was performed under the following conditions; initial denaturation at 95°C for 10 min followed by 40 cycles of 15 s at 95°C and 1 min at 60°C. Fluorescence was detected at the end of the extension reaction. The purified DNA fragments amplified using the primer sets, agg-F and agg-R or C-CmicF and C-CmicR for the respective strain were spectrophotometrically quantified using Biospec-nano (Shimazu) and used as a template DNA to obtain the standard curve. The copy numbers of genome in the culture were calculated based on the copy number of 16S rRNA gene per genome, i.e., three in *C. aggregans* (NC_011831) and one in *C. thioidismutans* (Kojima et al., 2016).

**Sulfide and Sulfate Concentration Changes by *C. aggregans*-Dominated Microbial Mats**

Microbial cell aggregates (microbial mats) that develop in hot spring water at 65°C at Nakabusa hot spring, Nagano, Japan were collected. The major member of these mats was *C. aggregans* as has been reported previously (Kubo et al., 2011; Everroad et al., 2012; Otaki et al., 2012). Approximately 1 g (wt weight) of the mats was placed into 70 ml glass vials containing 50 ml of a salt solution (1 mmol L^{-1} NaCl, 1 mmol L^{-1} Na2HPO4, pH 8.5) under N₂ gas, and the vials were sealed with butyl rubber stoppers and aluminum seals. After pre-heating the vials at 65°C in the dark for 1 h, NaHCO₃ and Na₂S solutions were added to the vials (final concentration, 1 and 0.3 mmol L⁻¹, respectively) and the vials were incubated at 65°C in the light (incandescent lamp; approximately 80 µmol m⁻² s⁻¹) or dark. Sodium molybdenum oxide was added to the vial (final concentration, 20 mmol L⁻¹) when indicated. Periodically 0.2 ml of the solution was collected from the vials for determining sulfide and sulfate concentrations in the cell-free supernatant, as described above.

**RESULTS AND DISCUSSION**

**Effects of Sulfide and Elemental Sulfur on the Growth of *C. aggregans* NA9-6**

As shown in Figure 1, photoautotrophic growth was observed in the axenic culture of *C. aggregans* NA9-6 with H₂ as the sole electron source (closed circles). However, no marked growth was observed with sulfide (crosses), and the addition of sulfide on the growth with H₂ showed some inhibitory effect (closed triangles). No significant increase in OD was detected in the absence of sulfide and H₂ (data not shown). From these observations, we supposed that the absence of the growth on sulfide as the sole electron source is possibly due to the early formation of elemental sulfur from the oxidation of sulfide by *C. aggregans*. This was partly supported by the observation that the H₂-dependent growth was largely suppressed in the presence of sublimed sulfur (open triangles, Figure 1). Elemental sulfur has been known to inactivate sulfhydryl groups in enzymes (Libenson et al., 1953; Pestana and Sols, 1970), but its inhibitory mechanism for bacterial growth has not been elucidated yet. Abiotic production of polysulfide from elemental sulfur (Kamyshny, 2009) may also inhibit the sulfide-dependent growth by suppression of the enzyme reaction of sulfide:quinone oxidoreductase.

**Co-cultivation of *C. aggregans* and *C. thioidismutans* With Thiosulfate**

The culture solution of *C. aggregans* NA9-6, cultivated under autotrophic conditions with H₂ was mixed with the culture of *C. thioidismutans* TF1 that was cultivated in the presence of thiosulfate as the electron source and ferrihydrite as the sulfide scavenger. The mixture was cultivated in the autotrophic medium containing thiosulfate but without ferrihydride under N₂:CO₂ (80:20) atmosphere. After more than 10 subcultures in medium without ferrihydrite, microscopic observation of the culture found no particles of ferrihydrite and iron sulfide. Only cells of both bacterial species, i.e., 200–300 µm length multicellular filamentous cells (*C. aggregans*) and 1.0–2.0 µm × 0.5–0.6 µm rods (*C. thioidismutans*) were observed (data not shown). Bacterial growth of the co-culture was evaluated by measurement.

![FIGURE 1](image-url) | Effect of sulfur compounds on the autotrophic growth of axenic culture of *C. aggregans*. *C. aggregans* was cultivated in the autotrophic medium without sulfide and elemental sulfur (closed circle), 1 mmol L⁻¹ of sulfide (closed triangles), 5 mg ml⁻¹ of sublimed sulfur (open triangles) under H₂:N₂:CO₂ (24: 56:20, v:v:v) atmosphere, and 1 mmol L⁻¹ sulfide under N₂:CO₂ (80:20) atmosphere (crosses). Mean values of OD at 610 nm for three culture tubes are shown.
of OD at 610 nm (Figure 2, open circles). OD increased almost exponentially during 8 days of cultivation and reached a maximum of 0.25 after that. The axenic culture of C. aggregans did not show such growth under the same conditions in the presence of thiosulfate (open triangles). No marked growth of the co-culture was observed in the dark (closed circles) and in the medium lacking thiosulfate or CO₂ in the light (data not shown).

Figure 3 shows changes in concentrations of thiosulfate, sulfate, and sulfide in the co-culture along with the changes in the culture OD. Consumption of thiosulfate during growth was confirmed. Thiosulfate consumption was accompanied with the production of sulfate; approximately 1.8 mmol L⁻¹ of thiosulfate was consumed and 3.1 mmol L⁻¹ of sulfate was produced during 8 days of cultivation. 0.3 mmol L⁻¹ of sulfide was detected at 6 days of cultivation, but the sulfide concentration was below 0.08 mmol L⁻¹ after 8 days.

No accumulation of sulfide in the co-culture in the light suggested that C. aggregans grew using sulfide produced by C. thiodismutans as the electron source. C. aggregans worked as a biotic sulfide scavenger for C. thiodismutans through the photo-oxidation of sulfide, as previously described in co-culture of a sulfur-disproportionating bacterium in the genus Desulfocapsa with a purple sulfur bacterium in the genus Lamprocystis that oxidized sulfide to sulfate (Peduzzi et al., 2003). However, the role of the sulfur-disproportionating bacterium is different from the present study (described below).

**Co-cultivation of C. aggregans and C. thiodismutans With Sulfide**

The co-culture of C. aggregans NA9-6 and C. thiodismutans TF1 in medium containing thiosulfate (Figure 4, closed circles) was inoculated into medium containing 1 mmol L⁻¹ sulfide but no thiosulfate and continuously co-cultivated (Figure 4, closed triangles). Residual thiosulfate was not expected at the time of inoculation as it was not detected at stationary phase as day 10 as shown in Figure 3. After inoculation with sulfide, immediate growth was observed suggesting sulfide metabolism had already proceeded in the culture with thiosulfate as indicated in Figure 3 and described above. After sulfide-dependent growth stopped 8 days after inoculation, sulfide was added again as indicated by the arrow in the figure, and additional growth was observed. Microscopic analysis indicated the growth of both bacterial
strains (Supplementary Figure S1). No growth occurred in the absence of sulfide and thiosulfate (data not shown).

Growth of each bacterial strain in the co-culture was evaluated by quantitative PCR (qPCR) targeting the 16S rRNA gene of each strain after repetitive subcultures with sulfide. Figure 5 shows the qPCR results and the changes in concentrations of sulfide and sulfate in the culture. C. aggregans grew with the growth of C. thiodismutans during 6 days of cultivation. The growth of both strains was accompanied with the complete consumption of approximately 1 mmol L\(^{-1}\) sulfide and the accumulation of 0.5 mmol L\(^{-1}\) sulfate. No further growth was observed after 8 days, but the growth of both strains was observed again after the supplementation of 1 mmol L\(^{-1}\) sulfide into the culture. Ratio of (C. aggregans cells):(C. thiodismutans cells) was roughly calculated to be 30:1 ∼ 40:1 based on the qPCR results. This was consistent with microscopic observation (Supplementary Figure S1). These results indicate that C. aggregans fixed CO\(_2\) to grow in the co-culture.

The growth of C. aggregans under co-culture conditions indicated that C. aggregans grew autotrophically using sulfide as the electron source. The doubling time was 41.4 ± 0.9 h\(^{-1}\). This growth rate was approximately 2.5-fold higher than that of photoautotrophic growth using H\(_2\) in the axenic culture of C. aggregans (strain NA9-6) as shown in Figure 1. The growth of C. thiodismutans and accumulation of sulfate in the co-culture suggested that C. thiodismutans utilized elemental sulfur produced by C. aggregans as the electron source. Chloroflexus aurantiacus OK-70-fl which is phylogenetically close to C. aggregans grows photosynthetically with sulfide as the electron source, but lacks the ability to oxidize elemental sulfur (Klatt et al., 2007). Madigan and Brock (Madigan and Brock, 1975) reported in the culture of this bacterium that sulfur particles were observed around the cells with a microscope. In contrast, the deposited sulfur particles were not observed in the co-culture of C. aggregans with C. thiodismutans (Supplementary Figure S1).

Chloroflexus spp. are widely found in sulfidic hot springs and are known to possess genes for carbon fixation (Klatt et al., 2013; Weltzer and Miller, 2013). Recently, thermophilic sulfur-disproportionating bacteria were detected in various phylogenetic lineages from thermal environments including terrestrial hot springs (Mardanov et al., 2016; Thiel et al., 2017; Nishihara et al., 2018; Wilkins et al., 2019). However, their function in situ and interspecies interactions have not been examined yet. In the co-culture established in this study, C. aggregans likely produces elemental sulfur and the elemental sulfur seems to be simultaneously consumed by C. thiodismutans, whose population was 1/30 ∼ 1/40 of C. aggregans. Spatial proximity of these bacterial species may be related to their interactions through exchange of sulfur compounds in natural environments. An observation related to the spatial proximity was reported for purple sulfur bacteria that oxidized sulfide to sulfate and sulfur disproportionating bacteria at chemoclone of a lake (Peduzzi et al., 2003; Tonolla et al., 2004, 2005). In natural environments, the both bacteria form cell aggregates together which are expected to increase the exchange efficiency of sulfur compounds and to overcome sulfide limitations. At Nakabusa hot springs, C. aggregans forms dense cell aggregates (microbial mats) with other bacteria which adhere to solid surface (Nakagawa and Fukui, 2002; Kubo et al., 2011; Everroad et al., 2012; Otaki et al., 2012) in sulfidic hot spring water.

We also examined the photo-oxidation of sulfide in C. aggregans-dominated microbial mats. Chloroflexus-dominated microbial mats were collected from under hot spring water at Nakabusa and a piece of the microbial mat was incubated anaerobically in artificial sulfidic hot spring water at 65°C.
In the light, sulfide concentration gradually decreased with the increase in sulfate concentration within 12 h of incubation (Supplementary Figure S2a). The increase of sulfate was inhibited by the addition of molybdate (Supplementary Figure S2b) which is an inhibitor of dissimilatory sulfate reduction as well as sulfur-disproportionation (Taylor and Oremland, 1979; Finster et al., 1998). The addition of molybdate resulted in suppression of the sulfide consumption which was observed without molybdate in the light. These results suggest that elemental sulfur produced by photo-oxidation of sulfide was efficiently converted to sulfate and sulfide by elemental sulfur-disproportionation in the natural microbial mats.

Figure 6 summarizes schematically the conversion of sulfur compounds and the associated electron flow in the novel symbiotic system with *C. aggregans* and *C. thiodismutans* in vitro with isolated strains as well as in microbial mats *in situ*. Sulfide is externally provided as the sole electron donor and *C. aggregans* converts it to elemental sulfur using light energy autotrophically. The elemental sulfur is used by *C. thiodismutans* with anaerobic chemolithoautotrophic growth producing sulfide and sulfate simultaneously through the process called disproportionation. The produced sulfide can then be used by *C. aggregans* again, and with all of these processes, externally provided sulfide is converted to sulfide by the symbiotic autotrophic system with two different autotrophic organisms performing photosynthesis and chemosynthesis. The electrons externally supplied with sulfide should mostly be used by *C. aggregans* to fix CO₂ finally and only a few percent of electrons will be used by *C. thiodismutans* based on the observation that the amount of genome copies (Figure 5) and cells (Supplementary Figure S1) of *C. aggregans* was about 30 times larger than that of *C. thiodismutans* and the cell mass should be roughly parallel to the electron input to CO₂. This explanation is consistent with the idea that most ATP is supplied by light-induced cyclic phosphorylation in *C. aggregans* and, on the other hand, ATP is produced by energetically unfavorable and electron-consuming process of the disproportionation of elemental sulfur to sulfide and sulfate in *C. thiodismutans*.

**AUTHOR CONTRIBUTIONS**

SK, NK, KM, and SH designed the study and analyzed and interpreted the data. SK performed the experiments in co-cultures. NK performed the experiments in natural microbial mats. SH supervised the experiments. SK, KM, and SH wrote and revised the manuscript. All the authors approved the final version.

**FUNDING**
