High-hole mobility polycrystalline Ge on an insulator formed by controlling precursor atomic density for solid-phase crystallization

Kaoru Toko, Ryota Yoshimine, Kenta Moto & Takashi Suemasu

High-carrier mobility semiconductors on insulators are essential for fabricating advanced thin-film transistors, allowing for three-dimensional integrated circuits or high-performance mobile terminals. We investigate the low-temperature (375–450 °C) solid-phase crystallization (SPC) of Ge on a glass substrate, focusing on the precursor conditions. The substrate temperature during the precursor deposition, $T_d$, ranged from 50 to 200 °C. According to the atomic density of the precursor and the $T_d$ dependent SPC properties, the precursor conditions were determined by three regimes: the low-density regime ($T_d < 100$ °C), high-density regime ($100 \leq T_d \leq 125$ °C), and nucleation regime ($T_d > 125$ °C). The use of the precursor in the narrow high-density regime enabled us to form SPC-Ge with a hole mobility of 340 cm$^2$/Vs, the highest value among semiconductor thin films grown on insulators at low temperature (<900 °C). The origins of the high hole mobility were determined to be both a large grain size ($5 \mu$m) and a low energy barrier height (6.4 meV) for the grain boundary. The findings from and knowledge gained in this study, that is, the influence of the precursor conditions on subsequent crystal growth, will be universal and applicable to various materials.

Germanium has been proposed as a major candidate for next-generation electronic devices because of its high carrier mobility and good compatibility with Si$^{1-3}$. In particular, the hole mobility of Ge is the highest among semiconductor materials, which can be used to realize high-performance complementary metal-oxide-semiconductor (CMOS) devices$^4$. The developments of gate stacks and source/drain junction technologies have led to high effective mobilities in Ge metal-oxide-semiconductor field-effect-transistors (MOSFETs) exceeding those in Si-MOSFETs$^4-7$. For expanding the application of Ge-MOSFETs in system-in-displays (system-on-panels) or three-dimensional integrated circuits, Ge on insulator (GOI) technology has been developed using mechanical transfer$^8$, oxidation-induced condensation$^9,10$, epitaxial growth on Si on insulator (SOI)$^{11,12}$, and rapid-melting growth$^{13-16}$. To avoid thermal damage to the substrates and to lower the process costs, the low-temperature formation (<600 °C) of GOI is necessary. Polycrystalline Ge (poly-Ge) thin films have been directly formed on glass or plastic substrates at low temperatures using solid-phase crystallization (SPC)$^{17-21}$, laser annealing$^{22-24}$, chemical vapor deposition (CVD)$^{25,26}$, flash lamp annealing (FLA)$^{27}$, and metal-induced crystallization (MIC)$^{28-32}$. The use of these techniques has allowed researchers to fabricate Ge thin-film transistors (TFTs) via all-temperature processes$^{9,21,27,32}$. The performance of the Ge-TFTs, however, has been no match for that of Si-MOSFETs. To further improve Ge-TFTs, one needs to study not only device technology but also crystallization techniques.

In 2009, we demonstrated a hole mobility of 140 cm$^2$/Vs for poly-Ge on glass formed by two-step SPC of amorphous (a–) Ge at 425 °C followed by 500 °C$^{17}$. In the last couple of years, the highest hole mobility has been updated frequently: FLA has achieved 200 cm$^2$/Vs$^{27}$, followed by Au-induced crystallization achieving 160–210 cm$^2$/Vs$^{11,32}$. On the other hand, incorporating Sn in Ge has been found to be effective for enhancing the hole mobility$^{33-35}$. The SPC of a-GeSn has achieved a hole mobility of 130 cm$^2$/Vs$^{34}$, which was then enhanced to 320 cm$^2$/Vs by controlling the thickness of the a-GeSn layer$^{35}$. The present study demonstrates a simple method to

Institute of Applied Physics, University of Tsukuba, 1-1-1 Tennodai, Tsukuba, Ibaraki, 305-8573, Japan. Correspondence and requests for materials should be addressed to K.T. (email: toko@bk.tsukuba.ac.jp)
achieve pure poly-Ge with a hole mobility of 340 cm²/Vs by controlling the atomic density of an a-Ge precursor. This hole mobility is the highest ever recorded for a semiconductor thin film including Ge, Si, compound, oxide, and organic materials formed on insulators at temperatures below 900 °C.

Results

The as-deposited Ge layers, precursors for SPC, were evaluated by X-ray reflectivity (XRR) and Raman spectroscopy. Figure 1a shows that the density of the Ge layer approaches that of crystalline Ge with increasing the deposition temperature $T_d$ and becomes nearly saturated at $T_d > 100$ °C. The density of the Ge layer for $T_d = 50$ °C almost agrees with the data from previous study on the a-Ge layer deposited without heating the substrate. Figure 1b shows that samples with $T_d = 50, 100$, and $150$ °C exhibit broad peaks near 270 cm⁻¹, corresponding to a-Ge. The sample with $T_d = 200$ °C exhibits a sharp peak near 300 cm⁻¹, corresponding to crystalline Ge-Ge bonding, in addition to a broad peak near 270 cm⁻¹. This result indicates that the sample with $T_d = 200$ °C includes both crystalline and amorphous states. The optical studies suggest the following: (i) higher $T_d$ provides denser a-Ge; and (ii) crystalline Ge nuclei start to form in the a-Ge layer at $T_d > 150$ °C.

The samples were then annealed to induce SPC, where the growth temperature $T_g$ ranged from 375 to 450 °C. The samples were evaluated by Raman spectroscopy. Figure 2a shows that all samples annealed at 450 °C for 5 h exhibited sharp peaks corresponding to crystalline Ge. These peaks are almost symmetrical, suggesting that the Ge layers are completely crystallized. All peaks shifted to lower wavenumbers than that of a bulk Ge substrate, originating from the tensile strain. Generally, as-deposited amorphous semiconductor layers have stress caused by nanovoids or roughened surfaces. This should affect the subsequent SPC; however, the initial stress is likely released during the crystallization of a-Ge. We therefore consider the tensile strain in the resulting Ge layers originates from the difference in the thermal expansion coefficients between Ge and the SiO₂ substrate. We note that samples with $T_g = 100$ and $150$ °C exhibit larger tensile strains than other samples. This behaviour is likely caused by the large grain growth for samples with $T_g = 100$ and $150$ °C, as revealed in Fig. 3. As represented in Fig. 2b, annealing at 375 °C for 140 h crystallized the samples with $T_d ≥ 100$ °C, but not those with $T_d ≤ 75$ °C. We examined the $T_g$ dependence of the growth rate from the annealing-time evolution of the Raman spectra, representatively shown in the inset in Fig. 2c. The crystallinity of the Ge layer was defined as the ratio of the Raman peak intensity of c-Ge to that of a-Ge. Figure 2c shows that the annealing time for completing crystallization is dramatically reduced by increasing $T_g$. This means that the higher $T_g$ provides a higher growth rate, accounting for the results in Fig. 2b. The full width at half maximum (FWHM) of the Ge-Ge peaks were evaluated from the Raman spectra and are summarized in Fig. 2d. The FWHM depends on both $T_d$ and $T_g$. The FWHM is a minimum at approximately $T_d = 125$ °C and increases with decreasing $T_g$. The sample with $T_g = 125$ °C and $T_d = 375$ °C exhibited the minimum FWHM value (3.7 cm⁻¹). This value is close to that of a bulk-Ge wafer (3.0 cm⁻¹) and the smallest among poly-Ge formed at low temperatures (<600 °C). This indicates the high crystal quality of the Ge layer obtained in this study.

The electrical properties of the resulting poly-Ge layers were evaluated by Hall effect measurements. All samples showed p-type conduction, similar to conventional non-doped poly-Ge. This is because dangling bonds in Ge provide shallow acceptor levels and then generate holes at room temperature. Figure 4a shows...
that the hole concentration depends on \( T_d \) and is a minimum at approximately \( T_d = 75–100 \) °C. Figure 4a also shows that the hole mobility depends on both \( T_d \) and \( T_g \) as with the grain size and FWHMs of the Raman peaks. The hole mobility is a maximum at \( T_g = 125 \) °C and increases with decreasing \( T_g \). The sample with \( T_g = 125 \) °C and \( T_d = 375 \) °C exhibited the highest hole mobility, 340 cm²/Vs. Figure 4b shows that the hole concentration decreases with increasing grain size, suggesting that dangling bonds in grain boundaries generate holes similar to those in crystal grains.\(^6,10,17,39\). Figure 4b also shows that the hole mobility tends to increase with increasing grain
size in the same $T_d$, but overall, the hole mobility depends on $T_d$ rather than grain size. For example, the sample with $T_d = 175^\circ$C exhibited higher hole mobility than the sample with $T_d = 75^\circ$C, whereas the grain size shows an opposing trend. This behaviour suggests that the hole mobility is not determined only by grain size, but also by another factor.

According to the carrier conduction model in polycrystalline semiconductors proposed by Seto\textsuperscript{40}, the carrier mobility limited by grain boundary scattering can be determined using the following equation:

$$\mu = \frac{Lq}{\sqrt{2\pi m^*kT}} \exp \left( -\frac{E_B}{kT} \right).$$

(1)

where $\mu$ is the carrier mobility, $E_B$ is the energy barrier height of the grain boundary, $T$ is the absolute temperature, $L$ is the grain size, $m^*$ is the effective mass, and $k$ is the Boltzmann constant. Figure 5a shows that the $T$ dependence of the hole mobility varies with $T_d$, indicating the difference in $E_B$\textsuperscript{40}. The Arrhenius plot of $\mu T^{1/2}$ exhibited downward-sloping straight lines for all samples. This behaviour indicates that the carrier conduction in the poly-Ge layers is limited by grain boundary scattering. Figure 5b shows that $E_B$, determined by the slopes of $\mu T^{1/2}$, depends on $T_d$. For $T_d = 125^\circ$C, $E_B$ exhibits the minimum value, 6.4 meV. The trap state density $Q_t$ in the grain boundary can be determined using the following equation:\textsuperscript{40}

$$Q_t = \frac{8\varepsilon N\varepsilon_d}{q}.$$  

(2)

where $N$ is the carrier concentration, $\varepsilon$ is the dielectric permittivity, and $q$ is the elementary charge. Figure 5b shows that $Q_t$ depends on $T_d$. The $E_B$ and $Q_t$ for $T_d = 50^\circ$C nearly agree with those of conventional poly-Ge whose precursors were formed without heating the substrates\textsuperscript{17,22,34}. For $T_d = 125^\circ$C, $Q_t$ exhibits the minimum value, $4.4 \times 10^{11}$ cm\textsuperscript{-2}. From the equations (1) and (2), $\mu$ can be expressed by the following equation:

$$\mu = \frac{Lq}{\sqrt{2\pi m^*kT}} \exp \left( -\frac{q^2 Q_t^2}{8\varepsilon NkT} \right).$$

(3)

The equation (3) indicates that $Q_t$ has greater influence on $\mu$ than $L$. Reflecting that, the $T_d$ dependence of the hole mobility completely agrees with that of $Q_t$ (Figs 4a and 5b). On the other hand, we determined $L$ from the electrical properties of the sample with $T_d = 450^\circ$C by using the equation. The results are plotted in Fig. 3g, showing that the data from the electrical properties exhibits the same behaviour as that from the EBSD measurement. These results indicate that $\mu$ depends on not only $Q_t$ but also $L$. We therefore conclude that the high hole mobility ($340 \text{cm}^2/\text{V}s$ for $T_d = 125^\circ$C) observed in this study is due to both the large $L$ and low $Q_t$.

**Discussion**

The crystal quality and electrical properties of the poly-Ge layer formed by SPC varied with the deposition temperature, $T_d$, of the precursor Ge layer. According to Fig. 1 and the $T_d$ dependent SPC properties, the precursor conditions can be determined by three regimes: the low-density regime ($T_d < 100^\circ$C), high-density regime ($100 \leq T_d \leq 125^\circ$C), and nucleation regime ($T_d > 125^\circ$C). In the low-density regime, the atomic distance in a-Ge is larger than that of crystal Ge. Therefore, the lateral growth rate of Ge nuclei during SPC should be low considering that SPC progresses by the migration of atoms during annealing. This speculation is consistent with the results on the growth rate shown in Fig. 2c. The low lateral growth rate result in poly-Ge with small grains because the grain size in SPC is determined by the balance between nucleation and lateral growth. When the atomic density of the a-Ge precursor is lower than that of crystalline Ge, the volume of the resulting SPC-Ge is smaller than that of the precursor. The volume change may cause the voids (dangling bonds) at the grain boundary. This leads to the high trap state density $Q_t$ at grain boundaries and then lowers the hole mobility.

The nucleation regime should be $T_d > 125^\circ$C considering the behaviours of the grain size and electrical properties of the SPC-Ge. Although the sample with $T_d = 150^\circ$C exhibits no Raman peak (Fig. 1b), the Ge...
precursor layer may contain nuclei which are smaller or less than the detection limit of the Raman measurement. In the high-density regime, the atomic distance in the a-Ge precursor is close to that of crystalline Ge. The growth rate of Ge nuclei during SPC is therefore high, resulting in poly-Ge with large grains. The difference in the atomic density between the a-Ge precursor and resulting poly-Ge is small, leading to low $Q_t$. The hole mobility is therefore high in the high-density regime. In the nucleation regime, the as-deposited Ge layer has dense crystalline Ge nuclei, which is common in vapor deposition. Because SPC starts from the nuclei, the poly-Ge results in small grains. The nuclei perturb the atomic distance of the a-Ge region in the precursor, leading to high $Q_t$. The hole mobility is therefore low in the nucleation regime. Thus, choosing a narrow window for $T_d$ allows us to form the high-density amorphous precursor, which is essential for realizing high-quality poly-Ge. In previous studies, the effects of the deposition temperature of a-Si on the subsequent SPC were examined; however, the crystal quality and electrical properties were not improved dramatically. This is probably because the substrate temperature was not set at the high-density regime but the nucleation regime considering that the grain size decreased with increasing $T_d$. We consider that the dramatic improvements of crystal quality and electrical properties occur for any materials as long as one can set the density of the amorphous precursors to the narrow high-density regime.

As shown in Fig. 6, the hole concentration is the lowest among poly-Ge, indicating that the Ge layer contains relatively few defects. The hole mobility of 340 cm²/Vs obtained in this study is the highest value among the Ge layers formed on insulating substrates at temperatures below the melting point of Ge (937 °C). The hole mobility is even higher than that of single-crystal Ge layers epitaxially grown from single-crystal Si templates. Moreover, the electrical properties of the present poly-Ge layer exceed those of bulk Si. These results mean that single-crystal wafers are no longer necessary for fabricating a high-hole mobility semiconductor thin film.

In conclusion, the condition of the precursor for SPC dramatically influences the crystal quality and electrical properties in the resulting poly-Ge layer. The a-Ge precursor prepared at 125 °C led to a large-grained (5 µm) poly-Ge layer whose grain boundary exhibited a low energy barrier height (6.4 meV) because of the low trap state density ($4.4 \times 10^{11}$ cm⁻²). This allowed for a hole mobility of 340 cm²/Vs, the highest value among semiconductor layers formed on insulators at temperatures below 900 °C. The growth temperature was as low as 375 °C, allowing for Ge devices on plastic substrates. These results open up the possibility for developing advanced CMOS devices as well as system-in-displays and three-dimensional integrated circuits. The findings from and knowledge gained in this study will be universal and applicable to various materials.

Methods
Sample preparation. The Ge precursors were deposited on SiO₂ glass substrates using the Knudsen cell of a molecular beam deposition system (base pressure: $5 \times 10^{-7}$ Pa). The deposition rate was 1.0 nm/min where the sample substrate was not heated. The deposition time was 100 min. The Ge source, manufactured by Furuuchi Chemical Corporation, had a purity of 99.999%. The substrate temperature during the deposition, $T_d$, ranged from 50 to 200 °C. We note that $T_d$ spontaneously rises from room temperature to 50 °C without heating the substrate because of the heat propagation from the Knudsen cell. The samples were then loaded into a conventional tube furnace in a N₂ atmosphere and annealed at 375 °C for 140 h, 400 °C for 40 h, and 450 °C for 5 h to induce SPC.

Material characterization. The XRR was performed using a Rigaku SmartLab. The Raman spectroscopy was performed using a Nanophoton RAMANplus, where the laser wavelength was 532 nm and the spot size was 20 µm. The SEM and EBSD analyses were performed using a JEOL JSM-7001F with a TSL OIM analysis attachment. The AFM was performed using a Shimadzu SPM-9600. The Hall effect measurement with the Van der Pauw method was performed using a Bio-Rad HLB500PC. The hole mobility and hole concentration were averaged over five measurements for each sample.
