Abstract

We present the discovery of KELT-22Ab, a hot Jupiter from the KELT-South survey. KELT-22Ab transits the moderately bright ($V \sim 11.1$) Sun-like G2V star TYC 7518-468-1. The planet has an orbital period of $P = 1.3866529 \pm 0.0000027$ days, a radius of $R_P = 1.285^{+0.121}_{-0.071} R_{\odot}$, and a relatively large mass of $M_P = 3.47^{+0.15}_{-0.10} M_{\oplus}$. The star has $R_* = 1.099^{+0.079}_{-0.046} R_{\odot}$, $M_* = 1.092^{+0.045}_{-0.041} M_{\odot}$, $T_{\text{eff}} = 5767^{+50}_{-49}$ K, log $g_* = 4.395^{+0.039}_{-0.060}$ (cgs) and [m/H] = $+0.259^{+0.085}_{-0.083}$; and thus, other than its slightly super-solar metallicity, appears to be a near solar twin. Surprisingly, KELT-22A exhibits kinematics and a Galactic orbit that are somewhat atypical for thin disk stars. Nevertheless, the star is rotating quite rapidly for its estimated age, shows evidence of chromospheric activity, and is somewhat metal rich. Imaging reveals a slightly fainter companion to KELT-22A that is likely bound, with a projected separation of $6''$ ($\sim$1400 AU). In addition to the orbital motion caused by the transiting planet, we detect a possible linear trend in the radial velocity of KELT-22A suggesting the presence of another relatively nearby body that is probably non-stellar. KELT-22Ab is highly irradiated (as a consequence of the small semi-major axis of $a/R_* = 4.97$), and is mildly inflated. At such small separations, tidal forces become significant. The configuration of this system is optimal for measuring the rate of tidal dissipation within the host star. Our models predict that, due to tidal forces, the semi-major axis of KELT-22Ab is decreasing rapidly, and is thus predicted to spiral into the star within the next Gyr.

1. INTRODUCTION

A large and rapidly increasing number of transiting exoplanets have been discovered in the recent years. The remarkable growth of this field has been initially propelled by photometric ground-based surveys, such as HATNet (Bakos et al. 2004), SuperWASP (Pollacco et al. 2006), XO (McCullough et al. 2005), TrES (Alonso et al. 2004), MEarth (Nutzman et al. 2009), Berta et al. 2012, TRAPPIST (Gillon et al. 2017), and the Qatar Exoplanet Survey (Alsubai et al. 2013). Space-based missions, including CoRoT (Baglin et al. 2006), Kepler (Borucki et al. 2010), and K2 (Howell et al. 2014) have been exceptionally successful, discovering a wealth of planets and revealing that compact systems including small planets are common. The population of exoplanets that have been discovered is incredibly diverse, with many planets being unlike anything seen in our own Solar System. Such a wide range of planetary properties and system architectures provides an interesting challenge to theories that attempt to describe how planetary systems form, and how they have evolved into the configurations that we see today.

The parameter space of exoplanet systems is becoming increasingly populated as new discoveries are made. Ground-based transit surveys are well-suited for identifying large, short-period gas giant planets. These so-called “hot Jupiters” typically have masses $\gtrsim 0.25 M_J$, radii between $\sim 1-2 R_J$, and orbital periods $\lesssim 10$ days. Statistical studies of planetary populations have revealed that this class of planet is inherently rare, with only about 1% of Sun-like stars estimated to host a hot Jupiter (Wright et al. 2012).

The existence of hot Jupiters provides a unique challenge and a valuable diagnostic for theories that describe how planetary systems form and evolve. Broadly speaking, hot Jupiters were either formed at or near their current orbital configuration, or were formed farther out and then migrated inward (Dawson & Johnson 2018). The processes by which a planetary system is formed and the physics that dictate its further evolution are becoming increasingly constrained as knowledge of planetary parameters improves and as better population statistics are derived from observational data. It is therefore important to discover and study exoplanets across a wide range of parameter space.

Understanding the properties of gas giants is an integral part of exoplanet science, particularly since they often dominate the mass and angular momentum budget of a planetary system. Although intrinsically rare, hot Jupiters are ideal targets for detailed characterization studies, especially when their host star is bright. The radius and mass of hot Jupiters can be measured with relatively high precision, revealing their bulk density. The atmospheric composition of these planets can be studied through transmission spectroscopy, where stellar light that passes through the planetary atmosphere during a transit is studied, revealing information about the atmosphere. Measuring orbital phase curves and secondary eclipses of hot Jupiters provides information about the albedo and global weather patterns for these highly irradiated planets. In addition to the scientific value of characterizing hot Jupiters, these endeavors serve the future of the field, as techniques are refined and technical challenges are addressed that push towards the ability to characterize smaller and more temperate worlds.

The Kilodegree Extremely Little Telescope (KELT) survey is comprised of two similar telescopes. KELT-North (Pepper et al. 2007) is located at Winer Observatory in Sonoma, Arizona, and KELT-South (Pepper et al. 2012) is situated at the South African Astronomical Observatory in Sutherland, South Africa. Both telescopes have a 42 mm aperture, a 26° x 26° field of view, and a pixel scale of 23″. The KELT survey is designed to detect giant transiting exoplanets, with optimal precision (≤1%) for stars between 8 $\lesssim V \lesssim 11$. The planetary systems discovered with KELT are particularly well-suited for detailed characterization studies.

Here we present the discovery of KELT-22Ab, a hot Jupiter on a short $P = 1.39$ day orbit, transiting a Sun-like star, but metal rich and with unusual kinematics, with a spectral type of G2 and a brightness of $V = 11.1$ mag.

In Section 2 we describe the survey data used to discover, and the follow-up observations used to confirm, KELT-22Ab. Section 3 presents properties of the host star. We use values from the literature and spectroscopically-derived stellar parameters, along with various models, to put the system into context. The results of our global fit are shown in Section 4 and our false positive analysis is explained in Section 5. We further discuss interesting aspects of the KELT-22 system in Section 6 and conclude with Section 7.

2. DISCOVERY AND FOLLOW-UP OBSERVATIONS

2.1. KELT-South Observations and Photometry

The star TYC 7518-468-1 (hereafter KELT-22A) was observed by the KELT-South telescope, in KELT South Field 32 (KS32), the J2000 central coordinates of which are $\alpha = 0^h 4^m 48^s 9^\gamma$ $\delta = -29^\circ 49^\prime 58^\prime\prime$. This field was also the original commissioning field of the KELT-South telescope, which was later included as a field in normal telescope operation. Commissioning data were taken between UT 2009 September 16 and UT 2009 December 30, where the field was observed 2294 times. During normal science operation between UT 2011 August 24 and UT 2015 December 28, 2918 images were taken, for a total of 5212 observations (commissioning + normal science operation). After our standard data reduction routine, which includes removal of outliers and systematic and long-term trends, 5049 observations remain. These were analyzed, revealing a candidate transit signal with a period of 1.3866536 days and a depth of $\sim 0.7\%$. The procedures for our data reduction and analysis, and candidate selection, are described in Kuhn et al. (2016). The discovery light curve, phased to the recovered period, is shown in Figure 1.

2.2. Photometric Time-series Follow-up

After identifying the candidate transit signal in the photometry from the KELT-South telescope, we then obtained follow-up observations with the KELT Follow-Up Network (KELT-FUN; Collins et al. 2018). These relatively high-cadence,
high-precision observations with larger telescopes allow us to reject various false-positive scenarios (e.g. a blended eclipsing binary) and serve to more precisely measure the depth, shape, and ephemeris of the transit event. The Tapir software package (Jensen 2013) was used to schedule the follow-up observations. The images were then reduced with the AstroImageJ (AIJ) software package (Collins & Kielkopf 2013; Collins et al. 2017). A total of 11 transits (5 full and 6 partial) were observed between 2015 August and 2017 December. However, only the four highest quality observations were included in our global fit, and are shown in Figure 2. The remaining seven light curves were consistent with a transit at the predicted ephemeris, but were not included in the global fit due to various issues (namely systematic effects and high photometric scatter).

KELT-22A has a close companion, CCDM J23367-3437B, that lies 6.1° to the southeast, and is about 0.45 mag fainter in the J-band. These two sources are completely blended in the aperture used by KELT. After ruling out nearby eclipsing binaries (EBs) as the cause of the signal, an important aspect of our follow-up observations is to determine which of these two sources is actually being eclipsed. This was done by carefully placing small apertures around KELT-22A and its neighbor separately, and then extracting a light curve for each source. In each reduction of data done in this manner, an event is seen in KELT-22A, and no variability is seen in the neighbor. Our analysis of radial velocity data corroborates this conclusion. However, light curves extracted this way are noisy, and are of insufficient quality for detailed analysis. We proceed by placing an aperture around both sources (KELT-22A and its companion) then extracting a light curve for their combined flux, and finally correcting for the flux contamination of the companion.

With this approach, it is necessary to properly account for the flux from the companion star when determining the parameters of the KELT-22A system (e.g. Ciardi et al. 2015; Siverd et al. 2018). This “deblending” procedure is described in more detail in Section 2. The light curves shown in Figure 2 have been corrected in this fashion. Prior to the deblending process, transit depths are about a factor of 1.5 smaller.

In the following sub-sections, we describe the facilities which observed a transit of KELT-22A that resulted in a light curve of sufficient quality to incorporate into our global fit. We note that additional light curves from Hazelwood Observatory, PEST Observatory, and the MINERVA telescope array assisted in our confirmation of this as a genuine exoplanet system.

4.

Fig. 2.—Top: Transit light curves of KELT-22Ab from the KELT Follow-Up Network, after correcting for the contaminating flux from the nearby stellar companion. The red line represents the best fit model from the global fit in that photometric band. Each light curve is offset vertically by an arbitrary amount for clarity. Bottom: All follow-up transits combined into one light curve (grey) and a 5 minute binned light curve (black). The red line is the combined and binned models for each transit. We emphasize that the combined light curve is only for display purposes; the individual transit light curves were used in our analysis.

2.3.2. TRES at FLWO

We obtained 11 spectra of KELT-22A with the Tillinghast Reflector Échelle Spectrograph (TRES; Szentgyorgyi & Fürezs 2007; Fürezs et al. 2008) on the 1.5 m telescope at the Fred Lawrence Whipple Observatory, Arizona, USA. TRES is a fiber-fed échelle spectrograph (with a 2.3′′ fiber), covering wavelengths between 3900 – 9100 Å, with a resolution of R ∼ 44000. KELT-22A was observed with TRES 11 times between UT 2017 September 26 and UT 2017 November 22. From these spectra we determine the RV orbit of the system, described in the following section. We also use these spectra to determine stellar properties, described in Section 3. Bisector spans (BSs) were also calculated, following the prescription of Buchhave et al. (2010). These are included in Table 1 and are included as part of the false-positive analysis presented in Section 5.

2.3.3. Radial Velocities

Our RV measurements from TRES are reported in Table 1. These values are consistent with the ephemeris determined from our photometric data and are plotted in the upper panel of Figure 3 along with the best-fit model, with residuals shown immediately below. The RV semi-amplitude is K = 592 ± 20 m s⁻¹. In addition to the oscillatory RV signal in KELT-22A caused by the planetary orbit, there is evidence for a linear trend of -2.06±0.93 m s⁻¹ day⁻¹ at low significance. From the RV signal, we find a minimum mass for the planet of M_p sin i = 3.46±0.15 M_J. RV data phased to the orbital period and the best-fit model and residuals are shown in the lower panel of Figure 3. The systemic RV of the KELT-22A system is -7.81 ± 0.1 km s⁻¹. The velocities quoted in Table 1 are the multi-order velocities relative to the strongest observation used as the template in the cross correlation analysis. The systemic velocity was derived from the single-order correlations of the Mg b order against a library of calculated spectra and with the zero point calculated using observations of IAU RV standard stars.

2.4. High-Contrast Imaging

As part of our standard process for validating transiting exoplanets, we observed KELT-22A with infrared high-resolution
adaptive optics (AO) imaging at Keck Observatory. The Keck Observatory observations were made with the NIRC2 instrument on Keck-II behind the natural guide star AO system. The observations were made on 2017 Dec 07 in the narrow-band Br − γ filter (λc = 2.1686 μm, ΔA = 0.0326 μm) in the standard 3-point dither pattern that is used with NIRC2 to avoid the left lower quadrant of the detector, which is typically noisier than the other three quadrants. The dither pattern step size was 3′′ and was repeated three times, with each dither offset from the previous dither by 0.5′′. The observations utilized an integration time of 10 seconds with one co-add per frame for a total of 90 seconds. The camera was in the narrow-angle mode with a full field of view of 10′′ and a pixel scale of 0.009942′′ per pixel. We use the dithered images to remove sky background and dark current, and then align, flat-field, and stack the individual images. The NIRC2 AO data have a resolution of 0.049′′ (FWHM).

As noted in Section 2.2, there is a stellar companion to the southeast of the primary star which is easily detected in Keck imaging (see Figure 4), as well as from 2MASS imaging. The primary star infrared 2MASS colors are consistent with the spectral type derived from the spectral energy distribution fit (Section 3.2) and the spectroscopic analysis of the star being a G2 main sequence star (Section 3.1). The companion star is approximately 0.4 magnitudes fainter than the primary star in the infrared and has colors that are consistent with the star being a late G-type or early K-type main sequence star (see Figure 5). Given the location of the stars in the color-magnitude diagram, the companion star cannot be a background or foreground star that is highly attenuated by dust along the line of sight. As such, the companion star must be at a similar distance to the primary star.

Our NIRC2 images reveal the projected separation of the two sources is 6.1′′ ± 0.5′′ at a position angle of 110.1° ± 0.5°, which is in full agreement with the relative separation and orientation of the targets as measured by 2MASS ~20 years earlier (1999 Jul 27). At a distance of 230 − 240 pc (from Gaia, see Table 2), the projected separation of the two stars is ~1400 AU, which corresponds to a ~50000 year orbital period for the stars. This lies comfortably within the stellar companion orbital period distribution for nearby stars (Raghavan et al. 2010). At such a long orbital period, the projected orbital motion from the 1999 2MASS epoch to 2017 Keck Epoch should only be ~0.04% of the entire orbit. Thus, the two stars should effectively be common proper motion pairs with little to no measurable relative motion if the two stars are bound. We therefore conclude that the two stars are most likely bound stellar companions.

To further test the relative motion between these two sources, we compare the 2MASS positions (epoch 1999.5) to the Gaia positions from DR1 (epoch 2015). From 2MASS imaging, the separation is 6.102″, at a position angle of 110.117°. Gaia DR1 reveals a separation of 6.122″, at a position angle of 110.252°. Over the 15 years between these observations, the separation has not changed to within the uncertainties, but the nominal 20 mas change, and change in position angle of about 0.14°, implies that the proper motions do not differ by more than 1 mas yr−1.

As was shown in Sections 2.2 and 2.3, the planet transits the brighter of this pair. The uppermost justifies our designation of the planet as KELT-22Ab (as in KELT-2Ab Beatty et al. 2012, KELT-4Ab Eastman et al. 2016, and KELT-19Ab Sivverd et al. 2018).

The radial velocities show that the transiting planet orbits the primary star and the AO imaging rules out the presence of any additional stars within ~0.5″ of the primary (we also note that only one set of lines is detected in our spectra of KELT-22A) and the presence of any additional brown dwarfs or widely-separated tertiary components beyond 0.5″ (see Figure 6). The sensitivities of the AO data were determined by injecting fake sources into the final combined images with separations from the primary targets in integer multiples of the central source’s FWHM (Furfan et al. 2017, Ciardi et al. 2018, Sivverd et al. 2018). The presence of the blended 6″ stellar companion is taken into account to obtain the correct transit depth and planetary radius as in, e.g., Ciardi et al. (2015).

At the projected separation of the two stars, which are nearly equal mass, the expected radial velocity amplitude of the primary star is, assuming the system is edge-on, ~0.5 − 1 km s−1, depending on the eccentricity of the orbit. The radial velocities show a linear trend of approximately 2 m s−1 per day. However, the time span of the radial velocity observations is only 80 days long and is thus a very small fraction of the entire orbit. Even at its steepest, the expected linear slope of the radial velocities caused by the companion star is on the order of 10−4 m s−1 d−1, which is significantly smaller than the trend seen in the radial velocities. If real, this trend is perhaps indicative of an additional planetary body in the system.

3. HOST STAR PROPERTIES

Table 2 lists various properties and measurements of KELT-22A. These properties come from the literature and this work.

3.1. Spectral Analysis

We determine estimates of some physical properties of KELT-22A using the TRES spectra. These spectra were analyzed using the Stellar Parameter Classification (SPC) procedure of Buchhave et al. (2012). We run the SPC procedure without fixing any parameters, and take the error-weighted mean value for each stellar parameter. This gives a value for the effective temperature of $T_{\text{eff}} = 5771 \pm 50$ K, a surface...
3.2. SED Analysis

We performed a fit to the broadband spectral energy distribution (SED) of KELT-22A as an additional constraint on the stellar parameters in the global system fit. We assembled the available broadband photometry from the literature (Table 2), with measurements spanning over the wavelength range 0.2–10 µm (Figure 7).

We fit the flux measurements with the stellar atmosphere models of Kurucz (1992). We adopted the $T_{\text{eff}}$, $\log g_*$, and $[\text{Fe/H}]$ values from the SPC analysis (Sec. 3.1), and the distance inferred from the measured Gaia parallax. Thus the only free parameter is the extinction ($A_V$). For $A_V$, we restricted the maximum permitted value to the full line-of-sight extinction value $A_V \leq 8$ mag.

![Fig. 5.— 2MASS color-color diagram for KELT-22A (lower black point) and its companion (upper black point), as in Ciardi et al. (2011). The green hashed area denotes the main sequence, while the blue hashed area shows the giant branch. The red hashed region is where L-dwarfs are found. Diagonal lines trace the reddening zone for typical galactic interstellar extinction ($R = 3.1$). The SED analysis presented in Section 3.2 gives a low reddening value that is consistent with zero.](image)

![Fig. 6.— Contrast sensitivity at the 5σ level and inset image of KELT-22A in $Br - \gamma$ as observed with the NIRCam camera at Keck Observatory, ruling out the presence of any additional stars within ~0.5″, and ruling out brown dwarfs or widely-separated tertiary components beyond 0.5″.](image)

extinction from Schlegel et al. (1998).

The high-resolution imaging (see Sec. 2.4) confirms a nearby companion star that is sufficiently well separated from KELT-22A that it should not contaminate the broadband photometry. We were careful to use only broadband flux values from catalogs where these two sources are clearly resolved. For example, APASS photometry for KELT-22A is likely contaminated by flux from the companion, and is therefore not included in the SED fit. We fit SEDs to both components, assuming (for the purposes of the fit) the same $A_V$ and distance for both.

The best fit is shown in Figure 7 and, ignoring the GALEX NUV passband that shows an excess indicative of moderate chromospheric activity,43 has a reduced $\chi^2$ of 3.3. We find for KELT-22A a best-fit $A_V = 0.00^{+0.03}_{-0.00}$. We can integrate the best-fit SED to obtain the (unextincted) bolometric flux at Earth: $F_{bol} = 6.73^{+0.48}_{-0.45} \times 10^{-10}$ erg s$^{-1}$ cm$^{-2}$. With the Gaia parallax and the adopted $T_{eff}$, this then allows a measure of the stellar radius, including the $-0.25$ mas offset in the Gaia parallax suggested in the literature (see, e.g., Stassun & Torres 2016): $R_* = 1.00 \pm 0.13 \, R_\odot$. We can use this empirical $R_*$ as a constraint on the global system fit below.

Finally, we use our two-component SED fit (Figure 7) to assess the degree to which our KELT-22A planet transit model is affected by flux contamination from the neighboring companion, considering that both stars are contained within a single KELT pixel, and all of our follow-up photometry was reduced using an aperture that includes both stars. Taking the ratio of fluxes in each bandpass for which we have transit observations, we obtain the following flux ratios ($f_B/f_A$): $f_V = 0.54$, $f_B = 0.56$, $f_J = 0.58$, and $f_I = 0.57$. These flux ratios are then used to correct the observed transit depths in the global system fitting below.

3.3. Stellar Models and Age

We can use the properties of KELT-22A to estimate its age as inferred from stellar evolution models. In Figure 8 we represent the $T_{eff}$ and $\log g$, of KELT-22A relative to the predicted evolutionary track of a star with the mass and metallicity of KELT-22A. Using the Yonsei-Yale models (YY; Yi et al. 2001), we observe that KELT-22A is a roughly solar-mass star still early in its main-sequence lifetime, and thus its slow evolution translates to a relatively large uncertainty on the age. Specifically, we infer an approximate age for KELT-22A of 1.5–5.0 Gyr. We do note that the KELT-22A SED indicates moderate chromospheric activity (see Sec. 3.2), which would tend to suggest a younger age within the permitted age range, assuming that this chromospheric activity is indicative of its primordial spin.

Even more intriguing are the kinematics of KELT-22A in the Galaxy. Given the Gaia DR1 proper motions of $(\mu_\alpha, \mu_\delta) = (88.5 \pm 1.6, -8.1 \pm 1.3)$ mas yr$^{-1}$, the Gaia parallax, and the absolute radial velocity as determined from the TRES spectroscopy of $-7.8 \pm 0.1$ km s$^{-1}$, we find that KELT-22A has a three-dimensional Galactic space motion of $(U, V, W) = (-66.0 \pm 10.3, -31.5 \pm 1.1, -23.3 \pm 4.6)$ km s$^{-1}$, where positive $U$ is in the direction of the Galactic center, and we have adopted the $\cos \nu$ values of 0.39 (see, e.g., Davis et al. 2011) determination of the solar motion with respect to the local standard of rest. These values yield a 18.3% probability that KELT-22A

![Figure 7. The SED fit for KELT-22A (black curve) and the neighboring star, CCMD J23367-3437B (cyan curve), showing the best-fit stellar atmospheric models. Red and black crosses show the photometric values and their errors for KELT-22A and CCMD J23367-3437B, respectively. These values for KELT-22A are listed in Table 1. The blue points are the predicted integrated fluxes at the corresponding passbands for KELT-22A.](image)

![Figure 8. Evolution of the KELT-22A system in the Kiel diagram. The red cross represents the KELT-22A parameters from the final global fit. The black curve represents the theoretical evolutionary track for a star with the mass and metallicity of KELT-22A, and the grey swath represents the uncertainty on that track based on the uncertainties in mass and metallicity. Nominal ages in Gyr are shown as blue dots.](image)
is a thick disk star, according to the classification scheme of Bensby et al. (2003). This is roughly an order of magnitude times larger than the probability of any other KELT discovery being a thick disk star according to the criteria given in Bensby et al. (2003).

We note that the Southern Proper Motion Program (SPM2; Platais et al. 1998) finds values of \((\mu_\alpha, \mu_\delta) = (90.3, -7.8)\) mas yr\(^{-1}\) for KELT-22A, which are generally consistent with those reported in Gaia DR1. Other catalogs, such as UCAC2 (Zacharias et al. 2004b), NOMAD (Zacharias et al. 2004a), XPM (Fedorov et al. 2011), SPM4 (Girard et al. 2011), APOP (Qi et al. 2015), UCAC5 (Zacharias et al. 2017) list similarly high proper motions. However, other catalogs list values that are significantly smaller, including Tycho-2 (Høg et al. 2000) and PPMX (which builds off of Tycho-2; Röser et al. 2008)). UCAC4 (Zacharias et al. 2012) includes proper motion measurements for both KELT-22A and its companion, listing \((\mu_\alpha, \mu_\delta) = (43.0, 6.7)\) mas yr\(^{-1}\) and \((\mu_\alpha, \mu_\delta) = (113.7, -827.5)\) mas yr\(^{-1}\), respectively. We adopt the values from Gaia DR1, and justify this choice by drawing attention to the consistency among SPM2, UCAC2, NOMAD, XPM, SPM4, APOP, and UCAC5. However, we note that there are some discrepancies between catalogs, and look forward to future measurements (e.g. a longer Gaia time baseline in subsequent data releases) to help resolve this issue.

To give these kinematics additional context, we computed the Galactic orbit of KELT-22A using the galpy\(^\text{44}\) package (Bovy 2015). We use our knowledge of the distance, systemic RV, and \((U,V,W)\), along with the “MWPotential2014” Galactic potential in galpy, and compute the motion of KELT-22A through the galaxy from now until 2 Gyr in the future. These results are shown in Figure 9. Figure 9 demonstrates that the Galactic orbit of KELT-22A not only covers a large range in Galactocentric distance, but also spans a somewhat large range in vertical distance above the plane. Stars of KELT-22A’s spectral type (G2V) have a typical scale height of \(z_d \sim 123 \pm 20\) pc (Bovy 2017). The orbit of KELT-22A is consistent with this.

Even more perplexing is the fact that KELT-22A appears to have a super-solar metallicity, with \([\mathrm{m/H}] \sim 0.26\), which is more typical of a relatively young (disk) star. Comparing to isochrones, we infer an age of 1.5 - 5.0 Gyr, but we note that there is a NUV excess in the SED fit, indicating chromospheric activity, which may point towards the age being on the low end of this range. Comparison to the MESA Isochrones and Stellar Tracks (MIST) project (Choi et al. 2016; Dotter 2016) isochrones in the analysis of Section 6.3 yields an age of 2.6 Gyr, using solar parameters and forcing the radius and density to be that found from the global fit. Finally, the \(v\sin I_\ast = 7.9 \pm 0.5\) km s\(^{-1}\) from TRES spectra is unusually high for a star of this spectral type, again suggesting that the star is young (and thus has not had time to spin down due to magnetic braking). There are two possible explanations for the rapid rotation, in that either the system is young, or that tidal interactions with the planet are acting (or have acted) to spin the star up. These are discussed further in Sections 6.2 and 6.3.

4. RESULTS

4.1. Light Curve Detrending and Deblending

Because KELT-22A and its neighbor are not fully resolved in the follow-up light curves, an aperture is placed around both sources when extracting photometry. We must then compensate for the flux from the neighboring star to accurately calculate the planetary radius. Without deblending, the planetary radius will be significantly underestimated. The flux ratios in each bandpass for which we have a follow-up light curve of sufficient quality are calculated in Section 3.2, and are then incorporated into the global model. Each light curve used in the fit includes airmass as a detrending parameter.

4.2. Global Model Results

Using a modified version of EXOFAST (Eastman et al. 2013), we simultaneously fit the follow-up time-series pho-
ometry and TRES RVs to properly determine the global parameters of the KELT-22A system. Specifically, EXOFAST is
an IDL-based fitting tool that runs simultaneous Markov chain Monte Carlo (MCMC) analysis to determine each parameter’s posterior probability distribution. From our analysis of the TRES spectra, we enforce a prior on \( T_{\text{eff}} \) and \([\text{Fe/H}]\) while setting a starting point for \( \log g_{\star} \). We do not enforce a prior on \( \log g_{\star} \) since it is expected to be better constrained from fitting the light curves (Seager & Mallén-Ornelas 2003; Mortier et al. 2014). The KELT light curve (see Figure 1) is not included in the global fit, but we set a prior on \( T_{\text{C}} \) and the period from our analysis of the KELT data. To get this prior, we run an EXOFAST fit on the KELT light curve using the determined Box-Least Squares (BLS) parameters as starting points. We use the YY isochrones or the empirical Torres relations (Torres et al. 2010) within the global fit to constrain \( R_{\star} \) and \( M_{\star} \). We use the flux ratios found in Section 3.2 to correct each light curve by accounting for the contaminating flux from the stellar companion to KELT-22A. We run separate YY and Torres global fits where the eccentricity is assumed to be zero. We also run separate YY and Torres fits where we fit for the eccentricity. The results of all four fits are consistent to 1σ and are shown in Tables 3 and 4. For the analysis and discussion in this paper, we adopt the YY circular fit results (column two in Tables 3 and 4). We do not conduct a transit timing variation analysis, because we do not have enough high-quality observations that capture the full event to make such an analysis worthwhile.

5. FALSE POSITIVE ANALYSIS

Many different methods were used to test various false-positive scenarios. KELT-22A and its companion are partially resolved in our photometric follow-up observations. For the photometric observations used in the global fit, in all cases careful placement of apertures reveals that KELT-22A does in fact have a transit event, while no such variability is apparent in its companion. This strongly suggests that the detected photometric variability is in KELT-22A, and not its companion. Our RV data, in which the two sources are clearly resolved, corroborate this by revealing an RV signal in KELT-22A that is consistent with the reflex motion caused by a planetary orbit. Furthermore, our AO observations reveal no additional stellar objects.

Our follow-up light curves cover the V, R, I, and i’ passbands, and all show a consistent depth. EBs and blended EBs typically produce depths that are chromatic across this range of filters (O’Donovan et al. 2006). While the achromatic nature of the measured transit depth in the light curves of KELT-22A does not absolutely rule out the possibility of an EB or blended EB, it is consistent with a planetary scenario.

To further test the planetary hypothesis, we examine the RV bisector spans using the procedure of Buchhave et al. (2010). If the observed variability is caused by an unresolved EB, a correlation between the bisector spans and the measured RV values is expected due to the line-profile asymmetries that a blended EB will produce through its orbital motion (Torres et al. 2004). We find no correlation between the RV values and the bisector spans, suggesting that the RV variation is caused by genuine orbital motion of KELT-22A.

Having ruled out all of the reasonable false-positive scenarios, we are confident that the photometric transit and the RV variability are intrinsic to KELT-22A, and are caused by a transiting exoplanet.

6. DISCUSSION

6.1. Stellar Multiplicity and Possibility of a Second Planet

The role of binarity enriches and complicates the formation and evolution of exoplanet systems. Planetary systems are found in various binary configurations (Ngo et al. 2016), and even in hierarchical triple systems (e.g. Eastman et al. 2016). Our analysis of KELT-22A and its companion suggests they are most likely bound (Section 2.4). The discovery of KELT-22Ab adds to the population of transiting short-period gas giants with widely separated stellar companions.

In addition to the RV signal caused by the orbit of KELT-22Ab, we detect a linear slope of \(-2.06^{+0.51}_{-0.53}\) m s\(^{-1}\) day\(^{-1}\) in our RV data at a somewhat low significance. If real, this trend is likely indicative of another body gravitationally bound to KELT-22A. Each TRES spectrum and its correlation plot was carefully inspected, and there is no evidence of a second set of lines. Our AO observations do not reveal a third stellar component beyond 0.5″ from KELT-22A. Using Equation 2 of Bowler (2016) and our measured RV trend, we find that the tertiary mass must be at least 2.8, 11.1, 280, or 1100 \( M_{\odot} \) if its semi-major axis is 0.5, 1, 5, or 10 AU. Given the lack of evidence of a third star in the system, this suggests that the tertiary body must have a semi-major axis of less than a few AU, so its orbit should be measurable with RVs within a few years. If this trend is later confirmed, it will be an interesting result regardless of the inferred mass. To date, only four confirmed hierarchical triple systems are known to host a planet (Johnson et al. 2018). Further observations are required to determine whether or not this trend is real.

6.2. Frequency Analysis

During the initial candidate selection process, it was apparent that KELT-22A had sinusoidal signals with periods of around eight days in its KELT light curve. This motivated a more targeted analysis of periodic signals (in addition to the planetary transit). A Lomb-Scargle (LS; Press et al. 1992; Zechmeister & Kürster 2009) analysis was performed.
to search for periodic sinusoidal signals in the survey light curve, as implemented in the VARTOOLS light curve analysis package (Hartman 2012). The computed periodogram is shown in Figure 11 (upper row). We do not detect a single dominant frequency, but rather a forest of peaks is evident with periods of 7 – 9 days. The top four peaks in this region are all of similar significance. The period, formal false-alarm probability (FAP), and signal to noise ratio (SNR) associated with these peaks are listed in Table 11. The periodogram peaks near one day and integer fractions of one day are aliases caused by the diurnal observing cycle of KELT.

The periodogram shown in Figure 11 is calculated from the entire KELT light curve, and the top peak is $P_0 = 8.2763 \text{ d}$. The entire light curve phased to this peak is shown in the bottom-left panel of Figure 11. Significant peaks of slightly different periods are found when different segments of the light curve are analyzed in this fashion. Regardless of the section of the KELT light curve analyzed, all of the significant peaks lie within the forest seen between 7 and 9 days.

The commissioning data span 95 days, with dense time coverage and a total of 2294 observations. The most significant peak from this section of the light curve is $P_1 = 7.6434 \text{ d}$. The commissioning data are phased to this period in the bottom-middle panel of Figure 11. Significant commissioning data of KELT-South begins 612 days after the commissioning phase is complete, and spans 1072 days with 2918 observations.

A LS periodogram is again computed for only the data taken during normal science operation. The top LS peak for this section of the light curve is $P_2 = 8.0552 \text{ d}$. The bottom-right panel of Figure 11 shows the normal science data phased to this period.

It is possible that these signals are associated with rotation of KELT-22A. Star spots on the stellar surface can rotate into and out of view, causing variation in the observed brightness at the rotation period of the star (e.g. Evans, Cargile et al. 2014). Star spots are not permanent features, but rather have finite lifetimes that can depend on a number of conditions (Bradshaw & Hartigan 2014, Giles et al. 2017). From our Sun, we can measure the Solar rotation period from sunspots, and find that it is latitude-dependent – that is, the Sun is differentially rotating. A frequency analysis of a differentially rotating star with transient star spots may be consistent with the periodogram features that we see in KELT-22A. The NUV excess in the SED of KELT-22A points to enhanced chromospheric activity, which could be consistent with the magnetic activity that causes star spots. These findings may be suggestive, but are insufficient to claim this as the definitive cause of the forest of peaks in the LS periodogram.

A more detailed study is required to further address this hypothesis. Regardless of the physical interpretation, because the light from KELT-22A and its companion are fully blended in KELT, we have no way to know from which sources these signals arise.

### TABLE 3

| Parameter | Units | Value | Adopted Value | Value | Value |
|-----------|-------|-------|---------------|-------|-------|
| $M_*$     | (M$_\odot$) | 1.094$^{+0.042}_{-0.040}$ | 1.092$^{+0.045}_{-0.041}$ | 1.103$^{+0.053}_{-0.052}$ | 1.104$^{+0.055}_{-0.054}$ |

Table 5: Periodic signals detected in photometry

| Period (d) | Log(FAP) | SNR |
|------------|----------|-----|
| $P_0$      | 8.2763   | 6.94 | 21.2 |
| $P_1$      | 7.6434   | 6.64 | 20.7 |
| $P_2$      | 8.0552   | 6.24 | 19.9 |
| $P_3$      | 7.8804   | 5.87 | 19.2 |

Table of periods detected in the light curve of KELT-22 that are possibly associated with stellar rotation.

with the available data.

Additionally, our measured $v \sin I_*$ and $R_*$ values imply that the stellar rotation period of KELT-22A should be $\sim 1.5$ days (assuming $\sin I_* \sim 1$), which is consistent with the forest of peaks in the periodogram. This suggests that this signal in the light curve is consistent with being due to the rotation of KELT-22A, but, again, we cannot confirm whether this is the case with our current data.

6.3. Tidal Evolution and Irradiation History

Using the parameters derived from our global fit as boundary conditions, we simulate the past and future evolution of the orbit of KELT-22Ab using the POET code (Penev et al. 2014), under the assumptions of a circular orbit, no other perturbing body, and a constant phase lag (constant tidal quality factor). This simulation examines the changes in the semi-major axis that arise from tidal forces acting between star and planet, and also the changes in incident flux (both due to the diminishing semi-major axis and the increasing luminosity).

![Fig. 11.](image-url) The top panel shows the Lomb-Scargle periodogram computed from the survey data for KELT-22A. There is a forest of peaks between 7 and 9 days. The lower row shows the photometry phased to the period associated with the strongest LS peak, where all observations are on the left, only commissioning data in the middle, and all of the normal science operation data on the right. The peak-to-trough amplitude is given in each of these panels.
The strength of these tidal forces is parameterized by the tidal dissipation parameter \((Q'_c)\), which is defined as the tidal quality factor divided by the love number \((Q'_c = Q_c/k_2)\). We test values from \(\log Q'_c = 6 - 9\). Higher values of \(Q'_c\) are less dissipative, while lower values allow tidal forces to dissipate energy quickly, forcing more rapid changes in the system.

An irradiation threshold of \(\sim 2 \times 10^8 \text{ erg s}^{-1} \text{ cm}^{-2} \) has been found, above which giant planets tend to become inflated (Demory & Seager 2011). KELT-22Ab is above this threshold at present (by about a factor of ten). Our model shows that regardless of the choice of \(Q'_c\), KELT-22Ab has been above this threshold throughout its entire evolutionary history (see upper panel of Figure 12). The planet is inflated, as evidenced by its large radius \((R_\text{p} = 1.285^{+0.12}_{-0.07} \, R_\star)\). This observation is consistent with a history of such high irradiation.

The particularly favorable \(a/R_\star = (4.97)\) of the KELT-22A system, combined with high planetary mass, makes this system a valuable laboratory for measuring the rate of tidal dissipation within the host star. For example, the orbital evolution calculations presented in Figure 12 (lower panel) show that the typically assumed value for \(\log Q'_c = 6\) predicts that systems like KELT-22 will move very quickly through the observed orbital period, predicting that such systems should be very rare. Collier Cameron & Jardine (2018), and before that Penev et al. (2012) used this reasoning to argue against such low values of \(Q'_c\). Further, the observed ~8 day spin period of KELT-22A (either from \(v \sin I_\star\) or from the photometric variability), is significantly shorter than expected given the Skumanich law for Sun-like stars. This may be a natural consequence of tidal spin-up, in which case direct measurements of \(Q'_c\) can be made, as in Penev et al. (2018).

The future orbital evolution of KELT-22Ab predicted by our model depends strongly on the value of \(Q'_c\). For lower values of \(Q'_c\) (log \(Q'_c\) between 6 and 7), the planet is predicted to spiral into the star within the next Gyr, while larger values of \(Q'_c\) will allow the planet to survive for longer.

Penev et al. (2018) provide a formula to calculate \(Q'_c\) with knowledge of the orbital period and the stellar rotation period. If the sinusoidal signals discussed in Section 6.2 are in fact caused by the rotation of KELT-22A (which is generally in agreement with the spectroscopically-derived \(v \sin I_\star\)), this gives us an estimate of the stellar rotational period. To proceed, we assume that the most significant peak in the periodogram \((P_{\text{peri}} = 8.2763 \, \text{d})\) is the stellar rotation period. We use the orbital period from the global fit \((P_{\text{orb}} = 1.3867 \, \text{d})\). We then find that \(\log Q'_c = 6.46\). This calculation is not extremely sensitive to the stellar spin period. If we instead use the shortest significant LS peak as the stellar rotation period, the result is essentially the same, \(\log Q'_c = 6.2236\). This value of \(\log Q'_c \sim 6.2\) for KELT-22A is generally consistent with values for \(\log Q'_c\) calculated for dozens of hot Jupiter systems in Penev et al. (2018), and suggests a strong coupling between the planetary orbit and stellar rotation, where tidal forces are causing the stellar rotation rate to increase, at the expense of a decrease in the semi-major axis. Given the stated assumptions, the orbital evolution model predicts that KELT-22Ab is moving through this semi-major axis quickly and will be consumed by its star within the next Gyr.

### 6.4. Predictions for measuring spin-orbit misalignment

With \(v \sin I_\star = 7.9 \pm 0.5 \, \text{km s}^{-1}\), KELT-22A is rotating relatively rapidly for an early G star. It is thus a good target for measurement of the angle between the planetary orbit and the stellar spin axis via the Rossiter-McLaughlin ef-fect or Doppler tomography. Based upon the system parameters and the formulae of Gaudi & Winn (2007), we estimate that KELT-22Ab should have a Rossiter-McLaughlin semi-amplitude of \(\sim 120 \, \text{m s}^{-1}\). This large value is thanks to the relatively large \(v \sin I_\star\) and transit depth. This should be easily measurable for a \(V = 11.1\) star like KELT-22A, even with the relatively short 2.4-hour transit duration. This will be interesting in light of the bound stellar companion, and also the possibility of an additional component. Such observations serve to test the proposed mechanisms that could generate misaligned hot Jupiters that rely on the presence of an additional object in the system (e.g., Fabrycky & Tremaine 2007; Naoz et al. 2013).

### 6.5. Comparative planetology

Many factors influence the formation of planetary systems. Among these are stellar multiplicity and metallicity. With the distant companion to KELT-22A, and its metal-rich composition, this system further fills in this parameter space, with a host star bright enough for detailed characterization studies (see Figure 13). The density and radius of known transiting exoplanets (including KELT-22Ab) are plotted against mass...
KELT-22Ab

We present the discovery of KELT-22Ab, a hot Jupiter transiting the bright $V = 11.1$, $K = 10.0$ Sun-like G2 star TYC 7518-468-1. The planet is massive ($M_P = 3.48 \, M_J$), large ($R_P = 1.285_{-0.071}^{+0.129} \, R_J$), and on a short 1.39 day orbital period. KELT-22A is metal rich ([m/H] = 0.26) and has an unusually high space velocity, with excursions up to $\sim 250$ pc out of the galactic plane. KELT-22A rotates relatively rapidly for a main sequence G2 star, with $v \sin I_*$ of $7.9 \pm 0.5$ km s$^{-1}$, and with photometric hints of a rotational period of $\sim 8$ days. Models that simulate the tidal interactions between star and planet predict that tidal forces are spinning up the star, with the consequence that the planet is losing orbital angular momentum, perhaps causing it to spiral into the star within the next Gyr. The brightness and relatively rapid rotation of KELT-22A and large transit depth make this an excellent candidate for measuring the spin-orbit alignment through either the Rossiter-McLaughlin effect or Doppler tomography. A linear trend in RV measurements hints at the possibility of a third body in the system (in addition to the widely separated binary companion). Future RV monitoring of the KELT-22A system is therefore warranted to either confirm or rule out this trend.

During the completion of this paper, we became aware of an independent discovery of this planetary system by the SuperWASP survey (WASP-173b; Hellier et al. 2018). Since the data we present in this paper were collected independently and the analysis performed before the announcement of WASP-173b, we have chosen to discuss our findings as an independent discovery of this planet, and we refer to it here as KELT-22Ab. However, we acknowledge the prior announcement of it as WASP-173b.

This project makes use of data from the KELT survey, including support from The Ohio State University, Vanderbilt University, and Lehigh University, along with the KELT follow-up collaboration. Work performed by J.E.R. was supported by the Harvard Future Faculty Leaders Postdoctoral fellowship. D.J.S. and B.S.G. were partially supported by NSF CAREER Grant AST-1056524. D.I.J gratefully acknowledges support from National Science Foundation award NSF-1440254. Work by S.V. Jr. is supported by the National Science Foundation Graduate Research Fellowship under Grant No. DGE-1343012 and the David G. Price Fellowship in Astronomical Instrumentation Work by G.Z. is provided by NASA through Hubble Fellowship grant HST-HF2-51402.001-A awarded by the Space Telescope Science Institute, which is operated by the Association of Universities for Research in Astronomy, Inc., for NASA, under contract NAS 5-26555. This work has made use of NASA’s Astrophysics Data System, the Extrasolar Planet Encyclopedia, the NASA Exoplanet Archive, the SIMBAD database operated at CDS, Strasbourg, France, and the VizieR catalogue access tool, CDS, Strasbourg, France. We also used data products from the Widefield Infrared Survey Explorer, which is a joint project of the University of California, Los Angeles; the Jet Propulsion Laboratory/California Institute of Technology, which is funded by the National Aeronautics and Space Administration; the Two Micron All Sky Survey, which is a joint project of the University of Massachusetts and the Infrared Processing and Analysis Center/California Institute of Technology, funded by the National Aeronautics and Space Administration and the National Science Foundation; and the European Space Agency.

7. CONCLUSION AND FUTURE WORK

in the next two panels in Figure [13]

If our models of the tidal forces between star and planet are even approximately correct, then KELT-22A is rapidly moving through this stage in its orbital evolution, and provides a valuable opportunity to constrain the behavior of tides in such systems. The hint of a third (possibly non-stellar) body in this system (as implied by the linear RV slope), the likely young age, and the very peculiar space motion through the Galaxy, motivate further study.
