(Received 4 March 2016; published 17 October 2016)

The lifetime of localized surface plasmon plays an important role in many aspects of plasmonics and its applications. In small metal nanostructures, the dominant mechanism of plasmon decay is size-dependent Landau damping. We performed quantum-mechanical calculations of Landau damping for the bright surface plasmon mode in a metal nanoshell with dielectric core. In contrast to the conventional model based on the electron surface scattering, we found that the damping rate decreases as the nanoshell thickness is reduced. The origin of this behavior is traced to the spatial distribution of plasmon local field in the metal shell. We also found that, due to the interference of electron scattering amplitudes from the two nanoshell metal surfaces, the damping rate exhibits pronounced quantum beats with changing shell thickness.

DOI: 10.1103/PhysRevB.94.155429

I. INTRODUCTION

Lifetime of localized surface plasmons (SP) in metal nanostructures is one of the fundamental problems in plasmonics that has been continuously addressed for about 50 years [1–5]. The importance of this issue stems from one of the major objectives of plasmonics—generation of extremely strong local fields at the nanoscale. The range of physical phenomena and applications related to this goal cuts across physics, chemistry, biology, and device applications. A small sample of examples includes plasmon-enhanced spectroscopies of molecules or semiconductor quantum dots near metal nanostructures, such as surface-enhanced Raman scattering (SERS) [6], plasmon-enhanced fluorescence [7–10], plasmon-assisted fluorescence resonance energy transfer (FRET) [11–14], and plasmonic laser (spaser) [15–20]. High Ohmic losses in bulk metal due to strong electron-phonon interactions impose limitations on the quantum yield of metal-based plasmonic devices, which can, to some extent, be remedied by reducing the metal component size.

However, at the length scale below ~10 nm, new limitations on the SP lifetime and, consequently, on quantum yield arise due to the quantum-size effects [1]. Among those, the most important is the Landau damping (LD) of SP—decay of SP into the Fermi sea electron-hole pair [21–31]. This process has been recently suggested as an efficient way of hot carriers excitation in plasmon-based photovoltaic devices [32–42]. Starting with the pioneering work of Kawabata and Kubo [43] for a spherical nanoparticle (NP), quantum-mechanical calculations of LD rate were performed, using random phase approximation (RPA) [43–50] or density functional theory (DFT) [51–58] methods, for several NP shapes. Excitation of an electron-hole pair with large optical frequency requires momentum relaxation to satisfy the energy and momentum conservation laws which, in small systems, can take place via the electron surface scattering. Based on this picture, it was suggested [59–63] that the SP LD rate in any small system should have the form

\[ \gamma_s = A \frac{\nu_F}{L}, \]  

where \( \nu_F \) is the electron Fermi velocity (hereafter we set \( \hbar = 1 \)) and \( L \) is the effective mean free path of ballistic electrons confined in a hard-wall potential well, while the phenomenological constant \( A \), measured in the range 0.3–1.5 [1], accounts for surface potential, electron spillover, and dielectric environment effects. Note that, for nonspherical NPs, the SP damping by interband excitations can complicate the LD size dependence. For example, absorption spectra for gold nanorods [22,27] and nanoshells [23,24] show overall narrowing of the SP resonance that is redshifted away from the interband transitions onset. At the same time, recent systematic studies of scattering spectra of single silver nanoparticles [29], gold nanorods [30], and gold nanodisks [31] revealed significant discrepancies with Eq. (1), while no size dependence was detected for the SP resonance width of single gold nanoshells [26], implying that LD is shunted by the bulk SP damping even for relatively thin shells.

There is also a physical argument that renders Eq. (1) invalid for nanostructures of general shape. Indeed, the rate of electron-pair excitation by the SP local field must be sensitive to the field distribution in the NP. Note that for a solid sphere, the dipole SP electric field in the NP is uniform and size independent, which is the reason Eq. (1) holds well for spherical NPs in a very wide size range [1]. However, in the general case, the local field distribution depends strongly on NP size or shape, so that the simple picture implied by Eq. (1) fails. Below we demonstrate that the effect of field distribution leads to a drastically different size and shape dependence of the LD decay rate in a nanostructure than that implied by Eq. (1).

In this paper, we present a quantum-mechanical calculation of the LD rate for bright SP modes in a metal nanoshell (NS) with a dielectric core. We find that, with decreasing NS thickness \( d \), the LD rate decreases as well, in sharp contrast to the surface scattering model [59–63] predicting an increase of \( \Gamma \) as the effective mean free path is reduced. Furthermore, for small overall NS sizes, the SP LD rate exhibits quantum beats as a function of shell thickness caused by the interference...
between electron scattering amplitudes from the inner and outer NS boundaries.

The paper is organized as follows. In Sec. II we outline our approach and present a formal expression for the LD rate in terms of the SP eigenmodes. In Sec. III we describe the plasmon eigenmodes in metal NS with dielectric core and evaluate the NS internal energy. In Sec. IV, we evaluate the power dissipated through electron-hole excitation by the SP eigenmodes. The calculated LD rates are discussed in Sec. V, and Sec. VI concludes the paper.

II. SURFACE PLASMON LANDAU DAMPING RATE IN COMPOSITE METAL-DIELECTRIC NANOSTRUCTURES

In this section we outline our approach for calculations of the plasmon damping rate in a composite metal-dielectric structure embedded in a dielectric medium. We assume that the structure is characterized by dielectric function of the form \( \varepsilon(\omega, \mathbf{r}) = \varepsilon'(\omega, \mathbf{r}) + i \varepsilon''(\omega, \mathbf{r}) \) and the retardation effects are unimportant. In the quasistatic case, the plasmon eigenmodes, labeled by \( n \) here, are determined by the Gauss’s law

\[
\nabla \cdot \{ \varepsilon'(\omega_n, \mathbf{r}) \mathbf{E}_n \} = 0, \tag{2}
\]

where \( \omega_n \) is the eigenfrequency, \( \mathbf{E}_n = -\nabla \Phi_n \) is the mode local field, and \( \Phi_n \) is the potential. In the following we assume that only the metal dielectric function \( \varepsilon_m(\omega) = \varepsilon'_m(\omega) + i \varepsilon''_m(\omega) \) is complex and dispersive. The decay rate of a plasmon mode is given by [64]

\[
\Gamma_n = \frac{Q_n}{U_n}, \tag{3}
\]

where \( U_n \) is the mode energy [65],

\[
U_n = \int \frac{dV}{16\pi} \frac{\partial(\omega_n \varepsilon_n')}{\partial \omega_n} |\mathbf{E}_n|^2 = \frac{\omega_n}{16\pi} \frac{\partial \varepsilon'_m}{\partial \omega_n} \int dV_m |\mathbf{E}_n|^2, \tag{4}
\]

and \( Q_n \) is the mode dissipated power

\[
Q_n = \frac{\omega_n}{2} \text{Im} \int dV \mathbf{P}_n \cdot \mathbf{E}_n, \tag{5}
\]

where \( \mathbf{P}_n \) is the polarization vector (\( V_m \) stands for the metal volume). In the local case, i.e., \( \mathbf{P}_n = \mathbf{E}_n (\varepsilon - 1)/4\pi \), \( Q \) is given by the usual expression [65]

\[
Q_n = \frac{\omega_n \varepsilon''_m}{8\pi} \int dV_m |\mathbf{E}_n|^2, \tag{6}
\]

which, together with the mode energy (4), yields the standard plasmon damping rate [66],

\[
\Gamma_n = 2\varepsilon''_m \left( \frac{\partial \varepsilon''_m}{\partial \omega} \right)^{-1}. \tag{7}
\]

For the Drude form of metal dielectric function, \( \varepsilon_m = \varepsilon_i - \omega_p^2/\omega(\omega + i\gamma) \), where \( \varepsilon_i \) is a weakly-dispersive interband contribution, \( \omega_p \) is the bulk plasmon frequency, and \( \gamma \) is the scattering rate, one obtains \( \gamma_n = \gamma \) for all modes.

The surface contribution \( Q'_n \) originates from the generation of electron-hole pairs by the plasmon local field near metal-dielectric interfaces and can be included in Eq. (5) by relating the polarization vector \( \mathbf{P}_n(r) \) to the microscopic electron polarization operator \( P(\omega; \mathbf{r}, \mathbf{r}') \) via the induced charge density: \( \rho(r) = \int d\mathbf{r}' P(\mathbf{r}, \mathbf{r}') \Phi(\mathbf{r}') = -\nabla \cdot \mathbf{P}(\mathbf{r}) \) [64].

Integrating Eq. (5) by parts, we obtain

\[
Q'_n = \frac{\omega_n}{2} \text{Im} \int dV dV' \Phi^*_n(r) P(\omega_n; r, r') \Phi_n(r'). \tag{8}
\]

In the first order, \( Q'_n \) is obtained within RPA as [67]

\[
Q'_n = \pi \omega_n \sum_{\sigma' \sigma} | \langle \sigma' | \Phi_n | \sigma \rangle |^2 \delta(\varepsilon_\sigma - \varepsilon_{\sigma'} + \omega_n), \tag{9}
\]

where \( \langle \sigma' | \Phi_n | \sigma \rangle = \int dV_n \psi^*_\sigma \Phi_n \psi_{\sigma'} \) is the transition matrix element between electron state \( \psi_{\sigma'} \) with energy \( \varepsilon_{\sigma'} \) below the Fermi level \( E_F \) and electron state \( \psi_\sigma \) with energy \( \varepsilon_\sigma \) above the Fermi level under the perturbation \( \Phi_n \) (factor 2 due to the spin degeneracy is included). Note that often in the literature, the plasmon surface-assisted decay rate \( \Gamma'_n \) is identified with the first-order transition probability rate, similar to Eq. (9) (up to the factor \( \omega_n/2 \)); it must be emphasized that, in a system with dispersive dielectric function, the accurate expression is \( \Gamma'_n = Q'_n/U_n \) [64]. In the rest of this paper, this expression will be used to calculate the SP damping rate in a metal NS.

III. PLASMON MODES IN METAL NANOSHELLS WITH DIELECTRIC CORE

Here we collect the relevant formulas for plasmonic eigenstates in a spherical NS with inner and outer radii \( R_1 \) and \( R_2 \), respectively, and core dielectric constant \( \varepsilon_c \) in a medium with dielectric constant \( \varepsilon_d \) (see inset in Fig. 1). In the quasistatic limit, the plasmonic eigenfunctions in each region have the form \( \Phi_{i,M}(r) = \Phi_i(r) Y_{LM}(\hat{r}) \), where \( r \) and \( \hat{r} \) are the magnitude and orientation of the radius vector with the origin at NS center, \( i = (c,m,d) \) denotes core, metal, and outside dielectric regions, respectively, and \( Y_{LM}(\hat{r}) \) are spherical harmonics. In each region, the eigenfunctions are superpositions of two independent solutions of Laplace equation in spherical coordinates, \( r^2 Y_{LM}(\hat{r}) \) and \( r^{-L-1} Y_{LM}(\hat{r}) \). The equation for eigenvalues is obtained by imposing standard boundary conditions on the radial part of potentials, \( \Phi_i^{(L)}(r) \), and radial component of electric field,

\[
\text{FIG. 1.} \ \text{Frequency of bright dipole plasmon mode in gold NS with various core and outside dielectrics is plotted vs NS aspect ratio. Inset: Electric field distribution for SiO}_2/\text{Au/H}_2\text{O NS with aspect ratio } R_1/R_2 = 0.7.}
\]
E_L^{(r)}(r) = -\frac{d\Phi_L^{(r)}(r)}{dr}, as
\[\varepsilon_{cm}\varepsilon_{md} + L(L + 1)\varepsilon_{cm}\varepsilon_{md}\kappa^{2L+1} = 0,\]
where \(\kappa = R_1/R_2\) is the NS aspect ratio, and we denoted \(\varepsilon_{\alpha\beta} = \varepsilon_\alpha - \varepsilon_\beta\) and \(\tilde{\varepsilon}_{\alpha\beta} = L\varepsilon_\alpha + (L + 1)\varepsilon_\beta\). The plasmon frequencies are obtained by solving Eq. (10) for the real part of metal dielectric function,
\[\varepsilon_\alpha'(\omega_L) = -\frac{\mu_L}{2} \pm \sqrt{\frac{\mu_L^2}{4} - \varepsilon_c\varepsilon_d},\]
\[\mu_L = \frac{(2L + 1)}{L(L + 1)} \left(\frac{\tilde{\varepsilon}_d}{1 - \kappa^{2L+1}} - \varepsilon_c - \varepsilon_d,\right)\]
where alternating (±) sign correspond to bright and dark plasmon modes, respectively. The bright plasmon spectrum matches that of a solid NP plasmon in the \(\kappa = 0\) limit: \(\tilde{\varepsilon}_md = L\varepsilon_m + (L + 1)\varepsilon_d = 0\). The higher frequency dark plasmon mode couples weakly to the external fields and will not be considered here.

In Fig. 1, we show the dependence of bright plasmon mode frequency \(\omega_L\) (for \(L = 1\)) on aspect ratio \(\kappa = R_1/R_2\) of Au NS with several choices of core and outside dielectrics. In all numerical calculations, the experimental dielectric function for gold as well as for core and outside dielectrics were used [68]. With decreasing shell thickness, after a prolonged plateau for \(\kappa\) up to approximately 0.5–0.7 (depending on dielectric content), the frequency develops a redshift. The inset shows electric field distribution for the dipole plasmon mode oscillating along the z axis in a NS with \(\kappa = 0.7\). Note that, in a thin NS, the electric field of bright plasmon is mainly concentrated outside of the metal shell, in contrast to the field distribution in a solid metal NP.

The normalized (dimensionless) radial eigenfunctions \(\Phi_L(r)\) in core \((r < R_1)\), shell \((R_1 < r < R_2)\), and outer dielectric \((r > R_2)\) regions have the form
\[\Phi_L^{(c)}(r) = (2L + 1)\varepsilon_m^{\prime\prime}k_L^{(c)}(r),\]
\[\Phi_L^{(m)}(r) = k_L^{(m)}(r) + \frac{1}{L + 1}\varepsilon^{md}_L(r),\]
\[\Phi_L^{(d)}(r) = \frac{2L + 1}{L + 1}\varepsilon^{md}_L(r),\]
and are continuous at the metal-dielectric interfaces,
\[\Phi_{1L} \equiv \Phi_L^{(m)}(R_1) = (2L + 1)\varepsilon_m^{\prime\prime}k_L^{(c)}(R_1),\]
\[\Phi_{2L} \equiv \Phi_L^{(m)}(R_2) = \frac{2L + 1}{L + 1}\varepsilon_m^{md}(R_2),\]
The radial electric fields satisfy the standard boundary conditions, i.e., \(\varepsilon_\alpha^{eL} = 0\) (r) is continuous, and take the following values at the interfaces (on the metal side)
\[E_{1L} = E_L^{(r)}(R_1) = -\frac{L}{R_1}\varepsilon_{cm}\Phi_{1L},\]
\[E_{2L} = E_L^{(r)}(R_2) = \frac{L + 1}{R_2}\varepsilon^{md}_m\Phi_{2L}.\]

IV. POWER DISSIPATED BY PLASMON MODES IN NANOSHELLS

We now turn to calculation of dissipated power Eq. (9) (we drop superscript s in the following). We represent the NS confining potential as a three-dimensional quantum well with hard boundaries at \(R_1\) and \(R_2\) and amplitude \(V_0\) \(V(r) = V_0\theta(r - R_1)\theta(R_2 - r)\). The role of realistic surface potential and nonlocal effects will be discussed later. The electron wave functions have the form \(\psi_n(r)Y_m(\theta)\), where \(n, l, m\) and \(e_L^{md}\) are electron radial, angular momentum, and magnetic numbers, respectively. Due to spherical symmetry, the angular part

Note that the electric field orientations at the inner and outer interfaces (on the metal side) are opposite. Using the above eigenfunctions, the plasmon mode energy can be straightforwardly calculated from Eq. (4). Since the eigenfunctions are harmonic functions inside each region, the integral in Eq. (4) reduces to the boundary terms, and, using the relations (17) between fields and potentials at the interface, we obtain
\[U_L = \frac{\varepsilon^{eL}}{16\pi L\varepsilon_{cm}} \frac{\partial\varepsilon^{eL}}{\partial\omega_L}\left[\frac{R_1^2L_{1L}^2}{L\varepsilon_{cm}} + \frac{R_2^2L_{2L}^2}{(L + 1)\varepsilon_d}\right].\]
factorizes out and Eq. (9) takes the form

\[ Q_L = \pi \omega_L \sum \frac{a_{ll}^n}{\omega_L} \left| M_{ll}^{nl,n'l'}(\omega_L) \right|^2 \delta(\epsilon_{nl} - \epsilon_{n'l'} + \omega_L), \]

(20)

where \( M_{ll}^{nl,n'l'} = \langle n'l'| \Phi_L|nl' \rangle \) is the radial transition matrix element and

\[ a_{ll}^n = \frac{1}{2L + 1} \sum_{\text{Morse}} \left| \int d\Omega Y_{lm} Y_{lm'} \psi_{nl} \psi_{n'l'}^* \right|^2 \]

(21)

is the angular contribution. The latter is nonzero only for \( l = l' \pm L \), and for typical \( l, l' \gg L \) can be approximated as \( a_{ll}^n \approx \delta_{ll}l/2\pi \).

The matrix element \( \langle \alpha|\Phi_L|\alpha' \rangle \) in Eq. (9) is dominated by the surface contribution, which can be obtained by first commuting twice the plasmon potential \( \Phi_L \) with the Hamiltonian,

\[ \langle \alpha|\Phi_L|\alpha' \rangle \approx \left\langle \alpha | H [ H, \Phi_L ] | \alpha' \right\rangle \approx \frac{1}{\omega_L^2} \langle \alpha | \nabla \Phi_L \cdot \nabla V | \alpha' \rangle, \]

(22)

which, after separating out the angular part, leads to the following expression for the radial matrix element,

\[ M_{ll}^{nl,n'l'} = \frac{V_0}{m\omega_L} \left[ \psi_{nl}(R_1)\psi_{n'l'}(R_1)E_{1L} - \psi_{nl}(R_2)\psi_{n'l'}(R_2)E_{2L} \right]. \]

(23)

Then, for infinitely high potential barrier (\( V_0 \to \infty \)), matching the wave functions across the well boundaries gives \( \sqrt{2m} V_0 \psi_{nl}(R_1) \approx -\psi_{nl}(R_2) \) (here prime stands for the derivative), and the matrix element takes the form

\[ M_{ll}^{nl,n'l'} = \frac{1}{2m^2\omega_L} \left[ \psi_{nl}(R_1)\psi_{n'l'}(R_1)E_{1L} - \psi_{nl}'(R_2)\psi_{n'l'}(R_2)E_{2L} \right]. \]

(24)

The first and second terms in the r.h.s. describe excitation, by the plasmon electric field, of a Fermi sea electron-hole pair accompanied by momentum transfer to the inner and outer boundaries, respectively. Correspondingly, \( Q_L \) can be decomposed as \( Q_L = Q_L^{11} + Q_L^{22} - 2Q_L^{12} \), where

\[ Q_L^{ji} = \frac{e^2}{8m^2\omega_L^2} E_{1L} E_{2L} \sum_{\text{bnr}} \psi_{nl}(R_i) \psi_{n'l'}(R_i) \delta(\epsilon_{nl} - \epsilon_{n'l'} + \omega_L), \]

(25)

and we used that \( a_{ll}^n \approx \delta_{ll}l/2\pi \).

Consider first the inner surface contribution \( Q_L^{11} \). For typical electron energies \( \epsilon_{nl} \sim E_F \), we can adopt semiclassical approximation for the electron wave functions:

\[ \psi_{nl}(r) = \frac{4m}{\sqrt{4\pi e}} \sin \int_{R}^{R_F} \sqrt{2m} e - \frac{(l + 1/2)^2}{r^2}, \]

(26)

where \( \tau_l(\epsilon) \) is the period of classical motion between two turning points. In this case, we find

\[ \psi_{nl}(R_1) = -\sqrt{4m\rho_l(R_1)/\tau_l}. \]

(27)

Since the plasmon energy \( \omega_L \) is much larger than the spacing \( \epsilon_0 = v_F/d \) between the energy levels with adjacent \( n \) (at fixed \( l \)) in a spherical well, the sums in Eq. (25) can be replaced by the integrals, \( \int d\rho_l(\epsilon) \) (with \( \epsilon < E_F, \epsilon' > E_F \)), where \( \rho_l(\epsilon) = d\eta/d\epsilon \) is the partial density of states related to the classical period as \( \rho_l = \tau_l/2\pi \) (see Appendix). The result reads

\[ Q_L^{11} = \frac{E_{1L}^2}{2\pi^2m^2\omega_L^2} \int_{E_F - \omega_L}^{E_F} d\epsilon \rho_l(\epsilon) \left( \rho_l(\epsilon + \omega_L, R_1) - \rho_l(\epsilon, R_1) \right). \]

(28)

Note that \( \rho_l \) cancels out, i.e., the level spacing disappears from the result. In the energy integral, the integration variable is first shifted as \( \epsilon \to E_F + \epsilon - \omega_L/2 \), where \( \epsilon \) now changes in the interval \( (\omega_L/2, \omega_L/2) \), and then rescaled to \( x = \epsilon/\omega_L \). The sum over \( l \) is replaced by the integral restricted by maximal value \( l \sim p_F R_1 \), that is obtained by the condition \( \rho_l(\epsilon, R_1) \geq 0 \). After the change of variables to \( s = l^2/(p_F R_1)^2 \), it contributes a factor proportional to the inner surface area. The result reads

\[ Q_L^{11} = \frac{E_{1L}^2 R_1^2}{2\pi^2m^2\omega_L^2} E_{2L} g(\omega/L_F), \]

(29)

where \( g(\xi) = 2 \int_{1/2}^{1/2} dx \int ds f(\xi, x) \) with \( f(\xi, x) = [(1 + \xi - s)^2 - \xi^2/4]^{1/2} \) is a dimensionless function normalized to \( g(0) = 1 \).

Turning to the outer surface term \( Q_L^{22} \), the main contribution into the r.h.s. of Eq. (25) comes from the terms with \( \rho_l(\epsilon, R_2) \geq 0 \) [otherwise \( \psi_{nl}(R_2) \) are exponentially small]. In this case, we have

\[ \psi_{nl}(R_2) = -(-1)^n \sqrt{4m\rho_l(R_2)/\tau_l}, \]

(30)

where the sign factor \( (-1)^n \) accounts for the parity of electron wave function with \( n - 1 \) nodes between \( R_1 \) and \( R_2 \). The rest of the calculation is carried in a similar way, and the result,

\[ Q_L^{22} = \frac{E_{1L}^2 R_1^2}{2\pi^2m^2\omega_L^2} E_{2L} g(\omega/L_F), \]

(31)

is proportional to the outer surface area.

Finally, consider now the interference term \( Q_L^{12} \). Using Eqs. (27) and (30), we write

\[ Q_L^{12} = \frac{2E_{1L} E_{2L}}{m^2\omega_L^2} \sum_{\text{bnr}} I(-1)^n \frac{l(\epsilon_{nl} - \epsilon_{n'l'} + \omega_L)}{\tau_l(\epsilon_{nl})\tau_l(\epsilon_{n'l'})} \times F_l(\epsilon_{nl}, \epsilon_{n'l'}) \delta(\epsilon_{nl} - \epsilon_{n'l'} + \omega_L), \]

(32)

with \( F_l(\epsilon, \epsilon') = \sqrt{\rho_l(\epsilon, R_1)\rho_l(\epsilon', R_1)\rho_l(\epsilon, R_2)\rho_l(\epsilon', R_2)} \). As \( \omega_L \) changes (e.g., with changing aspect ratio), the relative parity of electron and hole states, separated by energy \( \omega_L \), changes too, leading to a different sequence of alternating signs in the sum in Eq. (32) which, in turn, results in oscillations of \( Q_L^{12} \) (quantum beats). The number of states contributing into the sum in Eq. (32) is large, so that the oscillations

155429-4
can be described by substituting \((-1)^{n-n'} = \cos \pi (n-n') = \cos[\pi \int e^d \rho_p(\epsilon)]\). Then \(Q_{12}^{(1)}\) takes the form

\[
Q_{12}^{(1)} = \frac{E_{1L} E_{2L}}{2\pi^2 \omega_L^3} \int \int F(\epsilon, \epsilon + \omega_L) \times \cos \left[ \pi \int e^d \rho_p(\epsilon') \right], \tag{33}
\]

where \(l\) is restricted by the condition \(p_l(\epsilon, R) \geq 0\). Equation (33) can be brought to the form

\[
Q_{12}^{(1)} = \frac{\pi v_F}{\omega_L} E_{1L} E_{2L} G(\omega_L / E_F), \tag{34}
\]

where the dimensionless function \(G(\xi)\) is rather cumbersome and is given in the Appendix. For thin nanoshells, \(d/R \ll 1\), it can be evaluated analytically (see Appendix) and the result reads

\[
G(\xi) = -\frac{\sin D \sin(\xi D/4)}{D} \frac{\xi D/4}. \tag{35}
\]

where \(D = \omega_L / \epsilon_0 = \omega_L d / v_F\) is the ratio of plasmonic and electronic energy scales.

Putting all together, we finally obtain

\[
Q_L = \frac{E_L^2 R_L^4}{2\pi^2 \omega_L^3} (E_{1L}^2 + \kappa^2 E_{1L}^2 - 2\kappa^2 E_{1L} E_{2L} G). \tag{36}
\]

The last term in \(Q_{12}\) oscillates as a function of shell thickness \(d\) due to the interference of electron scattering amplitudes from inner and outer NS boundaries. These oscillations are, in fact, quantum beats caused by the change, with \(d\), of the number of electron levels with alternating parities within the plasmon energy \(\omega_L\) (i.e., the difference between numbers of even and odd states oscillates between 0 and 1). The oscillations period \(2\pi v_F / \omega_L\) depends weakly on the shell thickness through dependence of \(\omega_L\) on \(\kappa\) (see Fig. 1), and their amplitude slowly dies out with increasing \(d\).

In fact, the quantum beats of \(Q_{12}\) have a rather general origin. Indeed, excitation of an electron-hole pair with energy \(\omega\) is accompanied by momentum transfer \(p_0 \sim \omega / v_F\) and occurs in a region with the size \(r_0 \sim v_F / \omega\). Therefore, oscillations of the pair excitation rate with changing \(D = d / r_0\) reflect the nonlocality of surface-scattering mechanism of momentum relaxation.

In Fig. 3, normalized dissipated power for the bright dipole plasmon mode \(Q_1\) is plotted vs aspect ratio \(\kappa\) for overall NS sizes \(R_1 = 30\) nm and \(R_2 = 10\) nm. Numerical calculations were performed using the full expression for \(G(\xi)\) given by Eq. (A1) in the Appendix. While for larger NS with overall size \(R_1 = 30\) nm, oscillations of \(Q_1\) are relatively weak [see Fig. 3(a)], they become more pronounced for smaller NS \((R_1 = 10\) nm) [see Fig. 3(b)]. Note that, for smaller \(R_2\), the same values of \(\kappa\) correspond to smaller shell thicknesses. Another striking feature is the decrease of dissipated power for \(\kappa\) larger than 0.4. The reason for this behavior is that, with decreasing shell thickness, the local field is pushed outside the metal shell (see inset in Fig. 1) which, in turn, leads to the reduction of the transition matrix element.

![Fig. 3. Normalized dissipated power by bright dipole plasmon modes in gold NS with various core and outside dielectrics is plotted vs NS aspect ratio for (a) \(R_1 = 30\) nm and (b) \(R_1 = 10\) nm.](image)

**V. LANDAU DAMPING OF PLASMON MODES IN NANOSHELLS**

The plasmon damping rate, \(\Gamma_L = Q_L / U_L\) with \(Q_L\) and \(U_L\) given by Eqs. (36) and (19), respectively, takes the form

\[
\Gamma_L = \frac{2\omega_p \gamma_L}{\omega_L} \left( \frac{\partial \epsilon'_m}{\partial \omega_L} \right)^{-1}, \tag{37}
\]

where

\[
\gamma_L = 3v_F \frac{\epsilon_d(L + 1)}{4R_2 \left| \epsilon'_m(\omega_L) \right|} \frac{1 + \kappa^2 q_L^2 - 2\kappa^2 q_L G}{1 + \kappa^2 q_L^2(L + 1) \epsilon_d / \epsilon_c} \tag{38}
\]

is the LD rate. Here \(q_L = E_{1L} / E_{2L}\) is the electric fields’ ratio at the interfaces given by Eq. (18). In deriving Eq. (38), we used the relation \(\omega_p^2 = 4\pi n / m = 4p_F^3 / 3\pi m\) (for \(e = 1\)), where \(n\) is the electron concentration.

Equations (37) and (38) represent our central result. Apart from the dimensional factor \(v_F / R_2\), the LD rate (38) is determined by the ratio of plasmon local fields at the metal-dielectric interfaces \(q_L\). The last factor describes the relative contribution of the NS interfaces and includes the interference correction. Importantly, comparison of Eqs. (37) and (7) indicates that LD rate can be incorporated into the Drude scattering rate as \(\gamma = \gamma_0 + \gamma_L\), where \(\gamma_0\) is the bulk scattering rate, so the full plasmon damping rate is still given by Eq. (7), but with modified Drude dielectric function.
on the shell thickness is obtained from Eq. (38) as (for $f_0$) is plotted vs NS aspect ratio for (a) plasmon modes in gold NS with various core and outside dielectrics. The rate shows approximately linear decrease with $\gamma_1$ oscillations of $L\varepsilon_\mathrm{m}$ due to size quantization of the electron energy $\Delta\varepsilon$. Note that these oscillations cover the LD rate of the $L\varepsilon_\mathrm{m}$ and/or environments. Within our approach, the constant $A$ can be estimated by computing the effect of the above factors on the local field, which is, however, out of the scope of this paper.

In summary, we calculated the Landau damping rate of surface plasmons in metal nanoshells with dielectric core. We found that the damping rate decreases with the shell thickness due to the reduction of the local field magnitude inside a thin metal shell. We also found that the Landau damping rate exhibits quantum beats caused by the interference between electron scattering paths from the nanoshell inner and outer metal-dielectric interfaces.

VI. CONCLUSIONS

In conclusion, let us discuss the role surface potential, dielectric environment, and nonlocal effects near the metal surface on the plasmon LD that was extensively studied in solid NPs [51–58]. These effects mainly affect the overall magnitude of LD rates, but play no significant role in determining the LD dependence on the nanostructure shape which, according to our findings, is mainly determined by the local field ratio at the interfaces. Extensive theoretical and experimental studies of spherical NPs indicate that surface effects mainly affect the phenomenological constant $A$ [see Eq. (1)], but the overall $1/R$ dependence of the LD rate is unchanged [1]. In fact, the important role of local fields in plasmon LD rate can explain the relatively wide range of measured $A$ (0.3–1.5 [1]), which raised questions about the validity of the scattering model [56]. Indeed, as we mentioned in Sec. IV, excitation of an $e-h$ pair by plasmon local field takes place in a surface layer of thickness $r_0 \sim v_F/\omega$. For $v_F \approx 1.4 \times 10^6$ m/s in Au and Ag, we have $v_F/\omega \approx 1$ nm for $\hbar\omega = 1.0$ eV, i.e., for typical plasmon frequencies in the range 1.5–3.5 eV, the layer thickness is just a few A. In a thin surface layer, the local fields are strongly affected by the electron spillover and surface roughness effects as well as by the dielectric environment, which can lead to large variations of overall LD rate magnitude for different samples and/or environments. Within our approach, the constant $A$ can be estimated by computing the effect of the above factors on the local field, which is, however, out of the scope of this paper.

APPENDIX

Here we analyze function $G(\xi)$ in the interference term (34). After shifting integration variables in Eq. (33) as $\epsilon \rightarrow E_F + \epsilon - \omega_L/2$ and $\epsilon' \rightarrow E_F + \epsilon + \epsilon'$ and rescaling to $x = \epsilon/\omega_L$ and $s = l^2/(\rho F R)$, we arrive at (34) with

$$G(\xi) = 2 \int_{-1/2}^{1/2} dx \int_{-1/2}^{1/2} ds \sqrt{f(\xi,x,s)f(\xi,x',s')} \times \cos \left[ \pi \omega_L \int_{-1/2}^{1/2} dx' \rho[E_F[1 + \xi(x+x')]] \right].$$

(A1)
where $f(\xi, x, s) = \sqrt{(1 + \xi x - s)^2 - \xi^2}/4$, and the partial density of states is given by

$$ \rho_l(\epsilon) = \frac{m}{\pi} \frac{R_2 p_l(\epsilon, R_2) - R_1 p_l(\epsilon, R_1)}{2\pi \epsilon} = \frac{R_2}{\pi v_F} \left[ \sqrt{1 + \xi (x + x') - \kappa^2 s - \kappa \sqrt{1 + \xi(x + x')^{-2}}} \right]. $$

(A2)

For $\omega/E_F \ll 1$, the $x'$ integrals are easily evaluated, yielding

$$ G(\xi) = 2 \int_{-1/2}^{1/2} dx \int_0^{1+\xi x} ds \sqrt{f(\xi, x, s)f(\xi, x, \kappa^2 s)} \times \cos[w(\xi, x, s)\omega_L/\epsilon_0], $$

(A3)

where $w(\xi, x, s) = (\sqrt{f(\xi, x, \kappa^2 s)} - \kappa \sqrt{f(\xi, x, s)})/(1 + \xi x)$ with $f(\xi, x, s) \approx 1 + \xi x - s$ (here $\epsilon_0 = v_F/R_2$). Rescaling $s$ by $1 + \xi x$, Eq. (A3) factorizes as $G(\xi) = \int_{-1/2}^{1/2} dx (1 + \xi x)^2 S(\xi, x)$, where

$$ S(\xi, x) = \int_0^1 ds \sqrt{(1-s)(1-\kappa^2 s)} \times \cos[\alpha(\xi, x)(\sqrt{1-\kappa^2 s} - \kappa \sqrt{1-s})], $$

(A4)

with shorthand notation $\alpha(\xi, x) = (\omega_L/\epsilon_0)/\sqrt{1+\xi x}$. With substitution $s = 1 - \frac{1-x^2}{\alpha^2} \sinh^2 \alpha$, $S$ is brought to the form

$$ S(\xi, x) = \frac{4(1-\kappa^2)^2}{\kappa^3} \int_0^{\alpha_0} d\alpha (\sin \alpha \cosh \alpha)^2 \times \cos[\alpha(\xi, x)(\sqrt{1-\kappa^2} e^{-\alpha})], $$

(A5)

where $\sin \alpha_0 = \kappa/\sqrt{1-\kappa^2}$. For $\alpha(\xi, x) \gg 1$, the integral is dominated by the upper limit, and for thin shells, $1-\kappa \ll 1$, corresponding to $\alpha_0 > 1$, can be evaluated as

$$ S \approx -4 \sin[\alpha(1-\kappa^2) e^{-\alpha_0}] \alpha(1-\kappa^2 e^{-\alpha_0}) = -4 \sin[\alpha(1-\kappa)] \alpha(1-\kappa). $$

(A6)

With the above $S$ and after change of variable $t = \sqrt{1+\xi x}$, the expression for $G(\xi)$ takes the form

$$ G(\xi) = -\frac{8}{\xi D} \int_{t_-}^{t_+} dt t^3 \sin(tD), $$

(A7)

where $t_\pm = \sqrt{1 \pm \xi \xi}/2$, and $D = (1-\kappa)^2 v_L/\epsilon_0 = \omega_L d/v_F$. Note that even though for $\xi \ll 1$ the integration interval is small, the integrand is still an oscillating function since $D \gg 1$, and so the product $D \xi$ can be arbitrary. In this case, a straightforward evaluation yields Eq. (35).
