Ectodermal dysplasia-skin fragility syndrome with a new mutation

Sir,

Ectodermal dysplasia-skin fragility syndrome (EDDFS) was first described in 1997 by McGrath et al., in a 6-year-old British boy with skin fragility, short sparse hair, erosions and blistering. EDDFS occurs as a result of mutation in the PKP 1 gene, and is characterized by widespread skin fragility, alopecia, nail dystrophy, palmoplantar keratoderma and painful fissures. In literature, we could find about twenty cases [Table 1] describing this entity. and two of them are from Turkey.

A 29-year-old male patient was admitted with complaints of thickening and fissuring of the skin of the soles. His complaints were present since birth and he also gave a history of reduced sweating. His parents were second-degree relatives and his sister reportedly died at the age of 5 years with similar complaints. His parents and three brothers were asymptomatic.

Dermatological examination revealed diffuse keratoses and deep fissures in the palmoplantar regions. Erosions were seen on dorsal surface of the hands. The patient had a flat nasal bridge. His scalp was normal, but his hair appeared short, curly, thin and brittle. The hair pull test revealed easily broken hairs [Figures 1 and 2]. Dystrophic changes were seen in the nails as well. Histopathological examination revealed diffuse parakeratosis, prominent granular layer, submucosal cleavage in the focal area and increased intercellular edema between the keratinocytes.

DNA sequencing analysis was done which detected a novel heterozygous p.Val472Glyfs*28 (c.1414_1415delTG) mutation in our index case, and in the father and mother of the case. This mutation, which has not been previously reported, leads to premature protein termination. Two bioinformatics tools - PolyPhen-2 and Mutation Taster, predict the p.Val472Glyfs*28 (c.1414_1415delTG) change to be, “probably damaging”, and “disease causing”, respectively [Figure 3]. Ectodermal dysplasia-skin fragility syndrome was diagnosed with these findings.

Ectodermal dysplasia-skin fragility syndrome is a rare inherited autosomal recessive genodermatosis that is recently defined. EDDFS is characterized by PKP 1 mutation, which results in the characteristic clinical findings in the skin, hair and nails. It was learned that the patient’s sister died with similar symptoms when she was five years old. His mother, father and brothers had no related complaints.

PKP1 is a component of the desmosomal plaque. This protein contributes to the mechanical integrity of the desmosomes by binding desmosomal cadherins to keratin. PKP 1 protein is encoded by the PKP 1 gene. This gene is located, especially in the suprabasal cells and the outer layers of the hair follicles in the epidermis. EDDFS occurs as a result of loss of function mutations of this gene which result in changes in PKP 1 protein levels. Blister caused by trauma are specific findings of epidermolysis bullosa (EB) disease. Therefore, this syndrome is classified as a specific suprabasal form of EB simplex at the IIIrd International Consensus Meeting for the diagnosis and classification of EB.

EDDFS was first described by McGrath et al. in 1997. Some specific signs occur in the skin, hair and nails. Fragility and bullous lesions secondary to trauma can be commonly seen in EDDFS. Also, erosions, palmoplantar keratoderma and fissures secondary to keratoses are common. Alopecia or thinning hair which is dry, short and curly is the typical appearance. Dystrophic changes in the nail are also frequent findings. Hypohidrosis, pruritus, periocular fissures, cheilitis, growth retardation, and other aberrations are rare clinical findings [Table 1].

Hypohidrosis has been reported in a 40-year-old Japanese patient and a 20-year-old male Turkish patient. Cheilitis has been observed in a 2-year-old Indian male patient, and a 4-year-old Scandinavian woman. In our case, there were palmoplantar keratoderma with erosions of the skin, brittle hair and nail dystrophy. EDDFS may also be associated with cardiomyopathy, patent foramen ovale, chronic diarrhea and congenital megacolon. We did not observe any pathological findings in electrocardiogram, chest X-ray, pulmonary function tests and echocardiogram examinations. We also did not detect any other co-morbidity.

Ersoy et al. have reported EDDFS resulting from the homozygous mutation, 888delC, in the desmosomal protein plakophilin 1. Whittock et al. found a homozygous splice site mutation (1233–2 A→T; GenBank Z73678) in a 17-year-old male with EDDFS. Sequencing of the genomic DNA revealed a homozygous 5 base pair deletion in
We found p.Val472Glyfs*28 (c.1414_1415delTG) mutation in our case, our case’s father and the mother, unlike in other reports.

Treatment of EEDFS is generally symptomatic. Wound care and the diagnosis and treatment of secondary bacterial infections are important to reduce morbidity.²

exon 5 of the PKP1 gene, designated as c.897del5 (CAACC).⁸ We found p.Val472Glyfs*28 (c.1414_1415delTG) mutation in our case, our case’s father and the mother, unlike in other reports.

Treatment of EEDFS is generally symptomatic. Wound care and the diagnosis and treatment of secondary bacterial infections are important to reduce morbidity.²
Letters to the Editor

We are reporting this case due to the rarity in the literature. The detection of a new mutation for this disease makes it more interesting and adds to the present knowledge and understanding about the disease.

Table 1: Clinical characteristics of patients with Ectodermal dysplasia-skin fragility syndrome

| Case No | Age/race (in years) | Consanguineous | Skin fragility | Palmoplantar keratoderma | Alopecia | Hypohidrosis | Nail dystrophy | Cheilitis | Additional findings |
