Abstract: We perform imaging of a fundamental string from string scattering amplitudes, and show that its image is a double slit.
1 Introduction and summary

Have you ever seen a string? Since the discovery of string theory as a candidate for the unifying theory, the rich dynamics of strings has been revealed. For example, strings can be reconnected and be torn apart. They can be attached to branes or absorbed into. Furthermore, strings can undergo the transition to black holes. The black hole-string correspondence [1, 2] (see also [3, 4]) tells us that a single long string tends to shrink, if its self-gravity is turned on, and finally it becomes a black hole when its typical size reaches the Schwarzschild radius. Although it is expected that strings answer the microscopic degrees of freedom of black holes, secrets are still hidden inside horizons.

If possible, it would be worthwhile to shoot photos of a string. In physics and engineering, imaging technologies are widely used to take pictures of various objects. Imaging technologies allow us to investigate the inner structures of objects when they are hidden from the outside. Even if their structures are highly complicated, they provide us clear and intuitive ways to understand the structures. For example, the structure of the human body is highly complicated and cannot be seen directly from the outside. However, various imaging technologies, such as the X-ray imaging and the ultrasound wave imaging, enable us to study the functions of human organs, and find the causes of disease.

The string is a suitable target for applying such imaging technologies. The inner structure of a long string is unclear and expected to be highly complicated. And in fact, the traditional perturbative string theory is defined only through string scattering amplitudes, and thus if one wants to see a fundamental string itself, one needs the imaging from the scattering amplitudes, solving the inverse problem — it is a reconstruction of the internal structure by the scattering wave data.
In this paper, as the first step, we study tree-level scattering amplitudes of open bosonic fundamental strings, and reconstruct their images from the amplitudes. The imaging is just a Fourier transformation, as the standard optical theory tells. The reconstruction method works as an eye to look inside the scattering processes. The results of the imaging show that the images of the fundamental string are double-slits.

String scattering amplitudes have a lot of zeros, and we find that their pattern of brightness/darkness observed at the spatial infinity matches that of the standard double-slit experiment. This is the reason why the imaging via the string scattering amplitudes results in the images of the double slits.

As a simplest example, we consider the scattering of tachyons. We apply the imaging method to the s-channel pole of the Veneziano amplitude, and find that the image is a double slit. In the large level limit of the pole mass, the coincidence with the double slit is exact. We also apply the imaging method to the s-channel pole of the string decay amplitude of a highly excited string, using the amplitude obtained in [5, 6]. We find that the image is a set of multiple slits aligned on a straight line.

Slits in the images of the string scattering amplitudes are separated by the typical length of the fundamental string at the excited s-channel pole, which leads us to interpret that the slits are end points of the string.

Since the imaging technologies are natural to be applied to string theory, more applications in various situations will reveal hidden structure of a fundamental string.

This paper is organized as follows. In Sec. 2, we review the standard double-slit experiment, and present an imaging method to reconstruct a double-slit image from the amplitude on a screen. In Sec. 3, we study the Veneziano amplitude, and show that the image of a fundamental string read from the amplitude is indeed a double-slit. In Sec. 4, we apply the same method to other scattering process: a highly excited string decaying into two tachyons, and show that its image is a multi-slit. In Sec. 5, we provide possible interpretation of our results and discuss some implications to string physics.

2 Double-slit experiment

In this section, we review the standard double-slit experiment, and a method to reconstruct the image from the amplitude on a screen, to demonstrate that the amplitudes actually encodes the image of the double slit.

Let us put two slits S₁, S₂ on (z, x) = (±l/2, 0), and place the center of a spherical screen of radius L ≫ l at the origin. A wave with wavelength λₜₚ passes through the slits from the negative to the positive x-direction. An observer P is placed at (z, x) = (L cos θ', L sin θ') on the screen. See Fig. 1.

If the screen is sufficiently large, i.e. L ≫ l, the difference of two optical paths is given by

$$S₂P - S₁P \simeq l \cos \theta'.$$  \hspace{1cm} (2.1)
Figure 1. Double-slit is put at S\textsubscript{1} and S\textsubscript{2}, and scattered wave is observed at the point P.

Figure 2. The amplitude of waves in the double slit experiment, for $\pi l/\lambda_{ds} = 15$.

Thus the condition that the amplitude at P vanishes is

$$\cos \theta' \approx \frac{k' \lambda_{ds}}{2 l}$$

(2.2)

where $k'$ is an odd integer. More precisely, supposing that a spherical wave is emitted from the two slits with identical phase and amplitude $A$, the wave amplitude on the sphere placed at the spatial infinity $L(\gg l)$ is

$$A(\theta', \varphi') \approx 2A \cos \left(\frac{\pi l}{\lambda_{ds}} \cos \theta'\right).$$

(2.3)

Zeros of this amplitude is given by (2.2). The result is independent of another spherical coordinate $\varphi'$ as the slits are separated along the z-axis in this case.

The wave amplitude itself does not give the image of the slit, as understood in Fig. 2. Optical wave theory provides a method for the imaging. The popular method is just to put a lens of a finite size $d$ on the celestial sphere, and convert the wave amplitude with the frequency $\omega = 2\pi/\lambda_{ds}$ into the image on a virtual screen located at a focal point of the lens. The formula for converting the amplitude to the image is approximated just by a Fourier
transformation for $L \gg l$ (see [7, 8] for more details and brief reviews of the formula):

$$I(X, Y) = \frac{1}{(2d)^2 \sin \theta'_0} \int_{\theta'_0 - \tilde{d}}^{\theta'_0 + \tilde{d}} d\theta' \int_{\varphi'_0 - \tilde{d}/\sin \theta'_0}^{\varphi'_0 + \tilde{d}/\sin \theta'_0} d\varphi' e^{i\omega((\theta' - \theta'_0)X + (\varphi' - \varphi'_0)Y)} A(\theta', \varphi').$$

(2.4)

Here the coordinate $(X, Y)$ is the one on the virtual screen placed behind the lens, so the image $I$ of the optical wave is produced on that $XY$-plane. The location of the center of the lens is at $(\theta'_0, \varphi'_0) = (\theta'_0, \phi'_0)$, and a rectangular shape of the lens region is adopted for computational simplicity.

The lens size $d$ needs to cover at least several zeros of the amplitude to find a sharp image, otherwise the image is blur and no structure can be reconstructed from the amplitude. In the present case of the double-slit experiment, when one takes the limit $l \gg \lambda_{ds}$ the zeros of the amplitude are aligned densely, so the lens size $d$ can be taken quite small compared to $2\pi$. It means that the curvature effect of the celestial sphere in the imaging can be ignored and the formula (2.4) is validated.

Let us substitute the double-slit amplitude (2.3) into the imaging formula (2.4) and check if the image reproduces the shape (location) of the slits. The result is

$$I(X, Y) = A(-1)^{\tilde{k}} \sigma(Y/ \sin \theta'_0) \left( \sigma \left( X - \frac{l \sin \theta'_0}{2} \right) + \sigma \left( X + \frac{l \sin \theta'_0}{2} \right) \right)$$

(2.5)

where we have defined

$$\sigma(x) \equiv \frac{\sin \left( \frac{2\pi d}{\lambda_{ds}} x \right)}{\frac{2\pi d}{\lambda_{ds}} x}.$$  

(2.6)

See Fig. 3 for the meaning of this function $\sigma(x)$. The calculation is straightforward but we have just assumed that the center of the location of the lens satisfies the condition

$$\frac{l}{\lambda_{ds}} \cos \theta'_0 = \tilde{k} \in Z.$$  

(2.7)

to simplify the result. It can be met easily because we can find such an integer in the limit $l \gg \lambda_{ds}$ which we took as described above.

The density plots of the image function (2.5) are shown in Fig. 4. One clearly finds the position of the double slits. The parameters are chosen as: $2\pi d/\lambda_{ds} = 30$ and $l = 1$. The left figure is the image of the lens put at $(\theta'_0, \varphi'_0) = (\pi/2, 0)$. The location $\theta'_0 = \pi/2$ means that the lens is put at the right hand side in Fig. 1, facing the double slits head-on, and the distance between the images of the two slits should be the largest. On the other hand, when the location of the viewer is shifted in the $z$ direction in Fig. 1, the distance between the images of the slits should decrease. In fact, as seen in the middle and the right figures in Fig. 4, for $(\theta'_0, \varphi'_0) = (\pi/3, 0)$ and for $(\theta'_0, \varphi'_0) = (\pi/4, 0)$ respectively, one finds a consistent behavior.

In the next section, we apply this method for string scattering amplitudes, and see the images of the fundamental string.
Figure 3. The lens resolution, seen in the behavior of the function $\sigma(x)$ (2.6), for $2\pi d/\lambda ds = 10$ (left) and for $2\pi d/\lambda ds = 100$ (right). For large $d/\lambda ds$ (meaning that the wave length is small enough so that it detects many oscillations of the amplitude), this function is highly peaked at $x = 0$, and the resolution is high.

Figure 4. The $X$-$Y$ images of the double-slit experiment, reconstructed from the wave amplitudes at the spatial infinity. Left: seen from the head-on point $(\theta'_0, \varphi'_0) = (\pi/2, 0)$ facing the aligned slit. Middle: $(\theta'_0, \varphi'_0) = (\pi/3, 0)$. Right: $(\theta'_0, \varphi'_0) = (\pi/4, 0)$. As the viewer shifts from the head-on point, the distance between the slits decreases by the function $\sin \theta'_0$ consistently.

3 Images of string via Veneziano amplitude

In this section, we obtain the images of a fundamental string by using the Veneziano amplitude, and show that the fundamental string is a double-slit.

More specifically, we point out that the zeros of the Veneziano amplitude match the ones of the double-slit amplitude described in the previous Sec. 2. Then we reconstruct images of a string by the Fourier transformation of the Veneziano amplitude. The images show two columns (which are “slits”) standing apart at a distance of a typical length of strings.

3.1 Veneziano amplitude and its zeros

First, we describe our notation of the Veneziano amplitude, tachyon-tachyon to tachyon-tachyon scattering amplitude.

We label its four vertices with $1, 2, 2', 1'$. The momentum conservation law is

$$0 = p_1 + p_2 + p'_2 + p'_1. \quad (3.1)$$
Since each vertex is a tachyon, we have the on-shell condition
\[ p_1^2 = p_2^2 = p_1'^2 = p_2'^2 = -(-2). \] (3.2)

Here, we conventionally chose \( \alpha' = 1/2 \). In the following computations, we will use the same unit. The Mandelstam variables are defined as
\[ s = -(p_1 + p_2)^2 = -(p_1' + p_2')^2, \] (3.3)
\[ t = -(p_1 + p_2')^2 = -(p_1' + p_2)^2, \] (3.4)
\[ u = -(p_1 + p_1')^2 = -(p_2 + p_2')^2. \] (3.5)

These satisfy an identity
\[ s + t + u = 4 \cdot (-2). \] (3.6)

The Veneziano amplitude [9] is given by
\[ A_{\text{Ven}} = 2 \left[ A_{\text{st}}^{\text{Ven}} + A_{\text{tu}}^{\text{Ven}} + A_{\text{us}}^{\text{Ven}} \right], \] (3.7)
where
\[ A_{xy}^{\text{Ven}} = \frac{\Gamma(-\alpha(x))\Gamma(-\alpha(y))}{\Gamma(-\alpha(x) - \alpha(y))}, \quad \alpha(x) = 1 + x/2. \] (3.8)

The amplitude has \( s \)-channel poles at \( s = 2n \) for integers \( n \geq -1 \). Since we are interested in the images of a string formed at the scattering, we pull out one of the \( s \)-channel poles and look at the residue of the pole of the Veneziano amplitude. Using the reflection formula of the Gamma function and the identity (3.6), the residue of the \( s \)-channel pole is
\[ \tilde{A}_s^{\text{Ven}} = \lim_{s \to 2n} \frac{\sin \pi (-1 - s/2)}{\pi} \left( A_{\text{st}}^{\text{Ven}} + A_{\text{us}}^{\text{Ven}} \right) \]
\[ = \frac{1}{\Gamma(2 + n)} \left[ \frac{\Gamma(-1 - t/2)}{\Gamma(-2 - n - t/2)} + (t \leftrightarrow u) \right] = \frac{1}{\Gamma(2 + n)} \left[ \frac{\Gamma(-1 - t/2)}{\Gamma(2 + u/2)} + (t \leftrightarrow u) \right]. \] (3.9)

To evaluate this amplitude, we denote the magnitude of the momentum of the incoming tachyons is \( p \). In the center-of-mass frame, the momenta can be generically parametrized as
\[ p_1 = \begin{pmatrix} \sqrt{p^2 - 2} \\ p \sin \theta \\ p \cos \theta \end{pmatrix}, \quad -p_1' = \begin{pmatrix} \sqrt{p^2 - 2} \\ p \sin \theta' \cos \varphi' \\ p \sin \theta' \sin \varphi' \\ p \cos \theta' \end{pmatrix}, \]
\[ p_2 = \begin{pmatrix} \sqrt{p^2 - 2} \\ -p \sin \theta \\ -p \cos \theta \end{pmatrix}, \quad -p_2' = \begin{pmatrix} \sqrt{p^2 - 2} \\ -p \sin \theta' \cos \varphi' \\ -p \sin \theta' \sin \varphi' \\ -p \cos \theta' \end{pmatrix}. \] (3.10)
The parameter \( \theta \), which measures the angle of the incoming tachyon against the \( z \)-axis, will be fixed later for the convenience in numerical computations. Under this parametrization, the Mandelstam variables are expressed as

\[
\begin{align*}
    s &= 4(p^2 - 2) = 2n, \quad (3.11) \\
    t &= -2p^2(1 + \cos \theta \cos \theta' + \sin \theta \sin \theta' \cos \varphi'), \quad (3.12) \\
    u &= -2p^2(1 - \cos \theta \cos \theta' - \sin \theta \sin \theta' \cos \varphi'). \quad (3.13)
\end{align*}
\]

Let us look for zeros of the residue of the \( s \)-channel pole of the amplitude (3.9). It is zero if and only if

\[
0 = \Gamma(-1 - t/2)\Gamma(2 + t/2) + (t \leftrightarrow u) = \frac{\pi}{\sin \pi(-1 - t/2)} + (t \leftrightarrow u). \quad (3.14)
\]

This condition is equivalent to

\[
\begin{align*}
\pi(-1 - t/2) + \pi(-1 - u/2) &= 2\mathbb{Z}\pi, \quad (3.15) \\
\text{or } \pi(-1 - t/2) - \pi(-1 - u/2) &= (2\mathbb{Z} - 1)\pi. \quad (3.16)
\end{align*}
\]

If \( n \) is even, the first equation is satisfied for any angles. Then the amplitude is trivially zero. In the following discussion, we assume that \( n \) is odd. The second equation reduces to

\[
\cos \theta \cos \theta' + \sin \theta \sin \theta' \cos \varphi' = \frac{2\mathbb{Z} - 1}{n + 4}. \quad (3.17)
\]

Fixing \( \theta = 0 \) makes clear a comparison of this result to the double-slit experiment in Sec. 2. In the present case the zeros of the amplitude are at

\[
\cos \theta' = \frac{2k + n}{n + 4}, \quad (3.18)
\]

for an integer \( k \in \mathbb{Z} \). Rewriting this as

\[
\cos \theta' \simeq \frac{k'}{n + 4} = \frac{k'}{2p^2}, \quad (3.19)
\]

where \( k' \) is an odd integer, \( k' \in 2\mathbb{Z} - 1 \), we find that the location of the zeros is exactly the same as that of the double-slit experiment, (2.2), with the replacement

\[
p^2 = \frac{l}{\lambda_{ds}}. \quad (3.20)
\]

Here \( p \) is the magnitude of the tachyon momentum in the Veneziano amplitude, while \( l \) (\( \lambda_{ds} \)) is the slit-separation (wave length) in the double-slit experiment.

We have found here that the zeros of the Veneziano amplitude coincide completely with the double-slit experiment. In the next subsection, we look at the Veneziano amplitude in more detail and will find that indeed the imaging of the fundamental string results in a double-slit in the \( n \rightarrow \infty \) limit.
Figure 5. Images of a fundamental string, extracted and reconstructed from the $s$-channel pole of the Veneziano amplitude. The incoming angle is chosen as $\theta = \pi/2$. Various figures are for different choices of the viewer’s location (lens location) specified by $(\theta'_0, \varphi'_0)$. Brightness of these density plots is normalized in each plot. The red points in the images are the brightest points.

3.2 Imaging of a fundamental string

Here first we present images of a string by straightforward numerical evaluations, and after that, we analyze the images analytically in a certain limit to extract the structure.

The imaging formula described in Sec. 2 is

$$I(X, Y) = \frac{1}{(2d)^2 \sin^2 \theta'_0} \int_{\theta'_0 - d}^{\theta'_0 + d} \sin \theta'_0 \, d\theta' \int_{\varphi'_0 - d / \sin \theta'_0}^{\varphi'_0 + d / \sin \theta'_0} d\varphi' e^{ip((\theta' - \theta'_0)X + (\varphi' - \varphi'_0)Y)} \tilde{A}_{\text{Ven}}(\theta', \varphi'). \quad (3.21)$$

Here $d$ is the size of the lens whose center is put at $(\theta', \varphi') = (\theta'_0, \varphi'_0)$. The lens is applied to the wave signal $\tilde{A}_{\text{Ven}}(\theta', \varphi')$ which reached the asymptotic infinity with the angle $(\theta', \varphi')$ in the 2-dimensional spherical coordinate. The frequency of the wave, appearing in the formula (2.4), is now given by the tachyon momentum $p$. The wave amplitude is taken as the residue of the $s$-channel pole at $s = 2n$, of the Veneziano amplitude (3.9).

A straightforward numerical evaluation of the imaging (3.21) produces the images shown in Fig. 5 and Fig. 6. Since the tachyon scattering is in the center-of-mass frame, we can fix $\theta$ without losing generality. Fig. 5 and Fig. 6 are for $\theta = \pi/2$ and $\theta = \pi/4$, respectively, with $n = 11$. We find that in fact the images of the fundamental string are those of the double slits.
Analytic estimation of the image, which is useful to study the structure of the images, is possible. Let us investigate in particular the separation between the two slits. For simplicity let us take $\theta = 0$ to eliminate the $\varphi'$-dependence of the amplitude (3.9). We find

$$
\tilde{A}_{\text{Ven}} = \frac{1}{(n+1)!} \left[ \Gamma \left( \frac{n}{2} + 1 - \frac{n+4}{2} \cos \theta' \right) + \Gamma \left( \frac{n}{2} + 1 + \frac{n+4}{2} \cos \theta' \right) \right].
$$

(3.22)

To perform an analytic evaluation of the imaging formula for this amplitude, we need to find a simplified expression of the amplitude. A simplification occurs when we take a large $n$. Indeed, in the large $n$ limit the zeros are very close to each other, thus a small lens is sufficient for the imaging. This means that we need only a local expression of (3.22) around a certain value of $\theta'$.

Below, we obtain a simplified local expression of the amplitude around a zero specified by the integer $k$ given in (3.17). We present two expressions; one is for the region around the zero with $k = -(n+1)/2$, which means the expression for $\theta' \sim 0$ in the large $n$ limit, and the other is for a generic value of $k$.

First, notice that the amplitude (3.22) can be locally approximated by

$$
\tilde{A}_{\text{Ven}} \sim f(\theta') \cos (c\theta'),
$$

(3.23)

where $c$ is a constant dependent on the choice of $k$ of the central zero, and $f(\theta')$ is some smooth positive function giving the magnitude of the oscillation. This is obvious if we look...
at the plot of the amplitude (3.22) given in Fig. 7. The amplitude has zeros at (3.17) and does not diverge, so it can be approximated by the form (3.23) with a very simple function \( f(\theta') \).

The derivation of the explicit form of \( f(\theta') \) and the constant \( c \) is simple. The latter can be fixed by the distribution of the location of the zeros given in (3.17), and the magnitude function \( f(\theta') \) can be fixed by evaluating the slope of the amplitude at those zeros. A straightforward calculation shows

\[
\tilde{A}^\text{Ven}(\theta') \sim \pm \left[ \frac{2}{\pi n C_n^2} \right] \cos \left( \frac{n\pi}{2} \left( \theta' - \frac{\pi}{2} \right) \right) \quad (\theta' \sim \theta'_0 = \pi/2) \tag{3.24}
\]

This expression tells us that the magnitude function \( f(\theta') \) is constant around \( \theta' = \pi/2 \). And for a generic \( k \) (which means \( \theta' \sim \theta'_0 \) for generic \( \theta'_0 \)), we find

\[
\tilde{A}^\text{Ven}(\theta') \sim \pm \left[ \frac{2}{n\pi n C^2_n (1 - \cos \theta'_0)} \right] \left( \frac{1 - \cos \theta'_0}{1 + \cos \theta'_0} \right)^{-(n\sin \theta'_0/2)(\theta' - \theta'_0)} \cos \left( \frac{n\pi \sin \theta'_0}{2} (\theta' - \theta'_0) \right). \tag{3.25}
\]

We can see that the magnitude function \( f(\theta') \) is an exponentially growing function. As a consistency check, if one puts \( \theta'_0 = \pi/2 \) in this expression (3.25), it reduces to (3.24)\(^1\).

Let us evaluate the imaging formula (3.21) with these large-\( n \) approximated amplitudes (3.24) and (3.25). For the case \( \theta' \sim \pi/2 \), the expression (3.24) is completely the same as that of the double slit (2.3), and we find

\[
I_{\theta_0=\pi/2}(X,Y) \propto \sigma(Y) [\sigma(X - \pi p) + \sigma(X + \pi p)] \tag{3.26}
\]

where

\[
\sigma(x) \equiv \frac{\sin(pdx)}{pdx}. \tag{3.27}
\]

\(^1\)Note that the difference factor \( 1/n \) is irrelevant as it comes out by just how the combinatoric factor \( n C^2_n (1 - \cos \theta'_0) \) is evaluated in the sub-leading order in the large \( n \) expansion. In any case, the overall constant factor is not the issue to look at the structure of the images.
The function $\sigma$ is, as was described for the case of the double-slit experiment, is highly peaked at $x = 0$ in the limit $p \to \infty$. Thus the bright spots in the image are localized at

$$(X, Y) = (\pm \pi p, 0). \quad (3.28)$$

This is in fact a double slit. In the limit $n \simeq 2p^2 \to \infty$, the image consists of just two bright point-like spots, and the coincidence with the double-slit experiment is exact.

The distance $\Delta$ between the two bright points in the image is given by

$$\Delta = \pi \sqrt{2n} \quad (3.29)$$

in the string length unit $l_s = 1/\sqrt{2}$ which we took throughout the paper. The behavior $\Delta \sim \sqrt{n} l_s$ is consistent with the approximate length of a fundamental string at the excitation level $n$, as we will discuss in Sec. 5.

Next, let us evaluate the images with the generic $\theta'_0$ using (3.25). The result is

$$I_{\theta_0=\theta'_0}(X, Y) \propto \sigma\left(\frac{Y}{\sin \theta'_0}\right) \left[\sigma\left(X - \frac{\Delta(\theta'_0)}{2} + i\bar{X}_0\right) + \sigma\left(X + \frac{\Delta(\theta'_0)}{2} + i\bar{X}_0\right)\right] \quad (3.30)$$

where

$$\Delta(\theta'_0) \equiv \pi \sqrt{2n} \sin \theta'_0, \quad \bar{X}_0 \equiv \sqrt{\frac{n}{2}}(\sin \theta'_0) \log \frac{1 + \cos \theta'_0}{1 - \cos \theta'_0}. \quad (3.31)$$

This means that there are two slits which are located, in the complexified coordinates,

$$(X, Y) = \left(\pm \frac{\Delta(\theta'_0)}{2} + i\bar{X}_0, 0\right). \quad (3.32)$$

The imaginary part contributes to make the peak of $\sigma(x)$ smoother, as the pole deviates from the real axis. The real part gives a physical consistency with the spatial location of the double-slit: the distance between the bright spots in the image is $\Delta(\theta'_0)$. The factor $\sin \theta'_0$ in this $\Delta(\theta'_0)$ is expected from the spatial consistency since the position of the viewer is shifted from the equator and thus the two slits should be seen at an angle, exactly giving the factor $\sin \theta'_0$. Thus we conclude that the images seen at angle are spatially consistent with each other, which is a nontrivial check for the image slits to be present in the real space.

4 Images of highly excited string

In this section, we show that the slit-like behavior of a string is not limited to the Veneziano amplitude. As another clean example, we study a highly excited string (HES) decaying to two tachyons.

The amplitude formula for a HES decaying to two tachyons was computed in [5, 6]. We will briefly review their results but with slight modifications. Later, we list the location of the amplitude zeros, and point out that its amplitude zeros also match the ones of the double-slit in Sec. 2. Then we reconstruct images of a HES by the Fourier transformation of the amplitude. The images show multi-slits, which are understood as convolutions of double-slits.
4.1 Amplitude and its zeros

Following [6], we start with a string scattering amplitude for

tachyon, $J$ photons $\rightarrow$ 2 tachyons

as depicted in Fig. 8. After computing the amplitude, we pick out a pole which corresponds to an intermediate HES state. Momenta of one incoming tachyon and two outgoing tachyons are denoted by $p_1$, $p_2$ and $p_3$. Momenta of $J$ photons are chosen to be proportional to a null vector, $q$, and are given by $-N_a q$, where $N_a$ are integers and $a = 1, \cdots, J$. The momentum conservation law is

$$0 = (p_1 - Nq) + p_2 + p_3 \quad (4.1)$$

where

$$N = \sum_{a=1}^{J} N_a, \quad (N_a \geq 1) \quad (4.2)$$

When a pole of the intermediate state is picked out, $N$ and $J$ will be interpreted as the excitation level and the angular momentum of the HES, respectively. The on-shell conditions for the tachyon momenta are

$$p_1^2 = p_2^2 = p_3^2 = -(-2). \quad (4.3)$$

For simplicity, polarizations of photons are taken to be equal to each other and denoted by $\lambda$. Then, the conditions for the photon momenta and polarizations are given by

$$q^2 = 0, \quad \lambda^2 = 0, \quad q \cdot \lambda = 0. \quad (4.4)$$

For simplicity, we assume that

$$(p_2 + p_3) \cdot \lambda = 0. \quad (4.5)$$
This condition is satisfied, for example, in the center-of-mass frame. Then the amplitude is factorized as

\[ \mathcal{A}^{\text{HES}} = \prod_{a=1}^{J} \mathcal{A}_a, \quad \text{(4.6)} \]

\[ \mathcal{A}_a = \frac{(-p_2 \cdot \lambda) - (-p_3 \cdot \lambda)}{2} \times \left[ \frac{\Gamma(-\alpha_1^{(a)} + 1)\Gamma(-\alpha_2^{(a)}) - \Gamma(-\alpha_2^{(a)})\Gamma(-\alpha_3^{(a)}) + \Gamma(-\alpha_3^{(a)})\Gamma(-\alpha_1^{(a)} + 1)}{\Gamma(-\alpha_1^{(a)} - \alpha_2^{(a)} + 1)} \right], \quad \text{(4.7)} \]

where

\[ \alpha_i^{(a)} = N_a p_i \cdot q. \quad \text{(4.8)} \]

Each factor of the amplitude, \( \mathcal{A}_a \) has poles when \( 1 - \alpha_1^{(a)} \) is a negative integer. Poles at \( \alpha_1^{(a)} \sim N_a, \) \( \text{(4.9)} \) are located at the same position in the momentum space,

\[ v = -(p_1 - Nq)^2 \sim 2(N - 1). \quad \text{(4.10)} \]

Picking out this pole, we have a HES at an intermediate state. By taking the residues of \( \mathcal{A}_a \), we obtain the decay of the HES with the mass

\[ M^2 = 2(N - 1), \quad \text{(4.11)} \]

and the total angular momentum \( J \). Using an identity \( \alpha_1^{(a)} + \alpha_2^{(a)} + \alpha_3^{(a)} = 0 \), and the condition of the pole, \( \alpha_1^{(a)} \sim N_a \), we find

\[ \tilde{\mathcal{A}}^{\text{HES}} = \lim_{v \rightarrow 2(N-1)} \left( \prod_{a=1}^{J} \frac{\sin \pi \alpha_1^{(a)}}{\pi} \right) \mathcal{A}^{\text{HES}} \]

\[ = \prod_{a=1}^{J} \frac{(-p_2 \cdot \lambda) - (-p_3 \cdot \lambda)}{2} \left[ \frac{\Gamma(-\alpha_2^{(a)})}{\Gamma(N_a)\Gamma(-\alpha_2^{(a)} - N_a + 1)} + (2 \leftrightarrow 3) \right] \]

\[ = \prod_{a=1}^{J} \frac{(-p_2 \cdot \lambda) - (-p_3 \cdot \lambda)}{2} \left[ \frac{\Gamma(-\alpha_2^{(a)})}{\Gamma(N_a)\Gamma(\alpha_3^{(a)} + 1)} + (2 \leftrightarrow 3) \right] \quad \text{(4.12)} \]

Here, the first term is a contribution studied in [6].

In the center-of-mass frame, we take the following parametrization of the momenta,

\[ -q = \frac{1}{\sqrt{2N - 2}} \begin{pmatrix} 1 \\ 0 \\ 0 \\ -1 \end{pmatrix}, \quad \lambda = \frac{1}{\sqrt{2}} \begin{pmatrix} 0 \\ 1 \\ i \\ 0 \end{pmatrix}, \quad \text{(4.13)} \]

\[ p_1 - Nq = \begin{pmatrix} \sqrt{2N - 2} \\ 0 \\ 0 \\ 0 \end{pmatrix}, \quad -p_2 = \begin{pmatrix} \sqrt{2N - 2}/2 \\ \sqrt{2N + 6}/2 \sin \theta' \\ 0 \\ \sqrt{2N + 6}/2 \cos \theta' \end{pmatrix}, \quad -p_3 = \begin{pmatrix} \sqrt{2N - 2}/2 \\ -\sqrt{2N + 6}/2 \sin \theta' \\ 0 \\ -\sqrt{2N + 6}/2 \cos \theta' \end{pmatrix}. \quad \text{(4.14)} \]
Under this parametrization, the variables \( \alpha_i^{(a)} \) are expressed as

\[
\alpha_1^{(a)} = N_a, \\
\alpha_2^{(a)} = -\frac{N_a}{2} \left( 1 + \frac{\sqrt{2N + 6}}{\sqrt{2N - 2}} \cos \theta' \right), \\
\alpha_3^{(a)} = -\frac{N_a}{2} \left( 1 - \frac{\sqrt{2N + 6}}{\sqrt{2N - 2}} \cos \theta' \right).
\]

Let us look for zeros of the amplitude (4.12). It is zero if and only if

\[
0 = (-p_2 \cdot \lambda) = -(-p_3 \cdot \lambda),
\]

or

\[
0 = \Gamma(-\alpha_2^{(a)}) \Gamma(\alpha_2^{(a)} + 1) + (2 \leftrightarrow 3)
\]

for some \( 1 \leq a \leq J \). Calculations similar to those in Sec. 3 show that the amplitude is trivially zero if some \( N_a \) is even. In the following discussion, we assume that \( N_a \)'s are odd for any \( 1 \leq a \leq J \). Then we find that the zeros of the amplitude are at

\[
\frac{\sqrt{2N + 6}}{\sqrt{2N - 2}} \cos \theta' = \frac{2Z - 1}{N_a}.
\]

In the high excitation limit \( N_a \to \infty \), it is written as

\[
\cos \theta' \simeq \frac{k'}{N_a},
\]

where \( k' \) is an odd integer, \( k' \in 2Z - 1 \). We find that the location of the zeros is exactly the same as that of the double-slit experiment, (2.2), with the replacement

\[
\frac{N_a}{2} = \frac{l}{\lambda_{ds}}.
\]

Here \( N_a \) is an excitation level of the \( a \)-th mode such that \( N = \sum_a N_a \), while \( l \) (\( \lambda_{ds} \)) is the slit separation (wave length) in the double-slit experiment.

### 4.2 Imaging of a highly excited string

Here first we present images of a HES by straightforward numerical evaluations, and then understand the images analytically in a certain limit.

Since the amplitude depends only on the outgoing angle \( \theta' \), we restrict ourselves to imaging in this single direction. We use the following imaging formula

\[
I(X) = \frac{1}{(2d)^2 \sin \theta_0'} \int_{\theta_0' - d}^{\theta_0' + d} d\theta' e^{ip(\theta' - \theta_0')} A_{\text{HES}}^v \theta'(\theta').
\]

Here \( p \) is now the magnitude of the outgoing tachyon momentum \( p = \sqrt{2N + 6}/2 \). A straightforward numerical evaluation of the imaging formula (4.23) produces the images shown in Fig. 9. Both of the images are for \( \theta_0' = \pi/2 \), but with different numbers of excitations of \( N = \sum_{a=1}^J N_a \). We find that the images of a HES are those of multi-slits.
Figure 9. Images of a highly excited string, extracted and reconstructed from a HES intermediate state pole of the tachyon-photon amplitude. The size of the imaging lens is chosen as $d = 0.11$. The left panel, for a division $N = N_1 + N_2 = 19 + 39$, shows a 4-slit, while the right panel, for $N = N_1 + N_2 + N_3 = 19 + 39 + 79$, shows an 8-slit.

Such multi-slit structures can simply be understood by using the results in the Veneziano amplitude. When $N_a \gg 1$, the amplitude (4.12) reduces to a simple form

$$\tilde{A}_v^{\text{HES}} \simeq \prod_{a=1}^J \sin \theta' \left[ \frac{\Gamma \left( \frac{N_a}{2} (1 + \cos \theta') \right)}{\Gamma \left( \frac{N_a}{2} (1 - \cos \theta') \right)} + \frac{\Gamma \left( \frac{N_a}{2} (1 - \cos \theta') \right)}{\Gamma \left( \frac{N_a}{2} (1 + \cos \theta') \right)} \right] \tag{4.24}$$

up to a constant. Remark that each factor inside $\prod_{a=1}^J$ coincides with the Veneziano amplitude at $\theta = 0$ (3.22) with the replacement $n \rightarrow N_a$,

$$\tilde{A}_v^{\text{HES}} \simeq (\sin \theta')^J \prod_{a=1}^J \tilde{A}_v^{\text{Ven}} \bigg|_{n \rightarrow N_a} . \tag{4.25}$$

Thus the reconstructed image of a HES, the Fourier transformation of $\tilde{A}_v^{\text{HES}}$, is the convolution of the images of the Veneziano amplitudes with $n \rightarrow N_a$ as,

$$I^{\text{HES}} \simeq (\sin \theta')^J \star \prod_{a=1}^J I^{\text{Ven}} \bigg|_{n \rightarrow N_a} \star \ldots \star I^{\text{Ven}} \bigg|_{n \rightarrow N_J} . \tag{4.26}$$

Recall that the image of the Veneziano amplitude $I^{\text{Ven}}$ is a double-slit with a slit separation $l/\lambda_{\text{ds}} \simeq n/2$. With replacements $n \rightarrow N_a, \lambda_{\text{ds}} \rightarrow 1/\sqrt{N}$, the image of a HES is the convolution of double-slits with separations $\Delta_a \sim N_a/\sqrt{N}$. Then we can conclude that the image of a HES is a $2^J$-slit. Indeed it can be easily demonstrated that the convolution of double-slits with different slit separations is a multi-slit. Let

$$I_a(X) = \delta \left( X - \frac{\Delta_a}{2} \right) + \delta \left( X + \frac{\Delta_a}{2} \right) \tag{4.27}$$

be an ideal image of a double-slit with the slit separation $\Delta_a$. Then its convolution

$$I_a \star I_b(X) = \int_{-\infty}^{\infty} \! dX' \ I_a(X') I_b(X - X')$$

$$= \sum_{s_1, s_2 = \pm 1} \delta \left( X + s_1 \frac{\Delta_a}{2} + s_2 \frac{\Delta_b}{2} \right) \tag{4.28}$$
is a $2^2$-slit. Performing similar operations recursively, we can show that $J$-times convolution of the double-slit with different slit-separations is a $2^J$-slit as\footnote{Particularly when $\Delta_n/\Delta_1 \simeq 2^a$, the slits are equally separated.}

$$I_1 \ast \cdots \ast I_J(X) = \sum_{s_a=\pm 1} \delta(X + s_1 \Delta_1 \cdots + s_J \Delta_J). \quad (4.29)$$

We conclude that the image of the highly excited string reconstructed from its decay amplitude is a multi-slit.

5 Interpretation

In this section, we present several observations from the results obtained above, and provide their possible interpretations.

Firstly, we point out that the slit-like appearance of scattering amplitude images is an inherent feature of strings. Recall, for example, the Veneziano amplitude. At the zeros of the amplitude (3.17), each term of (3.9) becomes zero simultaneously. There is no non-trivial cancellation between the two terms. In other words, the zeros of the amplitude originate in the gamma functions in the denominator. These gamma functions are also the source of poles which correspond to intermediate excited string states. Thus the existence of a series of zeros (3.17) reflects the existence of a series of intermediate states in string theory. Remember that, contrary to string theory, perturbative quantum field theories have only a few intermediate states, and scatterings occur at a point.

Secondly, it is remarkable that the order of slit separations agrees with that of the total string length. Recall that the slit separations in the Veneziano amplitude and in the HES scattering amplitude (with $J = 1$) are

$$\Delta^\text{Ven} \sim \sqrt{n} l_s, \quad \Delta^\text{HES} \sim \sqrt{N} l_s, \quad (5.1)$$

respectively. Here $n$ is roughly the square of the invariant mass, and $N$ is roughly the square of the mass of a HES. On the other hand, the total length of a string with a mass $M$ is roughly estimated as

$$l_{\text{total}} \sim \frac{1}{\alpha'} M \sim \sqrt{N} l_s \quad (5.2)$$

since a string has a constant tension $\alpha'$. Thus, the slit separation and string length coincide with each other, meaning that the string may extend between the slits.

Thirdly, we stress that slits can only show up on a straight line both in the Veneziano amplitude and the HES amplitude. Technically, this is because the $\theta'$ dependence of their amplitude zeros is only in the form of $\pm \cos \theta'$. In fact, other types of $\theta'$ dependence with non-trivial phases $\cos(\theta' - \varphi')$ are required for the slit to show up away from the straight line. This can be easily demonstrated as follows. Suppose that we have three slits $S_1, S_2, S_3$ which are not on a straight line as in Fig. 10. If the location of $S_3$ is $(z, x) = (0, -l'/2)$,
Figure 10. Three slits are put at $S_1$, $S_2$, $S_3$, and scattered wave is observed at the point $P$. 

the optical path lengths are

\begin{align}
S_1P - OP &= \frac{l}{2} \cos \theta', \\
S_2P - OP &= +\frac{l}{2} \cos \theta', \\
S_3P - OP &= +\frac{l'}{2} \cos(\theta' - \pi/2).
\end{align}

Thus the location of the amplitude zeros depends not only on $\pm \cos \theta'$ but also on the phase-shifted $+ \cos(\theta' - \pi/2)$.

From these observations, we can provide an interpretation that the location of slits are the end points of a string. Firstly, we should remark that the order of the slit separation is not the random walk size $l \sim M^{1/2} \sim N^{1/4}$, but rather it is the total length of the string $L \sim M \sim N^{1/2}$. It motivates us to assume that the string behaves like a simple harmonic oscillator in the scattering processes.

Then there remain two possibilities: the locations of slits indicate (i) the nodes, or (ii) the end points, of the vibrating string. The first possibility is excluded since the HES amplitude with $J = 1, N \gg 1$ behaves like a double-slit as discussed in Sec. 4. If the nodes of the vibrating string are the origin of the slit image, the HES image with $J = 1, N \gg 1$ would have been a multi-slit, rather than the double-slit. Since this is not the case, thus we are left with the possibility (ii): slits are end points of the string.

Such an interpretation is also supported by the following scenarios. Suppose there is a classical vibrating string with markers attached to its end points, as an analogy of the world sheet with open string vertex operators inserted at its boundary. The long time average of the probability that the markers are found at a point $X$ is roughly evaluated by

\[
\int_0^T \frac{dt}{T} \delta(X - X_0 \sin \omega t) \sim \frac{1}{\sqrt{X_0^2 - X^2}}.
\]

\[\text{---} \]

\[3\text{The existence of such a slit-like structure within a scattering region is a sign of chaos. The chaoticity of string scatterings will be discussed in the authors’ next paper in preparation [10].}\]
Then it becomes maximum at the point where the string is fully extended to its maximum size. This is consistent with our results where slits appeared with the slit separations of the order of the total string length.

Another scenario is about the origin of interference patterns. Suppose that incoming two strings are shot along the \( z \)-direction and scattered at the origin. Our results have shown that if this scattering is observed from the \( x \)-direction, the image is the double-slit lined up along the \( z \)-direction. It would be natural to imagine that a string formed at the origin vibrates along the \( z \)-direction, and is torn apart when the string reaches its maximum length. Each of two pieces of the broken string can be scattered in any directions, though one must go in the opposite direction to the other. The observer in the \( x \)-direction can detect the scattered string with a definite probability. At the observation, the observer has two possibilities: the left one of the two pieces of the broken string reaches the observer while the right one goes in the opposite direction, or visa versa. The superposition of these two possibilities would be the source of the interference patterns which appear in the string scattering amplitudes.

These scenarios encourage us to state that the slits are the end points of a fundamental string.
