Cardiac mitochondrial phospholipid acyl chains regulate respiratory enzymatic activity. In several diseases, the rodent cardiac phospholipidome is extensively rearranged; however, whether specific acyl chains impair respiratory enzyme function is unknown. One unique remodeling event in the myocardium of obese and diabetic rodents is an increase in docosahexaenoic acid (DHA) levels. Here, we first confirmed that cardiac DHA levels are elevated in diabetic humans relative to controls. We then used dietary supplementation of a Western diet with DHA as a tool to promote cardiac acyl chain remodeling and to study its influence on respiratory enzyme function. DHA extensively remodeled the acyl chains of cardiolipin (CL), monolysoc-CL, phosphatidylcholine, and phosphatidylethanolamine. Moreover, DHA lowered enzyme activities of respiratory complexes I, IV, V, and I + III. Mechanistically, the reduction in enzymatic activities was not driven by a dramatic reduction in the abundance of supercomplexes. Instead, replacement of tetralinoleoyl-CL with tetracosahexaenoyl-CL in biomimetic membranes prevented formation of phospholipid domains that regulate enzyme activity. Tetracosahexaenoyl-CL inhibited domain organization due to favorable Gibbs free energy of phospholipid mixing. Furthermore, in vitro substitution of tetralinoleoyl-CL with tetracosahexaenoyl-CL blocked complex IV binding. Finally, reintroduction of linoleic acid, via fusion of leoyl-CL with tetracosahexaenoyl-CL in biomimetic membranes prevented formation of phospholipid domains that regulate enzyme activity. Tetradocosahexaenoyl-CL inhibited domain organization due to favorable Gibbs free energy of phospholipid mixing. Furthermore, in vitro substitution of tetralinoleoyl-CL with tetracosahexaenoyl-CL blocked complex IV binding. Finally, reintroduction of linoleic acid, via fusion of phospholipid vesicles to mitochondria isolated from DHA-fed mice, rescued the major losses in the mitochondrial phospholipidome and complexes I, IV, and V activities. Altogether, our results show that replacing linoleic acid with DHA lowers select cardiac enzyme activities by potentially targeting domain organization and phospholipid–protein binding, which has implications for the ongoing debate about polyunsaturated fatty acids and cardiac health.

Mitochondria have a central role in cardiac physiology by handling differing substrates such as pyruvate and fatty acids to produce the ATP needed to maintain homeostasis. In a range of metabolic diseases such as obesity, type 2 diabetes, heart failure, ischemia–reperfusion injury, and diabetic cardiomyopathies, cardiac mitochondria are subject to considerable dysregulation (1–5). One key impairment with cardiac mitochondria is the extensive remodeling of phospholipid acyl chains, most notably of the unique mitochondrial-specific phospholipid, cardiolipin (CL) (6, 7). For example, in diabetic cardiomyopathies, CL acyl chains undergo modifications that broadly include the depletion of the most abundant CL species (18:2)ω6, as well as an increase in longer polyunsaturated acyl chains (8, 9). In fact, the remodeling of mitochondrial phospholipid acyl chains is not just limited to cardiomyopathies, but is also reported with various other conditions such as aging, obesity, and Barth syndrome (10, 11).

The mechanisms by which phospholipid acyl chain remodeling promotes mitochondrial dysfunction remain unclear. Phospholipid acyl chains, particularly linoleic acid associated with CL, bind a multitude of trans-membrane and membrane-associated enzymes to regulate their activity. For instance, CL binds oxidative phosphorylation complexes I and III–V and the mobile electron carrier cytochrome c (12–17). However, it is unknown how remodeling of CL to specific fatty acids influences enzyme function.

DHA remodels the cardiac lipidome to lower enzyme activity

One unique remodeling event in the mitochondrial phospholipidome is an increase in the abundance of phospholipid species containing the long chain n-3 polyunsaturated fatty acid (PUFA) docosahexaenoic acid (DHA, 22:6) (6, 8, 9, 18). The elevation of cardiac DHA in differing cardiovascular diseases is highly paradoxical because this fatty acid is considered cardioprotective in animal models with some supporting evidence in humans (19, 20). A recent systematic review on the effects of n-3 PUFA supplementation in human subjects suggested that long-chain n-3 PUFAs can be used for ameliorating cardiovascular disease risk factors (21). However, not all research supports the health benefits of DHA. For instance, a rodent study showed that DHA did not improve cardiomyopathy induced by a Western diet (22).

Here, we used dietary intervention as a tool to study remodeling of mitochondrial phospholipids on respiratory enzyme activity. We first confirmed that cardiac DHA levels are elevated in human diabetics. We then established the metabolic profile of mice consuming Western diets in the absence or presence of DHA in addition to eicosapentaenoic acid (EPA). Next, the effects of experimental diets on the mitochondrial phospholipidome were investigated. The focus was on phosphatidylcholine (PC), phosphatidylethanolamine (PE), and CL because they are the most abundant phospholipids in the mitochondria by mass at 40, 30, and 15–20%, respectively (23). We then determined whether the experimental diets impaired mitochondrial respiratory enzyme activities because CL binds several of these enzymes (14, 16, 24–29). Mechanistically, we investigated whether DHA lowered enzyme activities due to modifications in the formation of supercomplexes, assembly of lipid domains that regulate protein activity, and phospholipid–protein-binding interactions (30–32). Finally, experiments were conducted to determine whether reintroduction of linoleic acid into mitochondria isolated from mice consuming DHA rescued remodeling in the phospholipidome and thereby enzymatic function.

Results

Cardiac DHA levels are elevated in human diabetics

Data from rodent studies demonstrate that cardiac DHA levels are elevated in different diseases (9, 18); however, evidence in humans is lacking. Therefore, cardiac DHA levels from non-diabetic and diabetic subjects were first assayed. Mitochondria could not be isolated because there was extremely limited tissue samples from surgery. Furthermore, fatty acid analyses had to be conducted with total extracted fatty acids due to the small amount of tissue obtained during surgery. Analyses with gas chromatography revealed that diabetics, compared to non-diabetics, had no changes in the relative levels of saturated fatty acids (Fig. 1A). The monounsaturated fatty acid 16:1 was lowered by 2.4-fold with diabetic subjects relative to the non-diabetics (Fig. 1B). n-6 PUFA levels were not modified (Fig. 1C). Analyses of the major n-3 PUFA showed that DHA levels were increased by 1.7-fold for the diabetic subjects compared with non-diabetic controls (Fig. 1D).

Subsequent studies were conducted with mice. It was first established how murine experimental diets influenced fat/lean mass, glucose clearance, and fasting insulin levels. The effects of EPA and DHA were tested at two different time points, including consumption of the fatty acids for 14 weeks or for 4 weeks (Fig. 2A). Mice fed the Western diet and the EPA- or DHA-enriched Western diets had increased total body weights by 1.3–1.4-fold relative to the lean control (Fig. 2B). The increase in total body weight was accounted for by an increase in fat mass with the Western and EPA- or DHA-enriched Western diets by 1.9–2.1-fold relative to the control (Fig. 2C). Mice fed the Western + EPA diet (14 and 4 weeks) and the Western + DHA diet (4 weeks) had elevated lean mass compared with lean animals (Fig. 2D). Mice fed the Western diets in the absence or presence of EPA or DHA generally had diminished glucose clearance (Fig. 2E), as quantified by the area under the curve (AUC) for glucose clearance (Fig. 2F). The only exception was the Western diet + EPA (4 weeks) (Fig. 2F). Mice fed the Western diets in the absence and presence of EPA (4 weeks) or DHA (14 and 4 weeks) had increased fasting insulin levels in comparison with lean mice (Fig. 2G). The Western + DHA diet (14 and 4 weeks) increased fasting glucose levels compared with the control and/or the Western diet (for 14 weeks) (Fig. 2H). HOMA-IR scores were consistently increased with all of the Western diets, except the WD + EPA (14 weeks), relative to lean mice (Fig. 2I). There were no statistically significant differences between EPA and DHA (14 and 4 weeks) for HOMA-IR scores. Altogether, the data suggested that supplementation with EPA or DHA did not improve glucose clearance, although long-term intake with EPA did not increase the HOMA-IR score relative to lean mice, consistent with previous work (33).

Murine cardiac mitochondrial CL and monolysoc-CL acyl chains are dramatically remodeled in response to Western diets in the absence and presence of EPA and DHA

We next established how the Western diets, particularly in the presence of EPA and DHA, targeted CL and monolysoc-CL (MLCL) acyl chains. An example of the raw LC/MS data are presented in Fig. S1A–D. LC/MS analyses are presented as heat maps in Fig. 3. CL species were classified as either major (Fig. 3A), intermediate (Fig. 3B), or minor (Fig. 3C) in terms of abundance. MLCL levels are shown in Fig. 3D.

The most abundant CL species, (18:2)n, was robustly reduced with all of the Western diets by 4.3–20.0-fold (Fig. 3A and Fig. S2, A–F). The Western diet, in the absence of EPA (4 and 14 weeks) or DHA (4 and 14 weeks), also increased a range of other major CL species relative to the control and the Western diet (Fig. 3A). CL species containing 22:6 were elevated in response to EPA intervention and robustly with DHA intervention (4 and 14 weeks). The increase in differing CL species came at the expense of lowering a range of CL species, notably containing 18:2 and 20:4 acyl chains (Fig. 3A). Several intermediate and minor CL species were also increased or decreased with the Western diet, in the absence or presence of EPA or DHA, when compared with the control by 2.0–14.0-fold (Fig. 3, B and C). There were also some differences between EPA and DHA (Fig. S2, A–F).
Murine cardiac mitochondrial PC and PE acyl chains are remodeled in response to a Western diet in the absence and presence of EPA and DHA

LC/MS analyses were also conducted with PC and PE phospholipids. Generally, the Western diet in the absence and presence of EPA (14 and 4 weeks) and DHA (14 and 4 weeks) lowered the abundance of PCs containing 16:0, 18:1, 18:2, and 20:3 acyl chains by 1–2-fold compared with the lean controls (Fig. 4A). For some species such as (18:2)PC, the effects were more robust with DHA (14 and 4 weeks) compared with EPA (14 and 4 weeks) (Fig. 4A). DHA also notably increased the levels of (18:2)(20:4)PC compared with control, Western diet, and Western diet/EPA fed mice. Similar trends were observed with PEs, where the Western diet in the absence or presence of EPA (14 and 4 weeks) and DHA (14 and 4 weeks) lowered species containing 16:0, 18:1, and 18:2 acyl chains (Fig. 4B). DHA had stronger effects than EPA on some PEs (Fig. 4B).

Cardiac mitochondrial respiratory enzyme activities are decreased with the EPA- and DHA-enriched Western diets

Subsequent experiments addressed whether the aforementioned changes in the mitochondrial phospholipidome were associated with impaired respiratory enzyme activities. We focused on long-term intake of EPA and DHA (14 weeks). Strikingly, mice that consumed the Western diet did not have a reduction in enzyme activities and combined enzyme activities when compared with the lean control (Fig. 5, A–G). The Western + EPA and Western + DHA diets (14 weeks), respectively, reduced complex I activity by 1.8- and 1.9-fold relative to the control diet (Fig. 5A). The EPA- and DHA-containing diets had no effect on complex II (Fig. 5B) and complex III (Fig. 5C) activities. Complex IV activity was lowered with the EPA- or DHA-enriched Western diets relative to the control and/or Western diet by 1.8–2.7-fold (Fig. 5D). The Western + DHA diet (14 weeks) also modestly reduced complex V activity by 0.6-fold relative to the control (Fig. 5E). The Western + DHA diet decreased the combined activities of complex I + III by 2.0-fold compared with the control (Fig. 5F). There was no effect of EPA- and DHA-enriched Western diets on complex II + III activities (Fig. 5G).

EPA and DHA do not robustly suppress formation of the major supercomplexes

The next study addressed whether decreased enzyme-specific activities with EPA or DHA (14 weeks) were mechanistically driven by a reduction in mitochondrial supercomplex formation or in the expression levels of the complexes (34). Long-term intake of EPA or DHA had no major effect on the majority of the supercomplexes, which are depicted as supercomplexes
Figure 2. Metabolic profile of mice consuming a Western diet in the absence or presence of EPA and DHA for differing time points. A, schematic of the diet feeding schedule for mice consuming the control (CON), Western diet (WD), and Western diet containing EPA or DHA ethyl esters. B, body weights at the end of the 14-week feeding period. Fat (C) and lean (D) mass was determined by Echo-MRI. E, whole-body glucose tolerance test was performed by intraperitoneal injection of glucose after a 5-h fast. F, AUC, calculated by integration of the raw glucose tolerance test curves shown in E. G, fasting insulin; H, fasting glucose levels. I, homeostasis model assessment for insulin resistance (HOMA-IR) index scores. Data are the average ± S.D. from 8 to 20 independent experiments. Asterisks indicate significance from control (CON) (*, p < 0.05; **, p < 0.01; ***, p < 0.001; ****, p < 0.0001). Horizontal bars with asterisks indicate significance between treatments. For simplicity, statistical significance is not indicated between time points (14 and 4 weeks).
1–5 (Fig. S3, A–F) (35). The notable exception was that mice consuming the Western/H11001DHA diet had a reduction in the amount of supercomplex 4 when compared with the control and Western diets by 2.5- and 2.7-fold, respectively (Fig. S3 E).

Blue native-PAGE analysis also revealed that there were no changes in the expression of complexes I–V in the Western and EPA- or DHA-enriched Western diets compared with the lean control (data not shown).

Replacement of (18:2)4CL with (22:6)4CL prevents the formation of lipid domains by influencing the Gibbs free energy of lipid–lipid mixing

Given that DHA did not robustly impair the abundance of the majority of supercomplexes, we investigated another potential mechanism by which respiratory enzyme activity could be lowered with DHA. We used a biophysical approach to determine whether DHA could target the formation of CL domains, which control phospholipid–protein binding that is critical for optimal enzyme function (36). Biomimetic mitochondrial membranes modeling the composition of the cardiac inner mitochondrial membrane were used because they allow for a controlled model system. (22:6)CL was specifically investigated given that it is a symmetric phospholipid and was elevated in response to DHA in the diet (Fig. 3 A and Fig. S2 F).

Cytochrome c was added to the biomimetic membranes because it is known to induce domain formation in giant unilamellar vesicles (37).
Imaging revealed that (18:2)₄CL promoted the formation of phase-separated domains (as visualized by NAO), which were diminished upon replacement of (18:2)₄CL with (22:6)₄CL (Fig. 6A). A range of phase-separated domain areas was measured with the NAO fluorescent probe and are presented as a frequency distribution. A Gaussian fit was applied to the frequency distributions with larger areas reflecting greater coverage of the NAO fluorophore on the perimeter of the giant unilamellar vesicles (Fig. 6B). Visual inspection of the frequency distributions were clearly different between (18:2)₄CL and (22:6)₄CL (Fig. 6B). Quantification of the average area occupied by the NAO probe showed that DHA prevented formation of phase-separated domains (Fig. 6C).

To explain how (22:6)₄CL prevented domain formation, monolayers of the same lipid mixtures modeling the inner mitochondrial membrane were constructed containing either (18:2)₄CL (Fig. 6D) or (22:6)₄CL (Fig. 6E) in the absence or presence of cytochrome c. This model system allowed us to investigate phospholipid mixing properties that are central for the formation of phase-separated lipid domains (38). The monolayer pressure area isotherms (Fig. 6, D and E) were then used to calculate the change in excess area per molecule in response to cytochrome c. The excess area per molecule values provide a quantitative change at the angstrom level on how phospholipids are mixing or de-mixing (i.e. lipid–lipid miscibility) (39).

In biomimetic mitochondrial monolayers containing (18:2)₄CL, the change in excess area per molecule was positive, indicating unfavorable lipid mixing (i.e. formation of phase-separated domains) (Fig. 6F). Upon replacement of (18:2)₄CL with (22:6)₄CL, this value became negative, indicating favorable mixing between phospholipids (i.e. no formation of phase-separated domains). We further calculated the change in Gibbs free energy of mixing upon the addition of cytochrome c. (18:2)₄CL had a positive change in Gibbs free energy of mixing, indicating unfavorable mixing of phospholipids (Fig. 6G). Replacement of (18:2)₄CL with (22:6)₄CL shifted the Gibbs free energy of mixing to a favorable negative value. Thus, these results established that (18:2)₄CL promoted phase-separated domains due to unfavorable lipid mixing. In contrast, the lack of domains in the presence of (22:6)₄CL was driven by favorable Gibbs free energy of mixing between phospholipids.

Replacement of (18:2)₄CL with (22:6)₄CL diminishes interactions with complex IV

CL domains are hypothesized to create a microenvironment that regulates protein activity through direct phospholipid-protein binding (12, 15, 25, 40) Thus, we further investigated whether replacement of (18:2)₄CL with (22:6)₄CL in biomimetic mitochondrial large unilamellar vesicles (LUVs) impaired binding interactions with immobilized complex IV using surface plasmon resonance (SPR) (41). Complex IV was selected because its activity was lowered with DHA, suggesting that the known high-affinity, CL-specific binding sites (27, 42–44) may be unable to accommodate remodeled CL. SPR binding curves showed dramatic differences in binding interactions between complex IV and LUVs containing either (18:2)₄CL (Fig. 7A) or (22:6)₄CL (Fig. 7B). Strikingly, there was a lack of detectable LUV–CIV interactions in the presence of (22:6)₄CL at LUV concentrations nearly 100-fold higher than the reported apparent $K_{d}$ value for CL binding to the high- and low-affinity sites on CIV (<0.1 and 4 μM, respectively) (43). Fitting of the binding...
DHA remodels the cardiac lipidome to lower enzyme activity
DHA remodels the cardiac lipidome to lower enzyme activity

The last set of experiments tested the possibility that the replacement of the predominant CL fatty acid, linoleic acid (18:2) with DHA (22:6), was driving the reduction in enzyme activity. Therefore, we fused cardiac mitochondria isolated from mice consuming the Western + DHA (14 weeks) diet with small unilamellar vesicles composed of (18:2)CL. We ensured that (18:2)CL fusion did not influence the fatty acids associated with PC or PE. LC/MS heat maps show no alterations in any of the acyl chains associated with PC (Fig. 8A) and PE (Fig. 8B) upon fusion with (18:2)CL.

CL and MLCL were analyzed in response to the fusion. LC/MS analyses are presented as heat maps in Fig. 8 for CL species that were classified as either major (Fig. 8A), intermediate (Fig. 8B), or minor (Fig. 8C) in terms of abundance. MLCL was also analyzed (Fig. 8D). Several intermediate and minor CL species were altered in the (18:2)CL mitochondrial fusion when compared with control and Western + DHA diets by 1.7–10.0-fold (Fig. 8, B and C).

Cardiac mitochondrial complex I, IV, and V activities were rescued upon introduction of (18:2)CL into the mitochondria of mice consuming DHA

We determined whether improvement in the CL lipidome of DHA-fed mice upon fusion of (18:2)CL rescued the impaired oxidative phosphorylation enzyme activities. The fusion of (18:2)CL to control samples had no effect on enzyme activity (data not shown). The fusion of (18:2)CL to mitochondria isolated from Western + DHA (14 weeks) rescued complex I activity (Fig. 9A). The fusion of (18:2)CL with the Western + DHA (14 weeks) diet did not influence complex II activity (Fig. 9B) and complex III activity was reduced relative to the control diet by 2.5-fold (Fig. 9C). (18:2)CL fusion rescued complex IV and complex V activities by 2.4- and 2.5-fold relative to the Western + DHA diet (Fig. 9, D and E). Complex II and II + III activities were not influenced by the introduction of (18:2)CL (Fig. 9, F and G).

Discussion

The rationale for the study was based on previous data showing rearrangement of cardiac mitochondrial phospholipid acyl chains, particularly CL, in several diseases like cardiomyopathies and diabetes, as well as aging (8–11, 18). In such scenarios, decreased mitochondrial supercomplex formation, decreased mitochondrial respiratory function, increased oxidative stress, and elevated cardiac DHA acyl chains levels are generally observed (18, 45–54).

Herein, we first confirmed mouse studies by demonstrating that DHA levels were elevated in human type II diabetics. A limitation of this study was that we were not able to assay whether DHA was specifically associated with the polar lipid pool, particularly CL. This was due to a very limited tissue sample size obtained during surgery. Given that the concentration of free fatty acids is significantly low in the heart (55), it is likely that DHA levels represent polar and neutral lipids. We also acknowledge that the size of the samples, which were very difficult to obtain, was small. Thus, future studies will need to further confirm whether DHA levels, particularly in CL, are elevated in human subjects while controlling for various confounding variables.

Following the human study, we performed experiments in a murine model to determine the potential underlying mechanisms by which DHA acyl chains influence mitochondrial enzymatic activity. A striking finding from the mouse study was that the Western diet in the absence of EPA or DHA dramatically remodeled the lipidome of the three major phospholipids of the mitochondria, but it had no effect on enzyme activity, even upon a strong reduction in (18:2)CL levels. These results are in agreement with our previous work that showed a high fat diet had no influence on mouse cardiac enzyme activity upon moderate remodeling of phospholipids (56). In contrast, remodeling of the phospholipidome upon dietary supplementation with EPA and DHA led to diminished enzymatic activity of select complexes. These results were consistent with a study showing that fish oil can lower liver mitochondrial complex IV and V activities (57).

DHA potentially lowers cardiac mitochondrial enzyme activities by influencing domain organization and protein–lipid binding

The data suggest two potential mechanisms, which are not mutually exclusive, by which DHA lowered respiratory enzyme function. One possibility was that DHA prevented CL domain formation. Studies with biomimetic membranes specifically that DHA levels were elevated in human type II diabetics. A limitation of this study was that we were not able to assay whether DHA was specifically associated with the polar lipid pool, particularly CL. domain formation, which was driven by the ability of DHA acyl chains to promote phospholipid mixing. The other possibility was that DHA prevented binding of linoleic acyl chains to specific complexes.

There are several binding sites within complex I and IV that could be influenced by DHA. There are nine binding sites for CL in bovine complex I and depletion of CL from complex I renders the enzyme inactive (24, 25). Similarly, CL is required for complex IV activity with four known CL-binding sites, two of which are considered high affinity. The high-affinity CL-binding sites are associated with the regulation of electron transport, and the loss of CL at these sites lowers enzymatic activity (26, 27). The two low-affinity sites are also important in the structural integrity of the complex in its dimer form (28, 58).

Figure 6. Replacement of (18:2)₄CL with (22:6)₄CL prevents formation of lipid domains due to a favorable Gibbs free energy of mixing. A, sample confocal images of biomimetic giant unilamellar vesicles containing either (18:2)₄CL or (22:6)₄CL. Cytochrome c (Cyt C) was added to promote phase separation, and images were visualized with the CL-specific probe NAO. Biomimetic membranes modeled the composition of the inner mitochondrial membrane. B, frequency distribution of the differing areas occupied by the NAO probe on the perimeter of the vesicles. A Gaussian fit was applied to the data. C, average area occupied by the NAO fluorophore measured with ImageJ software (National Institutes of Health). Each dot represents a single GUV. Monolayers were also constructed to assay lipid–lipid miscibility. Sample pressure–area isotherms of biomimetic monolayers are presented containing either (18:2)₄CL or (22:6)₄CL. Lipid–lipid miscibility was quantified at a physiologically relevant surface pressure of 30 millinewtons (mN)/m in terms of the change in excess area per molecule (F) and Gibbs free energy (G) of mixing upon cytochrome c addition. Negative values for excess area per molecule and Gibbs free energy indicate favorable lipid–lipid mixing. Positive values indicate unfavorable mixing. Data are average ± S.D. from 3 to 6 independent experiments. Asterisks indicate statistical significance relative to (18:2)₄CL: *p < 0.05; **p < 0.01, ***p < 0.001.

Figure 7. Replacement of (18:2)₄CL with (22:6)₄CL in biomimetic mitochondrial vesicles prevents binding to complex IV. Representative SPR sensorgrams of biomimetic LUVs containing (18:2)₄CL (A) or (22:6)₄CL (B) binding to complex IV are shown. LUVs modeled the composition of the inner mitochondrial membrane. Solubilized complex IV was immobilized to gold-plated carboxyl sensor chips using EDC/NHS chemistry (Nicoya Lifesciences). Binding of varying concentrations of LUVs were measured as a function of time. Small increases in the signals of (22:6)₄CL are attributed to non-specific binding interactions between the LUVs and sensor chip at high concentrations. Data in A were globally fit to a one-site binding model (solid black line, TraceDrawer) to determine k_on, k_off, and equilibrium dissociation constants. Binding constants (Table 1) were determined in three separate experiments using three different chips to account for chip-to-chip variability.
DHA remodels the cardiac lipidome to lower enzyme activity

Table 1

| Binding constants for biomimetic mitochondrial membranes containing (18:2)₄CL with complex IV |
|---------------------------------|-------------------------------------------------------------|
|                                  | (18:2)₄CL, (22:6)₄CL                                      |
| \(k_{on}\)                       | 500 ± 10 M⁻¹ s⁻¹                                         |
| \(k_{off}\)                      | 7.6 ± 0.2 (×10⁻³) s⁻¹                                    |
| \(K_D\)                         | 1.8 ± 0.6 µM                                             |

Thus, DHA acyl chains may lower enzyme function due to diminished binding of linoleic acid to either of the two complexes. Indeed, studies to determine the strength of the phospholipid–protein interactions with complex IV revealed that biomimetic membranes containing (22:6)₄CL did not bind to complex IV, whereas those containing (18:2)₄CL exhibited significant interactions with complex IV (presumably both the low and high affinity CL-binding sites). Disruption of (22:6)₄CL binding to complex IV could result in reduced conformational flexibility or electron transport, effectively reducing enzyme activity. Subsequent studies will need to test binding of other DHA-containing CL species with complex IV and other complexes. It was beyond the scope of this study to test CL-binding kinetics with all of the complexes.

Complex V activity was also lowered with DHA, which could be due to a specific disruption in CL domain formation. Complex V forms dimers, and CL is specifically needed to assemble the enzymes into larger oligomeric structures, which affects energy efficiency (16, 29, 59). It is possible that DHA, due to unique conformational flexibility, imparted disorder on the bilayer that leads to an impairment in the formation of higher order complex V oligomers that rely on the microdomain environment.

The effects of DHA on domain organization could also explain the reduction in complex I + III activity. Perhaps DHA lowered the ability of coenzyme q, the mobile electron carrier from complex I to complex III, to diffuse appropriately as the domains were disrupted. This would then explain why modifications to complex I and III activity alone did not recapitulate the results with complex I to III electron transfer. It is also conceivable that DHA impaired other aspects of membrane biophysical organization such as bending rigidity that could impede electron flow (60).

There are likely additional mechanisms by which DHA could lower respiratory enzyme function. These would include the possibility that an increase in acyl chain unsaturation with dietary DHA could manipulate CL turnover and thereby protein activity (61). In addition, DHA may have indirect effects on enzymatic responses by influencing the expression and activity of phospholipase \(A_2\gamma\), which cleaves select fatty acids from CL to regulate mitochondrial bioenergetics (62).

Despite the clear impact that mitochondrial membrane phospholipidome remodeling was having on respiratory complex activity, it is noteworthy that coupled ADP-stimulated respiration was not altered with EPA and DHA (data not shown). This effect mirrored our previous study where EPA/DHA supplementation in high-fat-fed mice did not significantly alter maximal respiration in the heart (63). This fact illustrates the complexity of mitochondrial bioenergetics and suggests that although discrete respiratory complexes may be altered individually, or even in aggregate (i.e., supercomplexes), there are additional factors that impinge on respiratory function as a whole when mitochondria are intact and fully coupled. Altogether, the data provide a roadmap for future studies that will require purification of differing respiratory enzymes to study how DHA acyl chains disrupt enzyme activity in the context of CL-protein binding and formation of CL domains.

Paradox on DHA

In conditions such as obesity and type 2 diabetes, which are linked to cardiovascular diseases, pathological remodeling of CL with EPA and/or DHA increases oxidative damage that contributes to mitochondrial dysfunction (64). For instance, a study showed that DHA levels in C2C12 cells were elevated upon up-regulation of ALCAT1 (a lyso-CL acyltransferase), which remodels CL to species containing highly oxidizable acyl chains and increased oxidative stress (64). A deficiency in ALCAT1 in a murine model protected against diet-induced obesity and insulin resistance (64). Shotgun lipidomic studies by Han et al. (9, 18) also showed a significant decrease in CL abundance and a profound remodeling of the remaining CL species to include DHA acyl chains in rat diabetic myocardium.

In contrast, many studies demonstrate that consumption of EPA/DHA can have beneficial effects in obesity and type 2 diabetes through pleiotropic mechanisms. The mechanisms for improvements with EPA and DHA consist of enhancing insulin signaling, maintaining glucose metabolism, reversing dyslipidemia, and resolving inflammatory signals via targeting of transcription factors and gene expression (65–68). For instance, in a similar study by our group, supplementation of EPA and DHA in high-fat diet led to increased levels of 4-hydroxyhexenal adducts in the myocardium, products of EPA/DHA-specific lipid peroxidation (63). In parallel with the increase in hydroxyhexenal adducts, antioxidant gene expression increased while mitochondrial reactive oxygen species production decreased in the heart, suggesting that high-fat diet supplementation with EPA/DHA caused a beneficial “hormetic” response in the heart. Similar effects were also seen to some extent in a recent small clinical trial of fish oil in patients prior to cardiac surgery. Anderson et al. (69) showed that patients consuming 4 g/day of EPA/DHA ethyl esters (Lovaza™) had increased myocardial peroxisome proliferator-activated receptor-\(\gamma\) activation, up-regulated fatty acid metabolic gene expression, greater expression/activity of antioxidant as well as anti-inflammatory enzymes, and increased palmitoyl–carnitine-supported respiration.

Role of linoleic acid in the myocardium

Introduction of linoleic acid in CL vesicles rescued the decrement in the phospholipidomic profile and enzyme activities of complexes I, IV, and V in response to DHA. These results demonstrate mechanistically that it is not the loss of linoleic acid alone that drives the impairment in enzyme function because the Western diet alone did not impair enzyme activities. Instead, it was the replacement of linoleic acid with DHA that promoted the reduction in activities. The notable excep-
tion was complex III activity, which was not restored upon introduction of linoleic acid. Perhaps DHA was bound to complex III in a manner that precluded displacement by linoleic acid associated with CL. Several of the known complex III CL-specific bindings sites are buried deep within protein cavities, presumably making displacement of the DHA-containing CL difficult due to structural constraints (15).

The (18:2) CL rescue data advance the field by highlighting the importance of n-6 PUFAs in mitochondrial membranes. There is considerable debate about the effects of n-6 PUFAs, notably linoleic acid, on cardiovascular health. Initially, linoleic acid was hypothesized to have benefits for cardiovascular outcomes because it lowers serum cholesterol (70, 71). However, recent studies challenge this notion about increasing the intake of linoleic acid at the expense of saturated fatty acids (72). For instance, several meta-analyses show that increasing the dietary consumption of n-6 PUFAs, at the expense of saturated fatty acids, does not lower the risk of death from cardiovascular dis-

Figure 8. Incorporation of (18:2) CL improves the cardiolipin lipidome of mitochondria isolated from DHA-fed mice. Heat maps of major (A), intermediate (B), and minor (C) CL acyl chains for mice consuming a control (CON), Western diet (WD), and WD + DHA. D, monolysoc-CL species in cardiac mitochondria are also shown. Data are the average ± S.E. from three independent experiments. Asterisks indicate significance from control (*, p < 0.05). Daggers indicate significance relative to WD + DHA + (18:2) CL (†, p < 0.05).
DHA remodels the cardiac lipidome to lower enzyme activity

Figure 9. (18:2)₂CL rescues the DHA-induced loss of complex I, IV, and V activities. A, complex I activity, measured by NADH oxidation for mice consuming a control (CON), Western diet (WD), and WD + DHA. B, complex II activity, measured by dichlorophenolindophenol reduction. C, complex III activity, assayed by cytochrome c reduction. D, complex IV activity, measured by cytochrome c oxidation. E, complex V activity, measured by the oxidation of NADH. F, complex I + III activity assayed by NADH oxidation coupled to cytochrome c reduction. G, complex II + III activity, assessed by succinate oxidation coupled to cytochrome c reduction. Activities were determined relative to total protein content and then normalized to citrate synthase (CS) activity. Data are the average ± S.E. from four independent experiments. Asterisks indicate significance from control (*, p < 0.05; **, p < 0.01). Horizontal bars with asterisks indicate significance between treatments.
eases (73–75). In addition to n-6 PUFAs, the role of n-3 PUFAs in cardiovascular diseases is still controversial. Meta-analyses on the consumption of EPA and DHA and coronary heart disease indicate that n-3 PUFAs may be associated with lowered cardiovascular risk (76, 77). However, a recent clinical trial showed that daily treatment with n-3 PUFAs did not decrease the prevalence of cardiovascular mortality or morbidity in patients with multiple cardiovascular risk factors (78). Our data suggest that linoleic acid is key for cardiac mitochondrial enzymatic activity, and its replacement, at least with select doses of DHA, could promote impairments.

It is conceivable that EPA and/or DHA could improve cardiac enzyme activities in other model systems. In this model, we did not find that DHA was improving fasting insulin or glucose clearance in contrast to other studies (33, 79). Thus, perhaps DHA could improve enzyme activities under conditions in which whole-body metabolism is improved. Furthermore, DHA in the triglyceride or free fatty acid form may have different effects on the mitochondrial phospholipidome and enzymatic activity, which was beyond the scope of this study.

Conclusions

The data demonstrate that remodeling of the murine cardiac mitochondrial phospholipidome in the absence of DHA had no influence on mitochondrial enzyme activities. In contrast, remodeling of the phospholipidome with DHA, in particular, leads to a reduction in complex I, IV, V, and I + III activities, potentially through mechanisms involving the formation of lipid domains and phospholipid–protein binding. These results suggest that increased levels of DHA in the myocardium in differing diseases may be targeting enzymatic activity. Furthermore, the impairments with DHA in the lipidome were generally rescued with the introduction of linoleic acid accompanied by an improvement in the activities of select complexes. This has implications for future studies on the balance between linoleic acid and n-3 PUFAs in the heart.

Experimental procedures

Human subjects

The Institutional Review Board of East Carolina University approved all aspects of human tissue and data collection for this study. The cohorts evaluated were type 2 diabetic and non-diabetic patients from Vidant Hospital undergoing elective coronary artery bypass graft surgery. The demographic and clinical data pertaining to the patients are shown in Table S1. The subjects were grouped either as non-diabetic or diabetic according to two major variables: 1) clinical diagnosis of diabetes; and 2) glycated hemoglobin (HbA1c) values of ≥6.1 extending up to ~1 year prior to surgery. It is the standard of care at Vidant Hospital to give all diabetic patients intravenous insulin when admitted for surgery, and all other pre-operative diabetic medications are noted in Table S1. Patients with enlarged atria, history of arrhythmia, or left ventricular ejection fractions < 30% were excluded from this study.

Human atrial appendage biopsy, tissue processing, and fatty acid analyses

After median sternotomy, and prior to institution of cardiopulmonary bypass, a purse-string suture was placed in the right atrial appendage to allow for placement of the venous cannula. A sample of the appendage directly superior to the purse string was dissected and immediately rinsed in ice-cold saline to remove excess blood, trimmed of the epicardial layer and pericardial fat, and frozen in liquid N2. Total fatty acids from the atrial appendage were extracted with organic solvents (HPLC grade, Sigma) and analyzed with gas chromatography as described previously (80). Stringent precautions were taken to prevent oxidation (80).

Animals and diets

All experiments were conducted in accordance with guidelines established by the Guide for the Care and Use of Laboratory Animals (National Institutes of Health Publication No. 85-23, revised 1996) and with prior approval by the Animal Care and Use Committee at East Carolina University and the University of North Carolina at Chapel Hill. Male C57BL/6 mice (Charles River, Wilmington, MA), 5 weeks old, were fed a low fat control diet, a Western diet (42% of kcal from milk fat), or a Western diet with 2% kcal from either EPA or DHA ethyl esters for 14 weeks (Envigo Inc., Indianapolis, IN). Short-term intervention with EPA and DHA was also tested, which entailed feeding mice the Western diet for 10 weeks followed by 4 weeks of the Western diet with either EPA or DHA. EPA and DHA ethyl esters (Cayman Chemicals, Ann Arbor, MI) were greater than 93% purity and were routinely tested for oxidation prior to and during the course of the study. The composition of the experimental diets is presented in Table S2. Mice were housed on a 12:12 h light/dark cycle with free access to water. Mice were sacrificed via isoflurane inhalation followed by cervical dislocation.

Metabolic profiling

Mice were fasted for 5 h prior to the administration of an intraperitoneal glucose injection (2.5 g/kg fat-free mass) of a 50% dextrose saline solution (Hospira Inc., Lake Forest, IL) (81). Blood glucose was monitored from the tail vein using an AlphaTrak 2 animal glucometer (Abbott) at 0, 15, 30, 60, and 90 min post-injection (82). Values were normalized to fasting blood glucose levels, and glucose tolerance was assessed by calculating the corresponding area under the curve (AUC). Blood samples, collected after the 5-h fast using microcapillary tubes, were used to quantify insulin levels with an ultra-sensitive mouse insulin ELISA kit (Crystal Chem Inc., Downers Grove, IL). Fat and lean masses were determined with whole-body EchoMRI (Active Field Resources, LLC, Houston, TX).

Isolation of mitochondria

Mitochondrial isolations were performed on ice, and all instruments and buffers were chilled to 4 °C before isolation using our established protocols (56). Cardiac tissue was removed and rinsed in mitochondrial isolation medium (MIM) containing 300 mM sucrose, 10 mM Na-HEPES (pH 7.2), and 1

mitochondria in the heart.
DHA remodels the cardiac lipidome to lower enzyme activity

mm EGTA (Sigma). The tissue was minced for 5 min and diluted in MIM + BSA (1 mg/ml BSA) (pH 7.4). Tissue was then subjected to homogenization with a Teflon Potter homogenizer. The homogenate was centrifuged at 800 × g for 10 min, and the supernatant was centrifuged at 12,000 × g for 15 min. The mitochondrial pellet was resuspended in MIM and stored at −80 °C. Protein content was determined using a BCA protein quantification assay (Thermo Fisher Scientific, Waltham, MA).

Electrospray ionization mass spectrometry
Phospholipid molecular species were determined in lipid extracts (0.2 mg) of mitochondrial protein by liquid chromatography with electrospray ionization mass spectrometry (LC/MS) and analyzed as described previously (83).

Small unilamellar vesicle formation and fusion with mitochondria
SUVs were generated using 0.025 mg of (18:2)4CL (Avanti Polar Lipids, Alabaster, AL) (84). Multilamellar vesicles (MLVs) were first constructed as shown previously (85). SUVs were then formed by the sonication of the MLVs using a Branson digital sonifier. SUVs were added to 1 mg of total mitochondrial protein and allowed to gently shake for an hour at 4 °C. Excess SUVs were then removed from the fused mitochondria, and the mitochondrial pellet was resuspended and stored at −80 °C.

Blue-native PAGE for quantifying supercomplex formation
Blue native-PAGE was performed as described previously (56). Briefly, pelleted mitochondria were resuspended in native-PAGE Sample Buffer (Life Technologies, Inc.) and solubilized using an 8:1 digitonin (Sigma) to protein ratio. After solubilization and centrifugation, the supernatants were collected and protein content was determined via a BCA protein quantification assay (Thermo Fisher Scientific). Samples were combined with 5% G-250 sample additive (Life Technologies, Inc.) and loaded onto the 3–12% BisTris gel (Life Technologies, Inc.). The gel was run on ice at 150 V for 3 h. Gels were fixed using 40% methanol and 10% acetic acid (Sigma) and destained in 8% acetic acid. Gels were imaged and quantified using the ChemiDoc Imaging System (Bio-Rad). Data were normalized to the total amount of protein in each sample.

Construction of biomimetic mitochondrial giant unilamellar vesicles (GUVs) to quantify domain organization
Biomimetic mitochondrial GUVs were constructed by co-dissolving lipids, 39.9 mol % 18:0–22:6 PC, 30.0 mol % 16:0–20:4 PE, 20 mol % (18:2)4CL or (22:6)4CL, 5 mol % 18:1–18:1PS, 3 mol % 18:1–18:1PI, 3 mol % 18:1–18:1PS, 2 mol % cholesterol (Chol) in chloroform (2.5 mg/ml). Lipid monolayers were constructed by spotting ~9.0 nmol on a subphase of 10 mM sodium phosphate buffer (pH 7.4). Biomimetic mitochondrial monolayers were analyzed in the absence and presence of cytochrome c. Excess chloroform was allowed to evaporate for 10 min prior to cytochrome addition and monolayer compression. Pressure-area isotherms were generated and analyzed as described previously (39). The excess area per molecule and Gibbs free energy were calculated upon the addition of cytochrome c (39). All lipid mixtures were acquired multiple times to ensure reproducibility.

Synthesis of LUVs
LUVs were constructed at room temperature, as described previously (39), using the same lipid mixture described above for GUV and monolayer studies containing either (18:2)4CL or (22:6)4CL.

SPR
SPR data were recorded on an OpenSPR system (Nicoys Life-sciences). For all experiments, PBS (10 mM Na2HPO4, 2.7 mM KCl, and 137 mM NaCl, pH 7.4) was used as the running buffer. Solubilized complex IV in 25 mM Tris-HCl buffer (pH 7.8), 5 mM EDTA, and 39 mM 11-dodecyl β-D-maltoside (Sigma) was diluted to 100 μg/ml in activation buffer and immobilized on a gold-plated carboxyl-functionalized nanosensor chip according to the manufacturer’s instructions using carbodiimide cross-link chemistry (Nicoys Life-sciences). After immobilization and blocking (10 min), LUVs in differing concentrations were injected (200 μl) and allowed to interact with the sensor for 10 min at a pump speed of 20 μl/min. Complete dissociation of LUVs from the immobilized complex IV was observed after 15 min. Interactions between complex IV and the LUVs were determined in triplicate using three different chips to
DHA remolds the cardiac lipidome to lower enzyme activity

eliminate the possibility of chip-to-chip variability. Sensorgrams obtained for the (18:2)₄CL were globally fit to a one-site binding model using TraceDrawer (Nicoya Lifesciences) to determine the association constant ($k_{on}$, M⁻¹ s⁻¹), dissociation constant ($k_{off}$ s⁻¹), and the equilibrium binding constant ($K_D$, μM). Rate constants were obtained from global fits using 4–5 concentrations of LUVs and are presented as average ± S.D. from three separate experiments.

**Mitochondrial kinetic assays**

Kinetic assays were conducted using a UV-visible 1800 spectrophotometer at 37 °C as demonstrated previously (56). Complex I activity was measured by monitoring the oxidation of 0.8 mM NADH (Sigma) at 340 nm. Complex II activity was measured by the reduction of 80 μM dichlorophenolindophenol (Sigma) at 600 nm. Complex III activity was assayed by monitoring the reduction of 40 μM cytochrome c (Sigma) at 550 nm. Complex IV activity was measured by monitoring the oxidation of 1 mM NADH (Sigma) at 340 nm. The activity of complexes I + III and II + III was measured by monitoring the reduction of 40 μM cytochrome c at 550 nm. Citrate synthase activity was assayed using 0.1 mM 5,5-dithiobis-(2-nitrobenzoic acid) (Sigma). Each reaction was performed in duplicate, and all activities were normalized to citrate synthase activity.

**Statistical analyses**

Data are presented as average ± S.D. All data are from multiple independent experiments, as indicated in the figure legends. Each independent experiment consisted of one mouse per diet group. The human data were analyzed with an unpaired one-tail t test because previous studies have established an increase in DHA levels in the myocardium (18); therefore, the null hypothesis for this study was set to test whether diabetics would increase DHA levels. The mouse data were normally distributed based on a Kolmogorov-Smirnov test. Thus, these results were analyzed with parametric statistics using GraphPad Prism 7 software. Statistical significance was established using a one-way analysis of variance followed by a post hoc Bonferroni test. $p < 0.05$ was considered significant.
