Role of WWOX and NF-κB in lung cancer progression

Szu-Jung Chen¹, Shenq-Shyang Huang¹ and Nan-Shan Chang¹,²,³*

Abstract

It is generally agreed that the pro-inflammatory, pro-survival transcription factor NF-κB is a tumor promoter. Tumor necrosis factor alpha (TNF-α or TNF) mediates NF-κB activation. Tumor suppressor WWOX (FOR or WOX1) is a downstream effector of the TNF signaling. Thus, activation of both WWOX (FOR or WOX1) and NF-κB may occur during TNF signaling and/or under stress conditions. Indeed, the first WW domain of WWOX induces the activation of NF-κB-responsive promoter without TNF participation. It appears that WWOX counteracts with NF-κB regulating cell survival and death. For example, WWOX becomes activated with Tyr33 phosphorylation and relocates together with NF-κB and many transcription factors to the nucleus to cause neuronal death in sciatic nerve-transected rats. While WWOX is frequently lost in lung cancer and many other cancers, NF-κB activation-induced cancer promotion probably requires WWOX-independent signaling networks to induce expression of pro-survival factors. The antagonistic role of WWOX and NF-κB in the regulation of lung cancer progression is discussed.

Keywords: WWOX; Tumor suppressor; Tumor necrosis factor; NF-κB; Lung cancer

Inflammatory TNF-α/NF-κB pathway in lung cancer

Inflammatory cytokines are involved in the pathogenesis of lung cancer progression [1]. The cytokines may drive the activation of nuclear transcription factors, which fosters the generation of favorable microenvironment for sustaining the growth of cancerous cells. As a pro-inflammatory cytokine, tumor necrosis factor alpha (TNF-α or TNF) participates in many events that lead to oxidative stress, vasodilatation, edema formation, and fever. Prosurvival transcription factor nuclear factor-κB (NF-κB), for example, is a downstream effector of the TNF-α pathway, and is being regarded as a crucial factor during cancer initiation and progression [2,3]. NF-κB could orchestrate the signals from different pathways, and interacts with signaling proteins such as transcription factors STAT3 and p53 or the ETS related gene ERG [4]. The transcriptional activity of NF-κB could also be affected by kinases from other signal pathways, such as GSK3-β, p38, and PI3K [4]. Networking analysis revealed that NF-κB directly or indirectly interacts with BCL-3 (B-cell CLL/lymphoma 3), ESR-1 (estrogen receptor 1), NR3C1 (nuclear receptor subfamily 3, group C, member 1; glucocorticoid receptor), ELF1 (E74-like factor 1; ets domain transcription factor) and many more. Indeed, there are many binding partners with NF-κB [4,5], the molecular mechanisms underlying NF-κB integration with these signals is largely unknown.

NF-κB is a homo- or heterodimeric complex from a composition of the Rel-like domain-containing proteins RELA/p65, RELB, NFKB1/p105, NFKB1/p50, REL and NFKB2/p52 [4,5]. The heterodimeric p65-p50 complex can be found in cells in most cases. NF-κB is frequently localized or sequestered in the cytoplasm. This is mainly due to the regulatory effect of inhibitor protein IκBα. IκBα binds and masks the nuclear localization signals of NF-κB. IκBα can be phosphorylated at Ser32 and Ser36 by a specific IκB kinase (IKK) complex and is then degraded in a ubiquitin/proteasome-dependent manner [4-6]. Degradation of IκBα results in activation or nuclear accumulation of NF-κB. The IKK complex is composed of two catalytic components IKKα and IKKβ and a regulatory subunit IKKγ (NEMO). The aforementioned event has been considered as a canonical pathway of NF-κB activation. For the noncanonical NF-κB activation, IKKα binds and
phosphorylates a p100 complex, in which p100 undergoes ubiquitination and is degraded to p52. NF-κB interacts with p52 for relocating to the nucleus and regulates gene transcription [4-6]. Tax, a viral regulatory protein from human T-cell lymphotropic virus type 1 (HTLV-1), is a key inducer of the NF-κB activation pathway and may contribute to the pathogenesis of viral oncogenesis [7,8].

Cancer initiation and progression can be considered as a chronic inflammatory process. Constitutive activation of NF-κB is frequently shown in cancer cells, and the activated NF-κB affects cancer cell growth, progression and metastasis. In lung cancer and chronic obstructive pulmonary disease (COPD), the NF-κB pathway is linked to the inflammatory signaling, oxidative stress response, and glycolysis and gluconeogenesis pathways, as revealed by proteomic analyses [9]. Bromodomain-containing protein 4 (Brd4) maintaining the constitutively active NF-κB in lung cancer cells by binding acetylated RelA [10]. However, NF-κB activity is needed to activate immune surveillance for the anti-lung cancer response [11]. In contrast, SOD2 (Superoxide Dismutase 2, Mitochondrial) induces the activation of NF-κB and increases IKKβ transcription in lung adenocarcinoma. The event favors the progression of lung cancer and confers poor prognosis in patients [12].

Unconventional inhibitors of NF-κB

The BCL-3 subfamily protein physically interacts with NF-κB in the nucleus and thereby functionally controls its transcriptional activity [13,14]. Like BCL-3, atypical inhibitors of NF-κB have been identified such as IκBζ, long, IκBζD, IκBζ short, IκBNS, and IκBη [13]. These proteins possess common structural domains such as ankyrin repeats, transactivation domains, and nuclear localization signal [13]. Binding of these proteins with DNA-anchored NF-κB modulates its transcriptional function. These atypical inhibitors are not subjected to degradation even after NF-κB activation by stimuli such as lipopolysaccharide or Interleukin 1 beta (IL-1β). Instead, their levels are raised intracellularly.

Additionally, we have determined that Zfra (zinc finger-like protein that regulates apoptosis) regulates TNF-α-mediated cell death by interacting with receptor adaptor protein TRADD (TNF receptor-associated death domain protein) and downstream JNK (c-Jun N-terminal kinase), NF-κB, and WWOX or WOX1 (WW domain-containing oxidoreductase) [15,16]. Transiently overexpressed Zfra sequesters NF-κB (p65), WW, p53 and phosphoERK (extracellular signal-activated kinase) in the cytoplasm, and that TNF-α or UV light could not effectively induce nuclear translocation of these proteins. This study directly demonstrated a cytoplasmic control of NF-κB activation by Zfra. Interestingly, nonsense mutations of caspase-8 activate NF-κB signaling in cancer cells [17].

TNF-α signaling and programmed cell death

TNF-α-mediated cell death is one of the biological events in development, aging, and metabolic turnover. In general, cells are highly organized in multicellular organism. The number of cells in each organism is strictly controlled during development. If cells are damaged or aged, they commit suicide by promoting an intracellular death program - the so-called programmed cell death. Apoptosis is one of the physiological death in a “programmed” manner. It is generally agreed that apoptotic cells undergo membrane blebbing and then shrinkage, nuclear condensation, nuclear membrane disassembly, and chromosomal DNA fragmentation [18-21]. Unfortunately, studies by time-lapse microscopy fail to support all types of apoptosis acting in this typical manner. Apoptotic bodies, which are generated from the whole cell membrane blebbing and fragmentation, are readily phagocytosed or cleared up by macrophages. Intracellular machinery responsible for the programmed cell death goes through a family of cysteine proteases, named caspases (also known as cysteine-aspartic proteases or cysteine-dependent aspartate-directed proteases) [20,21]. Caspases also participate in necrosis and inflammation. Caspases possess a cysteine at the active site, and once activated, target proteins are cleaved at specific aspartic acids [20,21]. That is to execute the programmed cell death.

Numerous intrinsic and extrinsic stimuli lead to signaling cascades that culminate in programmed cell death [22]. In the extrinsic or death receptor pathway, signals from extracellular environment such as TNF-α, toxins, hormones, growth factors, and/or cytokines, interact with membrane receptors so as to instigate the downstream cascade of protein/protein interactions and thereby generate biological effects from gene transcription and new protein production. These extrinsic signals may positively or negatively affect the execution of programmed cell death or apoptosis [23,24]. Several extrinsic signals, including Fas ligand [25], Apo2 ligand, and TNF-related apoptosis-inducing ligand (Apo2L/TRAIL), instigate apoptosis by binding to cognate receptors such as Fas, death receptor 4 (DR4), and death receptor 5 (DR5) [26,27]. By the same token, TNFα-induced cell death is mediated through specific cell surface receptors TNF-R1 and TNF-R2 [21,23].

In the intrinsic or mitochondrial pathway, damage to chromosomal DNA by oxidative stress, UV irradiation, or therapeutic chemicals may initiate the intracellular death pathway [28-30]. As a consequence, caspase activation occurs, which leads to cytochrome c release from the mitochondria into the cytosol. Cytochrome c binds and causes the aggregation of the adaptor protein Apaf-1 (Apoptotic protease activating factor 1), activation of procaspase-9 and subsequent nuclear DNA damage [28]. Cumulative evidence has shown that inhibitors of histone deacetylase activate the
The molecular action is that TRADD directly activating NF-κB cell apoptosis, TRAF2 promotes cell survival via activating the anti-apoptotic event [34-38]. In UV-activated development and progression is largely unknown. It has been determined that endogenous phosphorylated TRAF2 participates in suppression of TRAIL-induced autophagy via activation of JNK1 [43]. Additionally, TRAF2 controls the expression of lung Krüppel-like factor (LKLF) via the mitogen-activated kinase RIP1 [39,40]. Additionally, TRAF2 is a member of the TRAF family, and is responsible for activating canonical NF-κB pathways. In mouse embryonic fibroblasts (MEF), TRAF2 and TRAF5 double knockout suppresses TNFα-induced NF-κB activation. Conditional knockout of TRAF2 in B cells causes noncanonical NF-κB pathway activation [49]. That is, TRAF2 promotes canonical NF-κB pathway, but suppresses noncanonical NF-κB pathway [45,46,50,51].

TRAF2 is a 501-amino-acid protein, possessing a RING-type zinc finger domain, a coiled coil domain, and a MATH/TRAf domain (Figure 2). The RING-type zinc finger domain is associated with an E3 ubiquitin-protein ligase activity. The coiled coil domain mediates TRAF2 homo- or hetero-oligomerization, and a phosphorylation site at Thr117 is important for NF-κB activation. The MATH/TRAf domain binds to receptor cytoplasmic domains. The RING-type zinc finger domain activates both JNK/c-Jun and IKK/NF-κB pathways [52]. Deletion of RING-type zinc finger domain of TRAF2 (TRAf2-ΔR) has been widely used as a dominant negative inhibitor of TNF-α-induced activation of JNK and IKK. Stable expression of TRAF2-ΔR in TRAF2 and TRAF5 double knockout cells efficiently inhibits TNF-α-induced prolonged activation of JNK, but fails to suppress cell death. Moreover, stable expression of TRAF2-ΔR in TRAF2 and TRAF5 double knockout cells does not suppress the noncanonical NF-κB pathway [53].

In the canonical TNF/NF-κB pathway, activated TNF-R1 recruits TRADD, which in turn binds adaptor proteins FADD, TRAF2, TRAF5 and RIP1 [44] (Figure 1). These adaptor protein complexes activate the IKK kinases for IκB degradation and NF-κB activation [45,46]. Although activated TRADD triggers apoptotic signaling by recruiting FADD and caspase-8 and prolonging JNK activation, NF-κB activation leads to the expression of anti-apoptotic proteins such as cFLIP (cellular FLICE (caspase-8)-like inhibitory protein) and cIAP (cellular inhibitors of apoptosis), which block caspase-8 activation [47,48]. Lymphotoxin β receptor (LTβR) promotes noncanonical NF-κB signaling pathway bypassing activation of pro-apoptotic caspase cascades, but directly recruits TRAF2 and TRAF3, which then activates IKKα homodimers through NIK (NF-κB inducing kinase) (Figure 1). IKKα induces NF-κB p100 precursor phosphorylation, and the protein is processed to a p52 form for causing noncanonical NF-κB (RelB/p52 heterodimer) activation [45,46].

Tumor suppressor WWOX (FOR or WOX1) in signaling
Many outstanding review articles have described the in vitro and in vivo roles of tumor suppressor WW domain-containing oxidoreductase, designated WWOX, FOR, or WOX1, in tumor suppression, metabolic disorders, immune defects, bone tumors, neurodegenerative diseases and others [54-63]. Human WWOX gene, containing 1 million bases with 9 exons, is located in chromosome...
16q23.3–24.1. This region is known as a chromosomal common fragile site FRA16D. The encoded protein contains two N-terminal WW domains, a C-terminal short chain alcohol dehydrogenase/reductase (ADH/SDR) domain, and a D3 tail at the C-terminus. Additionally, an NSYK (Asn-Ser-Tyr-Lys) motif for binding with sex steroid hormones, a nuclear localization signal (NLS) (GKRKRV), and a mitochondria-targeting sequence in the ADH/SDR domain have been defined in WWOX [60-63] (Figure 3A). WWOX is located ubiquitously within the cell. It can be found in the cytoplasm, cell membrane/cytoskeleton, organelles and nucleus [60-63]. The first WW domain binds target proteins containing the proline-rich PPXY-motif(s) during signal transduction. For example, WWOX interacts with p73, activator protein 2γ (AP-2γ), ErbB4, ezrin, small integral membrane protein of the lysosome/late endosome (SIMPLE), and c-JUN [59-63] (Figure 3B). Transiently overexpressed WWOX blocks the nuclear accumulation of p73, AP-2γ, and c-JUN in vitro [54,60]. However, the observations are not true in vivo [54,60,64]. In the Wnt/β-catenin pathway, transiently overexpressed WWOX prevents nuclear import of Dishevelled [65]. Similarly, in the HGF/MET pathway, ectopic WWOX inhibits the MET C-terminal fragment for nuclear translocation and suppression of the downstream gene expression [66].

**Figure 1 TRAF2 signal pathway networks.** TRAF2 promotes canonical NF-kB pathway, and suppresses noncanonical NF-kB pathway [45,46,50,51]. TNF-R1 activates the canonical NF-kB pathway via recruiting TRADD, which in turn binds adaptor proteins TRAF2, TRAF5 and RIP1 [44]. These adaptor protein complexes activate the IKK (IkB kinase) proteins for NF-kB (p65/p50 heterodimer) activation, following phosphorylation and degradation of the inhibitory protein IkBα [45,46]. On contrary, LTβR (Lymphotoxin β receptor) promotes noncanonical NF-kB signaling pathway bypassing activation of the pro-apoptotic caspase cascades, but directly recruiting TRAF2 and TRAF3. IkKα homodimers are then activated through the upstream NIK (NFκB inducing kinase). IkKa induces NF-kB p100 precursor phosphorylation, followed by partially processing to a p52 form for leading to noncanonical NF-kB (p52/RelB heterodimer) activation [45,46].

**Figure 2 A schematic structure of TRAF2.** The full-length TRAF2 is composed of 501 amino acids (molecular weight 55 kDa). The RING-type zinc finger domain possesses an E3 ubiquitin-protein ligase activity through Lys63 (K63) or Lys48 (K48) activation. The coiled coil domain mediates TRAF2 homo- or hetero-oligomerization, and phosphorylation at Thr117 (T117) is needed for NF-kB activation. The MATH/TRAF domain binds to receptor cytoplasmic domains.
Moreover, WWOX is involved in stress and apoptotic responses (Figure 3B). WWOX is shown to stabilize tumor suppressor p53 via a direct binding interaction [64-70]. UV-induced WWOX activation with Tyr33 phosphorylation binds Ser46-phosphorylated p53. The binding interaction is independent of the WW domain-PPXY rule [60-63]. WWOX interacts with binding proteins via PPXY motifs. Protein of these categories are p73, activator protein 2y (AP-2y), ErbB4, ezrin, small integral membrane protein of the lysosome/late endosome (SIMPLE), c-Jun [59-63]. WWOX is involved in the Wnt/β-catenin pathway and the HGF (hepatocyte growth factor)/MET pathway. WWOX acts synergistically with p53 to mediate apoptosis, and that JNK and Zfra block the effect. Complement C1q induces an unconventional apoptosis of prostate cancer cells [59,60,62]. WWOX prevents neurodegeneration by inhibiting Tau hyperphosphorylation caused by ERK and GSK-3β [59,60,62]. Hyaluronidase Hyal-2 acts as a receptor for TGF-β1. During signaling, WWOX is activated and binds Smad4 and the protein complex is accumulated in the nucleus, which may lead to cell survival or death [59,60,62].

Figure 3 WWOX/WWOX1 and signaling networks. (A) A schematic structure of WWOX/WWOX1 (414 amino acids; molecular size 46 kDa) is shown. Two N-terminal WW domains are encoded by exon 1–4 of the WWOX gene, and the ADH/SDR domain by exon 4–8. There is a NLS (nuclear localization signal) between the two WW domains, and a NSYK motif in the ADH/SDR domain. The C-terminal tail D3 domain possesses an apoptotic function. The conserved phosphorylation sites are indicated [54-63]. (B) WWOX interacts with binding proteins via PPXY motifs. Protein of these categories are p73, activator protein 2y (AP-2y), ErbB4, ezrin, small integral membrane protein of the lysosome/late endosome (SIMPLE), c-Jun [59-63]. WWOX is involved in the Wnt/β-catenin pathway and the HGF (hepatocyte growth factor)/MET pathway. WWOX acts synergistically with p53 to mediate apoptosis, and that JNK and Zfra block the effect. Complement C1q induces an unconventional apoptosis of prostate cancer cells [59,60,62]. WWOX prevents neurodegeneration by inhibiting Tau hyperphosphorylation caused by ERK and GSK-3β [59,60,62]. Hyaluronidase Hyal-2 acts as a receptor for TGF-β1. During signaling, WWOX is activated and binds Smad4 and the protein complex is accumulated in the nucleus, which may lead to cell survival or death [59,60,62].

WWOX is involved in stress and apoptotic responses (Figure 3B). WWOX is shown to stabilize tumor suppressor p53 via a direct binding interaction [64-70]. UV-induced WWOX activation with Tyr33 phosphorylation binds Ser46-phosphorylated p53. The binding interaction is independent of the WW domain-PPXY rule [60-63]. The p53/WWOX complex may translocate to the mitochondria and further to the nucleus to mediate apoptosis in vitro and in vivo. And, JNK (c-Jun N-terminal kinase) and Zfra (zinc finger-like protein that regulates apoptosis) inhibit the apoptotic response [15,16,68,71-73]. Sex steroid hormones estrogen and androgen are shown to induce the complex formation of p53 and WWOX and their accumulation in the nucleus [74,75]. Complement C1q invokes WWOX activation via an unconventional pathway of apoptosis for causing cancer cell death [57,76]. WWOX prevents neurodegeneration by inhibiting Tau hyperphosphorylation caused by ERK and GSK-3β [54,60,62,77,78]. Hyaluronidase Hyal-2 acts as a receptor for TGF-β1. During signaling, the SDR domain of WWOX physically interacts with Hyal-2, and the resulting WWOX/Hyal-2 complex binds Smad4 and is then accumulated in the nucleus, which may increase cell survival or death both in vitro and in vivo [60,62,79]. A recent study has demonstrated that WWOX interacts with an oncoprotein latent membrane protein 2A (LMP2A), via the PPXY motif, in Epstein-Barr virus, and that this interaction induces activation of extracellular signal-regulated kinase (ERK), up-regulation of matrix metalloproteinase 9 (MMP9), and promotion of cell invasion [80]. Overall, interaction of WWOX with p53, JNK1, Zfra, c-Jun, CREB, and many others is WWOX activation-dependent [54,60,62,75]. That is, WWOX undergoes phosphorylation at Tyr33. CREB is shown to enhance the apoptotic function of WWOX [64].

Many proteins have one or 2–5 repeats of WW domains. It has been proposed that these domains can work in a coherent manner [81]. One report has demonstrated that the first WW domain of WWOX binds WW-binding protein 1 (WBPI) and WW-binding protein 2 (WBP2) signaling adaptors via PPXY motifs [82]. It is postulated that the first WW domain is responsible for the binding interaction, and the secondary WW
domain fails to interact with the PPXY motifs. By site-directed mutagenesis using synthetic peptides, co-immunoprecipitation and physical approaches, the secondary WW domain appears to act as a chaperone to stabilize the first WW domain [82]. Nonetheless, the regions flanking the WW domains (e.g. SDR domain and D3 tail) were not functionally examined and the physiological relevance of WWOX-WBPs interactions is not known.

Indeed, we have determined that the SDR domain of WWOX binds tau so as to block enzyme-mediated hyperphosphorylation [77,78]. Also, the SDR domain interacts with membrane Hyal-2 during TGF-β signaling [79]. MEK1, a mitogen-activated protein kinase, physically interacts with the SDR domain of WWOX, and that dissociation of this complex by phorbol ester induces apoptosis in leukemia cells [83].

**WWOX in tumor suppression and metabolic disorders**

WWOX protein expression is frequently downregulated in invasive cancer cell types [59-63]. Suppression of WWOX in invasive cells may be due to gene mutation, deletion, translocation, hypermethylation of CpG island in the promoter region [84], and mRNA translational blockade [70]. Restoration of WWOX in lung and other cancer cells inhibits their growth and tumorigenicity in vitro and in vivo [59-62]. Although downregulation of tumor suppressor WWOX expression has frequently been reported in various types of cancers, Wwox deletion did not necessarily increase the proliferation or development of premalignant lesions, suggesting that WWOX is not a classical tumor suppressor gene. Interestingly, in a spontaneous mutant lde/lde (lethal dwarfism with epilepsy) rat strain, frame deletion of Wwox gene has been shown, and the rat possesses aberrant Wwox protein expression in the central nervous system and development of seizure [85]. In knockout mouse model, the animals can only survive for one month and have defects in bone metabolism, splenic atrophy, and other deficiencies [59-61,86,87].

Two single nucleotide polymorphisms in *MAF* (musculoaponeurotic fibrosarcoma oncogene homologue) and *WWOX* genes are associated with reduced insulin secretion and hypertension [88]. MafA and c-maf are critical for the β- and α-cells islet development as well as insulin and glucagon biosynthesis [89]. However, WWOX gene inhibits pancreatic islet development by inactivation the Wnt/β-catenin pathway [65].

**WWOX in lung cancer**

Alterations in *WWOX* genes are associated with lung cancer development. WWOX is mapped to the chromosomal common fragile site FRA16D and several copy number variations (CNVs) are associated with this gene. It appears that loss of CNV-67048 genotypes in WWOX in Chinese predisposes their carriers to lung cancer [90]. Whether this affects WWOX gene expression and loss of exons is unknown. Similar studies also showed that the polymorphisms and haplotypes of WWOX gene are associated with the risk of lung cancer in southern and eastern Chinese populations [91]. Ectopic expression of wild type WWOX suppresses the growth human non-small cell lung cancers (NSCLCs) both in cell culture and in patients in a SDR domain-dependent manner [92,93]. WWOX gene expression may be considered as a prognostic biomarker in surgically resected, early-stage NSCLC. An epigenetic regulator/polycomb group protein Bmi1 is more highly expressed in small-cell lung cancer (SCLC) than in NSCLC, and acts by blocking the expression of WWOX at the transcriptional level [94]. MicroRNA miR-134 targeting WWOX expression is associated with head and neck carcinogenesis [95]. Again, alterations in the WWOX gene, including hypermethylation of WWOX gene promoter region and mutations, may contribute to lung carcinogenesis [96]. A recent study showed that ectopic WWOX is able to suppress autophagy for inducing apoptosis in methotrexate-treated human squamous cell carcinoma, and that induction of WWOX expression in SCC is associated with cure of this cancer in patients [97].

**WWOX and NF-κB in the regulation of lung cancer growth**

Substantial evidence has shown that NF-κB is both a mediator of inflammation and a promoter of carcinogenesis [98-100]. How NF-κB orchestrates inflammation toward carcinogenesis is largely unknown. A recent report showed that in the Gprc5a gene knockout mice, NF-κB activation occurs in airway epithelium, which ultimately leads to lung inflammation and tumorigenesis [101]. It appears that increased inflammatory autocrine and paracrine interactions contribute to carcinogenesis. Alternatively, noncanonical TBK1 and IKKc contribute to NF-κB activation and the inflammatory responses for carcinogenesis [100].

WWOX has been implicated in the regulation of the canonical and noncanonical NF-κB pathways in HTLV-1 Tax-mediated tumorigenesis. The viral oncoprotein Tax suppresses WWOX expression by inhibition of the noncanonical NF-κB pathway [6,8,39,58]. Conversely, WWOX effectively blocks Tax-induced activation of the canonical NF-κB pathway, whereas the noncanonical pathway is not affected [6,8,39,58]. The observations suggest the role of the noncanonical NF-κB pathway in contributing to carcinogenesis.

It appears that WWOX can override the pro-survival effect of NF-κB to apoptosis. We have determined that overexpression of the first WW domain of WWOX induces the activation of NF-κB-responsive promoter without the participation of TNF-α in vitro [64]. In sciatic nerve-transected rats, Wwox becomes activated with
Tyr33 phosphorylation and relocates together with NF-κB and many transcription factors to the nuclei to cause neuronal death [64]. Wwox binds activated CREB and c-Jun, but not NF-κB, as determined from both in vivo and in vitro experiments [64]. Complement C1q, which belongs to the TNF-α-like family of proteins, activates WWOX to induce cancer cell death [76]. Whether NF-κB is also activated is unknown. However, activation of NF-κB is shown during C1q stimulation of monocytes [102]. Thus, the functional relationship between WWOX and NF-κB has yet to be determined. While WWOX is frequently lost in lung cancer and many other cancers, NF-κB activation-induced cancer promotion probably requires WWOX-independent signaling networks to induce expression of pro-survival factors.

Finally, there are intriguing interactions among viral LMP2A, WWOX and NF-κB. WWOX binds LMP2A to induce ERK activation, MMP9 upregulation, and promotion of cell invasion [80]. LMP2A, together with NF-κB, protects B-cells from apoptosis by blocking B-cell receptor (BCR) signaling [103]. However, the effect of WWOX on B cell survival is unknown.

Review and conclusions

Activation of NF-κB is crucial for inflammatory response, as well as for carcinogenesis. NF-κB is activated by both canonical and noncanonical approaches. TNF-α is mainly responsible for the canonical NF-κB activation, and LTβR and CD40 for the noncanonical NF-κB activation. Complement C1q activates both WWOX and NF-κB [57,76,102]. WWOX fails to directly bind NF-κB. HTLV-I Tax-mediated tumorigenesis is associated with activation of NF-κB via both canonical and noncanonical pathways, and that WWOX may interfere with this pathway [58]. Apparently, there is a functional antagonism between WWOX and NF-κB. WWOX interacts with Epstein-Barr virus LMP2A, and the interaction activates ERK. Whether NF-κB becomes activated has yet to be determined. Nonetheless, the MEK/ERK signaling is prosurvival. Binding of WWOX with LMP2A may render functional inactivation of WWOX and thereby enhances cancer growth and invasion. Conformational and functional alterations of WWOX due to binding with LMP2A are likely. Phorbol ester is known to activate ERK, and that functional antagonism between WWOX and NF-κB is likely to occur during lung cancer initiation and progression. A balance of both proteins is critical in controlling cancer formation.

Abbreviations

WWOX: WW domain-containing oxidoreductase; NF-κB: Nuclear factor kappa-light-chain-enhancer of activated B cells; JNK1: cJun N-terminal kinase; Zfra: Zinc finger-like protein that regulates apoptosis; NSCLC: Non-small-cell lung carcinomas; SCLC: Small-cell lung cancer; ECM: Extracellular matrix; TNF-α: Tumor necrosis factor alpha; IkBα: Inhibitor of NF-κB alpha; IkBβ: Inhibitor of NF-κB beta; IKK: Kinase of inhibitor of IkB (IkBα or IkBβ).
