Statistical properties of giant pulses from the Crab pulsar

M.V. Popov

Received ; accepted

ABSTRACT

Aims. We have studied the statistics of giant pulses from the Crab pulsar for the first time with particular reference to their widths.

Methods. We have analyzed data collected during 3.5 hours of observations conducted with the Westerbork Synthesis Radio Telescope operated in a tied-array mode at a frequency of 1200 MHz. The PuMa pulsar backend provided voltage recording of X and Y linear polarization states in two conjugate 10 MHz bands. We restricted the time resolution to 4 μs to match the scattering on the interstellar inhomogeneities.

Results. In total about 18000 giant pulses (GP) were detected in full intensity with a threshold level of 6σ. We analyzed cumulative probability distribution (CPD) of giant pulse energies for groups of GPs with different effective widths in the range 4 to 65 μs. The CPDs were found to manifest notable differences for the different GP width groups. The slope of a power-law fit to the high-energy portion of the CPD evolves from −1.7 to −3.2 when going from the shortest to the longest GPs. There are breaks in the CPD power-law fits indicating flattening at low energies with indices varying from −1.0 to −1.9 for the short and long GPs, respectively. The GPs with a stronger peak flux density were found to be of shorter duration. We compare our results with previously published data and discuss the importance of these peculiarities in the statistical properties of GPs for the theoretical understanding of the emission mechanism responsible for GP generation.

Key words. pulsars: general – pulsars: individual: B0531+21 – Methods: statistical – Radiation mechanisms: non-thermal

1. Introduction

Giant pulses are one of the most striking phenomena of pulsar radio emission. Their flux density can exceed thousands of times the average pulse-integrated flux. Although recently there are reports of detecting excessively strong pulses from a number of pulsars (Johnston et al. 2001; Kramer et al. 2002; Romani & Johnston 2001; Johnston & Romani 2002; Kuzmin et al. 2004; Ershov & Kuzmin 2003; Knight et al. 2002; Romani & Johnston 2001; Johnston & Romani 2002; Kuzmin et al. 2004; Ershov & Kuzmin 2003; Knight et al. 2002), only the Crab pulsar and the millisecond pulsar B1937+21 generate giant pulses numerous enough to study their statistical properties. The very large fluxes of giant pulses are coupled with an extremely short duration. Indeed, the overwhelming majority of giant pulses from the millisecond pulsar B1937+21 are shorter than 15 ns (Soglasnov et al. 2004), while giant pulses from the Crab pulsar have a mean width of about few microseconds (Hankins 2000) with occasional bursts shorter than 2 ns (Hankins et al. 2003). The longitude position of giant pulses is remarkable in that it coincides with the position of high-energy emission (Moffett & Hankins 1996; Cusumano et al. 2003; Johnston et al. 2004; Knight et al. 2006). Furthermore, giant pulses originate in a very narrow phase window that in general does not correspond to the phase window of regular radio emission. In the millisecond pulsar B1937+21, giant pulses are observed at the very trailing edge of the average profile in both the main pulse and the interpulse (Cognard et al. 1996; Kinkhabwala & Thorsett 2000; Soglasnov et al. 2004). Popov et al. 2006 has recently suggested that giant pulses from the Crab pulsar are also seen at the trailing edge of the regular radio emission window, which they consider to be the precursor. In other words, they consider that radio emission in the main pulse and the interpulse of the Crab pulsar consists completely of giant pulses. Lastly, an essential property of giant pulses, by which they may be distinguished from normal strong pulses, is the distribution of their flux densities, which appears to follow a power law in contrast with the Gaussian or exponential flux distribution typical of regular (ordinary) individual pulses (Backer 1971; Hesse & Wielebinski 1974; Ritchings 1976). In this paper we present an analysis of giant pulse-energy distribution based on the observations conducted with the Westerbork Synthesis Radio Telescope (WSRT) at 1200 MHz using the PuMa (Vouette et al. 2002) pulsar backend.

2. Observations and data reduction

The observations were carried out in November 2003 as part of a multi-frequency observing campaign that also included Jodrell Bank at 1420 MHz, Effelsberg at 8350 MHz, Kalyazin at 600 MHz, Pushchino at 111 MHz, and Kharkov (UTR-2) at 23 MHz. Simultaneous optical observations were also made with the 6-m telescope of the Special Astrophysical Observatory and 2.8-m telescope at La Palma. The MAGIC and HESS gamma-ray telescopes in La Palma and Namibya also participated. While some results obtained at the separate observatories have already been published (Jessner et al. 2005; Popov et al. 2006), the joint analysis of multi-frequency observations will be presented in future publications.

We have analyzed the data obtained in observations with the WSRT during about 3.5 hours in two conjugate bands of 10 MHz each at a central frequency of 1197 MHz. Baseband

voltages of X and Y linear polarization states were recorded with two-bit sampling at Nyquist frequency. The coherent predetection dedispersion technique originally developed by Hankins (Hankins 1971; Hankins & Rickett 1975) was used to remove dispersion smearing in the received pulsar signal. We took the value of dispersion measure (56.757 pc cm$^{-3}$) and the timing model from the Jodrell Bank Monthly Ephemeris (Lyne 1982). The technique provides a formal time resolution of 100 ns, but the expected pulse-broadening time due to interstellar scintillations is in the range 2 to 4 $\mu$s, based on the estimation made by Kuzmin et al. (2002). Therefore, we averaged the recorded signal after dispersion removal and square-low detection synchronously with a topocentric pulsar pulse period into 8192 bins per period and with a resulting sampling interval close to 4.1 $\mu$s. The total intensity time series was finally formed and used for detection of giant pulses with the threshold level of 6$\sigma$. To provide better sensitivity for wider giant pulses, we developed a searching procedure which progressively tried to increase the averaging time interval ($\tau_{i}$) by 1, 2, 3, 4, 6, 8, 12, 16, 24, 32, and 48 samples, i.e. from 4.1 $\mu$s to 196 $\mu$s. The averaging time with the best signal-to-noise ratio (SNR) was selected as $W_{\tau}$ for the GP, detected simultaneously at several averaging times. The pulse energy $E$ (or average flux density) was calculated for the GP as a product of the SNR and the pulse width, equal to the averaging time, which corresponds to the best SNR value. In this approach we have different threshold levels both in peak flux density $F_{p}$ and in pulse energy $E$ for each separate averaging time. The value of the root-mean-square deviation (RMS or $\sigma$) goes down with increasing time averaging as the square root of time. Therefore, the threshold level in peak flux density $F_{p}$ decreases with increasing averaging time as $F_{p}(\tau) \propto 1/\sqrt{\tau}$, while the threshold level in pulse energy $E$ increases with $\tau$ as $E(\tau) \propto \sqrt{\tau}$.

For the Crab pulsar, the system temperature is notably influenced by the impact of the Crab Nebula, whose flux density can be approximated by the relation $F_{\nu} = 955\nu^{-0.27}$ Jy ($\nu$ in GHz) (Allen 1973; Bietenholz et al. 1997), which gives $F_{1200} = 909$ Jy at 1200 MHz. In our observations we used all 14 dishes of the WSRT in tied-array mode, where all telescopes are added coherently, with the width of synthesized beam being equal to 34 arcsec, thus reducing the contribution from the Crab Nebula to the system noise by a factor $f_{s} = \Omega_{s}/\Omega_{CN} = 0.14$ to the value $F_{CN} = 127.6$ Jy. Here $\Omega_{CN}$ is a solid angle of the Crab Nebula, and $\Omega_{s}$ a solid angle of the intersection of the synthesized beam with the Crab Nebula. However, there is still the contribution from the individual dishes; the system temperature of every 25-m dish was increased by the Crab Nebula emission by $\Delta T_{CN} = F_{1200}G = 86.3$ K, where G is the gain of a single telescope, equal to 0.095 at 1200 MHz. The intrinsic system temperature in the absence of the Crab Nebula is 30 K at 1200 MHz, and the resulting total system temperature is thus 116.3 K, equivalent to $F_{sys} = 87.4$ Jy for the gain in the tied array (1.33 K/Jy), which when combined with the nebula contribution to the tied array becomes $F_{tot} = F_{sys} + F_{CN} = 215$ Jy. One can see that WSRT reduces the contribution of the Crab Nebula to the system noise considerably when compared with the single dish observations at this frequency. This improvement will permit us to follow the statistics of giant pulses from the Crab pulsar to the lower energies; namely, the limiting RMS ($\sigma$) value in one polarization is $F_{10}/\sqrt{B\tau}$, with $B = 10$ MHz, and $\tau = 4.1$ $\mu$s the RMS is equal to 33.5 Jy. For total intensity, the RMS will be reduced by $\sqrt{2}$, and the threshold of 6$\sigma$ in peak flux density will be equal to 142 Jy. The threshold will be lower for averaged records, with a limiting value of 20 Jy for giant pulses, which have a maximum effective width of about 200 $\mu$s. In total 17869 giant pulses were detected over 37000 pulse periods with 14994 giant pulses located at the longitude of the main pulse and 2875 giant pulses associated with the interpulse. The background rate was determined by counting events at quiescent phases of the pulsar period and the corresponding values were taken into account in our statistical calculations. In fact, at the lowest range, between 6$\sigma$ and 7$\sigma$, only about 10% of all pulses we potentially incorrectly identified as giant pulses.

3. Results

Figure[1] represents the complete set of data showing peak flux density $F_{p}$ versus the effective pulse width $W_{\tau}$. The striped nature of the diagram is caused by the procedure of giant pulse detection, which is based on the discrete values of averaging time $W_{\tau}$. The diagram demonstrates the peculiarity of the statistics on giant pulses: the strongest pulses clearly have a shorter duration; namely, there are no pulses with peak flux density greater than 1000 Jy that are wider than 16 $\mu$s. As a consequence, giant pulses with different durations have different distributions in pulse energy, and the distribution in giant pulse width depends on the range of pulse energy used. Therefore, in our analysis, we separated the giant pulses belonging to the main pulse longitudes into five groups by their widths: (a) – GPs with the effective width $W_{\tau}$ of 4.1 $\mu$s, (b) – GPs with the $W_{\tau}$ of 8.2 $\mu$s, (c) – combined group of GPs with the $W_{\tau}$ of 12.3 and 16.4 $\mu$s, (d) – combined group of GPs with the $W_{\tau}$ of 24.5 and 32.8 $\mu$s, and (e) – combined group of GPs with the $W_{\tau}$ of 49.2 and 65.6 $\mu$s. A separate group (f) was formed for the GPs detected at the longitude of the interpulse with the $W_{\tau}$ of 4.1, 8.2, and 12.3 $\mu$s. Then, pulse energy, or integrated flux density, was calculated as $E = F_{p} \times W_{\tau}$.

In our analysis we use cumulative probability distribution (CPD), which gives the number of pulses $N(E)$, above pulse en-
Table 1. The list of parameters of the power-law fits to the CPDs displayed in Fig.2.

| Group | \( W_c(\mu s) \) | \( \gamma_{\text{high}} \) | \( \gamma_{\text{low}} \) | \( E_{\text{break}} \) (Jy \cdot \mu s) |
|-------|----------------|-----------------|-----------------|-------------------|
| (a)   | 4.1            | 1.7             | 1.1             | 4000              |
| (b)   | 8.2            | 1.8             | 1.0             | 3500              |
| (c)   | 12.3, 16.4     | 2.3             | 1.2             | 4000              |
| (d)   | 24.5, 32.8     | 2.5             | 1.4             | 4000              |
| (e)   | 49.2, 65.6     | 3.2             | 1.9             | 5000              |
| (f)   | 4.1, 8.2, 12.3 | 1.6             | 1.6             |                   |

The absence of any break in the power-law fit for the CPD of the GPs belonging to the interpulse longitudes is good proof that the observed breaks in the CPDs of the main pulse GPs were not caused by selection effects, since we used exactly the same procedure for GPs detection irrespective of pulse longitude. A possible explanation is that we observe the regions where the GPs are generated in the main pulse and the interpulse at different impact angles relative to the GP beam, which has a half width of about 5 degrees. Indeed, the comparison of the CPDs (combined for the width groups (a), (b), and (c)) for the main pulse and the interpulse shows that the CPDs would be identical if one were to multiply the interpulse GP energies by a factor of about 4 and increase their rate of occurrence by a factor of about 2. Therefore, the weakest detected interpulse GPs with a pulse energy of about 1000 Jy \cdot \mu s, when observed at the same impact angle as the main pulse GPs (multiplied by 4), will have pulse energies of 4000 Jy \cdot \mu s, which is above the break point.

4. Discussion and conclusions

The CPD function of the GPs originating at the longitudes of the main pulse manifests gradual changes in the power-law index from \(-1.7\) to \(-3.2\) at the high energy part of the CPD, and from \(-1.0\) to \(-1.9\) at the low energy portion of the CPD. As a rough guide, all GPs can be separated into two main groups: short GPs belonging to groups (a) and (b), and long GPs with an \( W_c \) greater than 8.1 \( \mu s \). It is interesting to note that the CPD power-law index of about \(-1.7\) for short GPs is close to the exponent determined for the CPD of the GPs from the millisecond pulsar B1937+21, which was found to be equal to \(-1.8\) at 430 MHz (Cognard et al. [1996]). The value was confirmed by Kinkhabwala & Thorsett (2000), and recently estimated by Soglasnov et al. [2004] as \(-1.4\) at 1650 MHz. All GPs from the millisecond pulsar are very short, lasting only 1-2 \( \mu s \) as measured by Kinkhabwala & Thorsett (2000), while Soglasnov et al. [2004] have found that the majority of GPs from this pulsar are shorter than 15 ns.

Argyle & Gower (1972) were the first to present the CPD for GPs from the Crab pulsar. They combined the results of observations made at 146 MHz with the 26-m Penticton radio telescope and with the 46-m dish at the Algonquin Radio Observatory and found that the CPD was consistent with the power-law exponent of \(-2.5\) for the main pulse and with the exponent for the interpulse events equal to \(-2.8\).

Recently Cordes et al. (2004) in their multifrequency study of the Crab pulsar’s giant pulses presented histograms of GP peak amplitudes (S) at 0.43 and 8.8 GHz. The histograms represent the PD functions, i.e. number of events per interval of SNR in logarithmic binning \( d(\log S) \). They found power-law segments in the distributions with the slopes \(-2.3\) and \(-2.9\) at 0.43 and 8.8 GHz, respectively. To compare this result with our study of the CPD functions one has to convert the number of events presented by Cordes et al. (2004) from logarithmic binning to linear binning \( d(\log S) = \ln 10 dS/S \). Then, for a power-law fit with linear binning the slope will change from \(-\beta\) to \(-\beta+1\):

\[
N(S) \propto (S)^{-\beta} d\log(S) \propto (S)^{-(\beta+1)} dS
\]

for the power-law fit of the CPD \( \gamma = -\beta - 1 \), as was explained in Sect. 3. Thus, the values of the power-law exponent \( \beta \) found by Cordes et al. (2004) in their histograms may be immediately compared with our values of the exponents \( \gamma \) for the power-law fit of the CPDs. In fact the inspection of the histogram of Cordes et al. (2004) for 0.43 GHz has enabled us to distinguish a break at an \( S/N \) value of about 30 where the slope changes from \(-2.3\) to \(-0.7\) in the peak amplitude distribution of the main pulse GPs, while the distribution for the interpulse GPs does not manifest such a break. With the given equivalent flux system temperature of 1262 Jy, the receiver band of 12.5 MHz, and a sample interval of 128 \( \mu s \), the \( S/N = 30 \) break point at 0.43 GHz will correspond to a pulse energy of about 120000 Jy \cdot \mu s.

In his PhD thesis Moffett (1997) presents the CPD functions at 1.4 GHz based on observations conducted with the VLA with a time resolution of 160 \( \mu s \). In Fig. 4.3 (page 62) Moffett distinguishes a break in power-law fit of the CPD of the main pulse GPs at a level of 12 Jy corresponding to a pulse energy of about 2000 Jy \cdot \mu s, where the slope changes from \(-3.0\) to \(-1.8\) when going from the high flux densities to the lower. Again, the CPD for the GPs originated at the longitudes of the interpulse (Figure 4.4) does not show a break going straight with the slope of \(-1.7\) until it merges with noise at a level of about 6 Jy.

Comparing the values of break-point pulse energy (BPPE) 120000 Jy \cdot \mu s at a frequency of 0.43 GHz (Cordes et al. [2004]), 5000 Jy \cdot \mu s at a frequency of 1200 MHz (this paper), and 2000 Jy \cdot \mu s at a frequency of 1400 MHz (Moffett [1997]), we have found that the BPPE follows a simple power-law frequency dependence \( BPPE(v) \approx 7(v)^{-3.4}Jy \cdot \mu s \), with the exponent \(-3.4\) close to the mean spectral index for the main pulse component of the average profile \(-3.0\) (Moffett [1997]). The conclusion can be considered as support for the suggestion
Fig. 2. The CPD of giant pulses with pulse energy above the displayed value for different groups of giant pulses classified by their effective width $W_e$ as described in the Table. Straight lines represent the fit by power-law functions with the parameters indicated in the Table. The last plot (f) represents giant pulses belonging to the interpulse.

that all emission in the main component consists entirely of giant pulses (Popov et al. 2006).

Lundgren et al. (1995) has collected about 30000 GPs from the Crab pulsar at 812 MHz with the Green Bank 43-m radio telescope in 10 days of observations simultaneous with the Compton Gamma Ray Observatory (CGRO) in May 1991. They did not distinguish GPs belonging to the main pulse and the interpulse. Their flux-density distribution was fitted with a power-law function for $S > 200$ Jy, and the exponent was found to be equal to $-3.46$, the exponent being equal to $-2.46$ for the CPD used in our analysis. The BPPE value is expected to be 14 kJy $\cdot$ $\mu$s at 812 MHz according to the frequency relation we derive above. The value corresponds to 50 Jy flux density with $307.5 \mu$s averaging time used by (Lundgren et al. 1995), and it is well below their threshold of 120 Jy. The dramatic roll-off at the rather high pulse energy of about $200$ Jy $\times$ $300 \mu$s = $60$ kJy $\cdot$ $\mu$s found by (Lundgren et al. 1995) was not observed in the CPDs at 430, 1200, and 1400 MHz discussed above. It was not observed in the CPD at 600 MHz either, which goes straight with the slope of $-2.2$ at least down to a pulse energy of about
Therefore, it is difficult to reconcile their results with those from the many independent data sets mentioned above.

The power-law form of the observed CPDs can be compared with the field statistics of possible emission mechanisms responsible for the generation of GPs, as discussed by Cairns (2004) who used the values of the exponents of PD functions for comparison. The very short-time flux density variations are responsible for the generation of GPs, as discussed by Cairns et al. (2004), who treated the micropulses as solitons of the radio-wave envelope propagating through the magnetospheric plasma of the pulsar.
