The dynamics of fermionic many-body systems is investigated in the framework of Boltzmann-Langevin (BL) stochastic one-body approaches. Within the recently introduced BLOB model, we examine the interplay between mean-field effects and two-body correlations, of stochastic nature, for nuclear matter at moderate temperature and in several density conditions, corresponding to stable or mechanically unstable situations. Numerical results are compared to analytic expectations for the fluctuation amplitude of isoscalar and isovector densities, probing the link to the properties of the employed effective interaction, namely symmetry energy (for isovector modes) and incompressibility (for isoscalar modes). For unstable systems, clusterization is observed. The associated features are compared to analytical results for the typical length and time scales characterizing the growth of unstable modes in nuclear matter and for the isotopic variance of the emerging fragments. We show that the BLOB model is generally better suited than simplified approaches previously introduced to solve the BL equation, and it is therefore more advantageous in applications to open systems, like heavy ion collisions.

I. INTRODUCTION

The dynamics of many-body interacting systems is a long-standing investigation embracing various domains at the boundary between collective and chaotic processes. From a one-body modelling perspective, the dynamics of fermionic systems [1, 2] is efficiently described with the time-dependent Hartree-Fock (TDHF) framework, or time-dependent local density approximation (TDLDA), in condense-matter applications [3, 4], as far as the variance of the involved observables is small and can be neglected. If this is not the case, additional excitation beyond mean-field correlations should be included, depending on the degree of excitation [5–7]. At low energy, as far as the system can be described in the small-amplitude limit, a scheme of coherent-state propagation within the time-dependent generator coordinate method (TDGCM) [8, 9], or a variational approach à la Balian-Véronéni [10, 11] is well suited. On the contrary, when the system experiences a violent dynamics, large fluctuations would spontaneously drive the system far away from the one-body TDHF evolution along many different directions, thus determining the shortcoming of the TDHF approximation (and the above mentioned extensions). To address large-amplitude regimes, solutions beyond the single-particle picture may be needed, for instance by propagating non-correlated states [12]. When even the low-energy regime is exceeded, dissipative behaviour results also from in-medium collisions, which are no more hindered by Pauli blocking.

In presence of mean-field instabilities, the collective dynamics may be driven to a chaotic regime: in a nuclear system, this would result in a highly non-linear process, leading to clusterisation from one-body density fluctuations, and oscillation of the neutron and proton fraction. The splitting of a composite system into fragments under violent perturbations signs the occurrence of the most catastrophic effect produced by large-amplitude fluctuations of the neutron and proton content. Such phenomenology, which is common in heavy-ion collisions at Fermi energies [13, 14], also characterises other fields, like solid-state physics (examples are metal clusters [15, 16] or electrons in nanosystems [17]), ultracold atomic gases [18, 19] or some areas of astrophysics [20–23]. The description of the fragmentation process can only be afforded within approaches beyond the mean-field approximation, incorporating the effect of many-body correlations, which induce fluctuations in the evolution of the one-body density. Adapted to such situation, stochastic approaches typically propagate a bunch of mean-field trajectories within various orders of approximations, like stochastic TDHF (STDHF) formulations [24–27], or analogue semiclassical schemes within the Boltzmann-Langevin (BL) transport equation [28, 29].

In the following we exploit the last mentioned BL approach in the form of the recently introduced Boltzmann-Langevin one body (BLOB) model [30, 31] to undertake an exhaustive analysis of the interplay between mean-field and many-body correlations in nuclear matter. We focus thereafter on crucial modelling issues, looking in particular at the dynamics of fluctuations, both in stable systems and in unstable conditions, leading to the disassembly of the system. The purpose is to examine virtues and limits of the BLOB approach, where the BL equation is solved in full phase space, and of corresponding approximations by carrying out a quantitative study of fluctuation amplitudes, and comparing with some analytic expectations which characterise Fermi liquids. This analysis is important also in the spirit of preparing reliable applications to heavy-ion collisions. Indeed a good reproduction of the fluctuation dynamics is crucial for the predictions of features, such as size and isotopic variances, of the products formed in nuclear reactions and to probe their link to the properties of the nuclear effective interaction.

In Sec. II we survey some basic steps leading from a stochastic beyond-mean-field framework to the BLOB
II. THEORETICAL SURVEY

A. N-body correlations in a stochastic one-body framework in dissipative regimes

It is usual to describe the evolution of an N-body system by replacing the Liouville-von Neumann equation with the equivalent BBGKY hierarchy which, for a two-body interaction \( V_{ij} \), yields the following chain of coupled equations

\[
\begin{align*}
\dot{\rho}_1 &= [k_1, \rho_1] + \text{Tr}_2[V_{12}, \rho_{12}] \\
\dot{\rho}_{12} &= [k_1 + k_2 + V_{12}, \rho_{12}] + \text{Tr}_3[V_{13} + V_{23}, \rho_{132}] \\
\dot{\rho}_{1 \cdots k} &= \sum_{i=1}^{k} \left[ k_i + \sum_{j<i} V_{ij}, \rho_{1 \cdots k} \right] \\
&\quad + \sum_{i=1}^{k} \text{Tr}_{k+1}[V_{ik+1}, \rho_{1 \cdots k+1}] \\
\cdots &= 
\end{align*}
\]

where \( \text{Tr}_k \) is a partial trace involving the many-body density matrix \( \rho_{1 \cdots k} \) (compact notation where the order corresponds to the number of indexes) and \( k_i \) are kinetic energy operators. This is the avenue for constructing beyond-mean-field approximations, obtained through custom truncations of the hierarchy, or by reducing the complexity of the involved contributions at given orders. For instance, the inclusion of interactions beyond two bodies would be necessary to account for additional nuclear-structure features [32], or cluster correlations, and the explicit inclusion of correlations beyond the order \( k = 2 \) would be necessary to describe high-coupling regimes [33].

If, on the other hand, a suited stochastic approach is adopted, simplified higher-order contributions can be introduced even though not explicitly implemented. Already in a first-order-truncation scheme (\( k = 1 \)) in a low-energy framework, it was found that a stochastic approach can be used to restore all the BBGKY missing orders approximately [34], and generate large-amplitude fluctuations; in this case, a coherent ensemble of mean-field states is propagated along different trajectories from an initial stochastic distribution. Such scheme is however insufficient for our purpose, which is addressing dissipative regimes. In this case, it is necessary to introduce in-medium collisions in a second-order scheme (\( k = 2 \)), explicitly, i.e. the first two lines of the set (1), from which kinetic equations are obtained [35–38]. If structure effects are neglected, it is then possible to propagate an incoherent ensemble of mean-field states, supplemented by a fluctuating term, in order to obtain a highly nonlinear character of the dynamics. The stochastic treatment is not obtained from exploiting a distribution of initial states but, progressing from a single initial state. It acts intermittently all along the temporal evolution, producing successive splits of a given mean-field trajectory \( \rho_1 \) into subensembles \( \rho^{(n)}_1 \):

\[ \rho_1 \rightarrow \{ \rho^{(n)}_1 ; n = 1, \ldots, \text{subens.} \}. \]  

This pattern then repeats for each element of the subensemble \( \rho^{(n)}_1 \) till eventually yielding trajectories ordered in bifurcating bundles, each one exhibiting a small variance around the mean trajectory of the corresponding envelope. In particular, in the time interval between two successive splits, when fluctuations are built up, the system propagates keeping the mean trajectory unchanged within each envelope. Thus this time, \( \tau \), has to be shorter than the time scales associated with the global effect of the collision integral and with the mean-field propagation.

B. Collisional correlations

This stochastic scheme is equivalent to imposing that \( \rho^{(n)}_1 \) and \( \rho^{(n)}_2 \), i.e. the probabilities to find two nucleons, 1 and 2, at two configuration points, are not all the time decorrelated, so that the two-body density matrix \( \rho^{(n)}_{12} \) recovers some correlations of the upper orders of the BBGKY sequence in addition to the standard product of independent one-body densities which builds up the mean-field term. We can write at a time \( t \):

\[
\begin{align*}
\rho_{12}^{(n)}(t) &= \tilde{\Omega}_{12} A_{12}(\rho_1^{(n)}(t) \rho_2^{(n)}(t)) \tilde{\Omega}_{12}^{\dagger} + \delta \rho_{12}^{(n)}(t) \quad ;
\end{align*}
\]

\[
\begin{align*}
\langle \delta \rho_{12}^{(n)}(t) \rangle_{\tau} &= 0 ;
\end{align*}
\]

\[
\begin{align*}
\langle \delta \rho_{12}^{(n)}(t) \delta \rho_{12}^{(n)}(t) \rangle_{\tau} &= \text{gain} + \text{loss} ,
\end{align*}
\]
where \( \Omega_{12} \) is the Möller wave operator \([39, 40]\) describing the diffusion of a particle with respect to another particle in the nuclear medium, related to a diffusion matrix \( G_{12} = V_{12} \Omega_{12} \), which is, in turn, related to the nucleon-nucleon differential cross section \([G_{12}]^{2} \sim d\sigma/d\Omega\). In this respect, the first term of the r.h.s. of eq. (3) contains collisional correlations, while the second term introduces a fluctuation of vanishing first moment around the collision integral \([6]\). It should be noticed that the average in Eqs.(4,5) refers to an ensemble of one-body trajectories fluctuating, over the time \( \tau \), around a mean trajectory which follows the Boltzmann equation. Setting \( \delta \rho^{(n)}_{12}(t) = 0 \) would then reduce to the (quantum) Boltzmann kinetic equation, which corresponds to a second-\( \delta \rho \) fluctuation of vanishing first moment around the collision integral. 

Finally, the description associated with one single mean-field trajectory \( \rho^{(n)}_{1} \) yields the following form of the BL equation containing an average collision contribution \( f^{(n)}_{\text{coll}} \) and a continuous source of fluctuation seeds \( \delta f^{(n)}_{\text{coll}} \).

\[
 i\hbar \frac{\partial \rho^{(n)}_{1}}{\partial t} \approx [\rho^{(n)}_{1} + V^{(n)}_{1}, \rho^{(n)}_{1}] + f^{(n)}_{\text{coll}} + \delta f^{(n)}_{\text{coll}}. \tag{6}
\]

It may be noted that Eq. (6) is similar to STDHF \([24]\), and it transforms into an extended TDHF (ETDHF) theory \([41–43]\) if the fluctuating term \( \delta f^{(n)}_{\text{coll}} \) is suppressed; ETDHF can in fact efficiently describe the behavior of some observable related to dissipative processes, but it can not follow possible bifurcation paths deviating from the mean trajectory. Through a Wigner transform we can then replace Eq. (6) by a corresponding set of semiclassical BL trajectories:

\[
 \frac{\partial f^{(n)}}{\partial t} = \{ h^{(n)}, f^{(n)} \} + f^{(n)}_{\text{UU}} + \delta I^{(n)}_{\text{UU}}, \tag{7}
\]

where the evolution of a statistical ensemble of Slater determinants is replaced by the evolution of an ensemble of distribution functions \( f^{(n)} \), which at equilibrium correspond to a Fermi statistics. \( h^{(n)} \) is the effective Hamiltonian acting on \( f^{(n)} \). The residual average and fluctuating contributions of Eq. (6) are replaced by Uehling-Uhlenbeck (UU) analogue terms. \( f^{(n)}_{\text{UU}} \) is related to the mean number of transitions within a single phase-space cell \( \Delta V_{f} \). While conserving single-particle energies, \( \delta I^{(n)}_{\text{UU}} \) acts as a Markovian contribution expressed through its correlation \([44]\)

\[
 \langle \delta I^{(n)}_{\text{UU}}(r,p,t) \delta I^{(n)}_{\text{UU}}(r',p',t') \rangle = \text{gain} + \text{loss} = 2 D(r,p;r',p',t') \delta(t - t'), \tag{8}
\]

where \( D \) is a diffusion coefficient \([28]\).

C. Obtaining the BLOB description: fluctuations in full phase space

From Eq.(4) and from the procedure detailed in ref. \([45]\), we assume that the fluctuating term \( \delta I^{(n)}_{\text{UU}} \) in Eq. (7) should involve the same contributions composing the average collision term \( f^{(n)}_{\text{UU}} \), i.e. the transition and the Pauli-blocking terms. This implies that also \( \delta I^{(n)}_{\text{UU}} \) should be expressed in terms of one-body distribution functions. This latter possibility can be exploited by replacing the residual terms \( (I^{(n)}_{\text{UU}} + \delta I^{(n)}_{\text{UU}}) \) by a similar UU-like term which respects the Fermi statistics both for the occupancy mean value and for the occupancy variance. In this case, for a free Fermi gas, the occupancy variance at equilibrium should be equal to \( f^{(n)}(1 - f^{(n)}) \) in a phase-space cell \( h^{3} \) and correspond to the movement of extended portions of phase space which have the size of a nucleon, i.e. the residual term \( (I^{(n)}_{\text{UU}} + \delta I^{(n)}_{\text{UU}}) \) should carry nucleon-nucleon correlations \([46]\).

A natural solution to satisfy such requirement is to rewrite the residual contribution in the form of a rescaled UU collision term where a single binary collision involves extended phase-space portions of equal isospin \( A, B \) to simulate wave packets, and Pauli-blocking factors act on the corresponding final states \( C, D \), also treated as extended phase-space portions. The choice of defining each phase-space portion \( A, B, C \) and \( D \) so that its isospin content is either 1 or \(-1\) is necessary to preserve the Fermi statistics for both neutrons and protons, and it imposes that blocking factors are defined accordingly in phase-space cells for the given isospin species. The above conditions lead to the BLOB equations \([30]\):

\[
 \frac{\partial f^{(n)}}{\partial t} - \{ h^{(n)}, f^{(n)} \} = I^{(n)}_{\text{UU}} + \delta I^{(n)}_{\text{UU}} = \int g \frac{\hbar p_{\nu}}{h^{3}} \int W(AB\leftrightarrow CD) F(AB\rightarrow CD) \, d\Omega, \tag{9}
\]

where \( g \) is the degeneracy factor. \( W \) is the transition rate, in terms of relative velocity between the two colliding phase-space portions and differential nucleon-nucleon cross section

\[
 W(AB\leftrightarrow CD) = |v_{A} - v_{B}| \frac{d\sigma}{dt}. \tag{10}
\]

\( F \) contains the products of occupancies and vacancies of initial and final states over their full phase-space extensions.

\[
 F(AB\rightarrow CD) = \left[ (1-f_{A})(1-f_{B})f_{C}f_{D} - f_{A}f_{B}(1-f_{C})(1-f_{D}) \right]. \tag{11}
\]

Details on the implementation of BLOB are given in appendix A. In practice, if the test-particle method is employed, so that the system is sampled by \( N_{\text{test}} \) test-particles each, and \( D \) should be agglomerates of \( N_{\text{test}} \) test-particles each, and the nucleon-nucleon cross section used in Eq. (10) should be scaled by the same amount \( N_{\text{test}} \) (Eq. (A1) ). Finally, the stochastic approach exploits the correlations carried in Eq. (9), recovering higher order than the \( k = 2 \) truncation, and inducing the BL fluctuations-bifurcation scheme.
D. Simplification through the SMF description: fluctuations projected

At variance with the above description, the stochastic term in Eq. (7) can be kept separate and treated as a stochastic force related to an external potential $U'$, like in the corresponding semi-classical stochastic mean field (SMF) model [47]. This leads to treatments where fluctuations are implemented only in the coordinate space, i.e. they are projected on the spacial density. The difference between Eq. (9) and usual stochastic mean-field approaches is that those latter build fluctuations from introducing a well adapted external force or a distribution of initial conditions which should be accurately prepared in advance. On the contrary, Eq. (9) introduces fluctuations in full phase space and let them develop spontaneously and continuously over time in a dynamical process.

Fig. 1 illustrates how this difference affects the statistics of effective in-medium collision (i.e. not Pauli blocked); it compares SMF and BLOB calculations performed in nuclear matter at 3 MeV temperature and at different densities in stable conditions, i.e. keeping the system uniform, and at equilibrium, i.e. when the average collision rate is constant in time (these conditions are described in details in Sec. IV). As a general trend, larger densities provide a larger number of collisions, we can further decompose fluctuations in isoscalar and isovector fluctuations of the one-body density, in the description of heavy-ion collisions [51].

In the following, we check how Eq. (9) handles isoscalar and isovector fluctuations of the one-body density, in equilibrated nuclear matter, with the aim of demonstrating that its implementation is better suited than approximate methods, like SMF, to sample the development of inhomogeneities (equivalent process to fragment formation in finite open systems) and the related observables. We therefore compare results obtained with BLOB and SMF.

III. STRATEGY: COMPARING BL APPROACHES IN NUCLEAR MATTER TO THE FERMI-LIQUID BEHAVIOUR

The purpose of stochastic one-body approaches with collisional correlations like SMF or BLOB is introducing aspects of the Fermi liquid behaviour, including fluctuations [49, 50], in the description of heavy-ion collisions [51].

In the following, we check how Eq. (9) handles isoscalar and isovector fluctuations of the one-body density, in equilibrated nuclear matter, with the aim of demonstrating that its implementation is better suited than approximate methods, like SMF, to sample the development of inhomogeneities (equivalent process to fragment formation in finite open systems) and the related observables. We therefore compare results obtained with BLOB and SMF.

A. Fluctuations in nuclear matter: analytic estimate

Let us consider nuclear matter at low temperature. Either from the stochastic fluctuating residual term of the BLOB treatment or from an external stochastic force in the SMF approach, we introduce a small disturbance in uniform matter $\delta f(r,p,t) = f(r,p,t) - f^0(p,t)$ which lets fluctuations develop in time around the mean trajectory $f^0$.

By considering neutron and proton distribution functions, we can further decompose fluctuations in isoscalar

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{figure1}
\caption{Mean-value (left) and variance (right) of the number of effective in-medium collisions per nucleon and per unit time $\delta t = 1 \text{ fm/c}$ for SMF (full black circles) and BLOB, as a function of density. The different open symbols correspond to BLOB calculations with different number of test particles. The dashed-lines on the left panel represent fits to mean-value spectra and they are replotted identically in the right panel, for comparison. The crosses in the righ panel correspond to the SMF variance (black dots) multiplied by $N_{\text{test}}$. An asy-stiff parameterisation is used for the symmetry energy (the characteristics of the interactions are defined in Sec. IV).}
\end{figure}
modes $\delta f^s$ and isovector modes $\delta f^v$:
\[
\begin{align*}
\delta f^s &= (f^s_n - f^s_0) + (f^s_p - f^s_0) \\
\delta f^v &= (f^v_n - f^v_0) - (f^v_p - f^v_0),
\end{align*}
\]  
(12)

(13)
corresponding to phase-space density modes where neutrons and protons oscillate in phase or out of phase, respectively. The temporal evolution of both those modes is obtained by applying the BL equation (7) to the phase-space fluctuations. For symmetric matter, and retaining only first-order terms in $\delta f^q$, one obtains:
\[
\frac{\partial \delta f^q}{\partial t} + \frac{P}{m} \nabla_r f^q - \frac{\partial f^q}{\partial t} \frac{\partial U^q}{\partial \rho^q} m \nabla_r \delta \rho^q = \frac{\partial f^q}{\partial t} \frac{P}{m} \nabla_r U',
\]  
(14)
where the index $q$ stands either for isoscalar ($q = s$) or isovector ($q = v$) modes, $f^q = f^q_n + f^q_0$, $U^q$ is the mean-field potential in the $q$ channel and $U'$ is an external stochastic force (SF) or a fluctuating stochastic field (BLOB). We dropped the average collision term $I_{UU}$ because we consider small temperatures.

To build our stochastic descriptions we assumed that, at least locally, fluctuations have a small amplitude around their mean trajectory so that $\delta f^q \ll f^q$. When the system is described as a periodic box, collective modes are associated to plane waves of wave number $k$. In this case, by expanding on plane waves expressed in Fourier components, we can study the evolution in time of phase space density fluctuations
\[
\delta f^q(r, p, t) = \sum_k e^{i(kr)} f^q_k(p, t) = \sum_k e^{i(kr)} e^{i(\omega_k t)} f^q_k(p)
\]  
(15)
and undulations in the density landscape $\delta \rho^q(r, t) = \sum_k e^{i(kr)} \rho^q_k(t)$. Rewritten in Fourier components, Eq. (14) takes the form
\[
i \omega_k f^q_k + \frac{i k \cdot P}{m} f^q_k - \frac{\partial f^q}{\partial t} \frac{\partial U^q_k}{\partial \rho^q} k \cdot P m \rho^q_k = \frac{\partial f^q}{\partial t} k \cdot P m f^q_k
\]  
(16)
where $U^q_k$ and $F^q_k$ are Fourier components of the potential $U$ and of the stochastic fluctuating field $U'$, respectively.

When the fluctuation modes are of stable nature, the response of the system to the action of the stochastic fluctuating field $F^q_k$ determines the equilibrium variance $(\sigma^q_k)^2$ associated to the fluctuation $\rho^q_k$. The inverse Fourier transform of $(\sigma^q_k)^2$ gives the equilibrium variance of spacial density correlations
\[
(\sigma^q_k)^2 \equiv \langle (\delta \rho^q(r))^2 \rangle = (2\pi)^{-3} \sum_k (\sigma^q_k)^2 dk
\]  
(17)
in a cell of volume $\Delta V$ at temperature $T$. At equilibrium, when the level density $N \equiv (g/h^3) \int \partial_t f^q dp$ for a degeneracy $g$ can be defined, these variances are related to the curvature of the free energy density $F^q(k)$ through the fluctuation–dissipation theorem so that
\[
(\sigma^q_k)^2 = \frac{T}{F^q(k)}; \quad (\sigma^q_k)^2 = \frac{T}{\Delta V} \langle \frac{1}{F^q(k)} \rangle_k
\]  
(18)
where $F^q(k) = \partial_{\rho^q} U^q_n + 1/N$, and for an average $\langle \cdot \rangle_k$ extending over all $k$ modes. On the other hand, for unstable modes, the diffusion coefficient $D$, or rather its projection on a given unstable mode $k$, $D_k$, determines the following evolution for the intensity of response $(\sigma^q_k)^2$ for the wave number $k$ [44, 52]:
\[
(\sigma^q_k)^2(t) \approx D_k \tau_k (e^{2t/\tau_k} - 1) + (\sigma^q_k)^2(t=0) e^{2t/\tau_k},
\]  
(19)
where both the initial fluctuation seeds $(\sigma^q_k)^2(t=0)$ and the fluctuation continuously introduced by the collisional correlations contribute to an exponential amplification of the disturbance, characterised by the growth time $\tau_k$.

### B. Scenarios for isovector and isoscalar fluctuations

In the following, starting from Eq. (16), we concentrate on the propagation of isovector modes, which are always of stable nature, and isoscalar modes, with a special focus on unstable conditions.

Isovector fluctuations, based on Eq. (18) and studied in Sec. IV for nuclear matter at several density values, define how isospin distributes among different phases and portions of the system. On the other hand, isoscalar fluctuations developing in mechanically unstable nuclear matter, which rely on Eq. (19), studied in Sec. V, coincide with the process of separation of those portions of the system into fragments. The latter scenario has been intensively investigated [7] foremost because in open dissipative systems, like heavy-ion collisions, it corresponds to a catastrophic process which can lead to the formation of nuclear fragments [53, 54]. The size-distribution of fragments and their formation time are ruled by the dispersion relation for wavelengths related to unstable $k$ modes so that, when unstable modes succeed to get amplified, inhomogeneities develop and eventually lead to mottling patterns at later times. Then, in this case, isovector fluctuations define the isotopic features of fragments and their connection to the symmetry energy [55].

### IV. RESULTS ON ISOVECTOR FLUCTUATIONS

Isovector effects in nuclear processes may arise from different mechanisms [56, 57], like the interplay of isospin and density gradients in the reaction dynamics, or nuclear cluster formation, or the decay scheme of a compound nucleus. In systems undergoing a nuclear liquid-gas phase transition, a role is played also by isospin distillation [7, 58], a mechanism which consists in producing a less symmetric nucleon fraction in the more volatile phase of the system along the direction of phase separation in a $\rho_n - \rho_p$ space, as an effect of the potential term in the symmetry energy [59, 60].

Along with these analyses, it is particularly instructive to investigate the developing of isovector fluctuations,
around the mean trajectory, in two-component nuclear matter.

A. Preparation of a stable and uniform system

We consider nuclear matter with periodic boundary conditions. We refer the reader to the appendix B for details on the parameters chosen for the calculations in the following sections.

Selecting isovector modes \((q \rightarrow v)\) in Eq. (16), the phase-space density corresponds to \(f^v = f_n - f_p\). In order to select the isovector behaviour, we keep only the isovector contribution in the nuclear potential. Indeed, in absence of isoscalar terms, the system is stable at all density values \(\rho_0\) and one can investigate how isovector fluctuations depend on \(\rho_0\).

\[
U^q \rightarrow U^v = 2[(\rho_n - \rho_p)/\rho^0]E_{\text{sym}}^{\text{pot}},
\]

where \(\rho^0\) is the uniform-matter density and \(E_{\text{sym}}^{\text{pot}}\) is the potential term in the symmetry energy. Following the procedure of ref. [55], \(U^v_{\text{sym}}\) is obtained from the above quantity by introducing an interaction range through a Gaussian smearing \(g_\sigma\) of width \(\sigma\), and by taking the Fourier transform; its derivative with respect to \((\rho_n - \rho_p)\) yields

\[
F^v(k) = (2/\rho^0)E_{\text{sym}}^{\text{pot}}(\rho^0)g_\sigma(k) + 1/N.
\]

Thus, from Eq. (18), we obtain the relation:

\[
F^v_{\text{eff}} = \frac{T}{2\Delta V} \frac{\rho^0}{(\sigma_{\rho^0})^2} = \frac{T}{2\Delta V} \frac{\rho^0}{\langle (\delta \rho_n(r) - \delta \rho_p(r))^2 \rangle},
\]

where \(F^v_{\text{eff}}\) can be assimilated to an effective symmetry free energy which, at zero temperature and neglecting surface effects, coincides with the symmetry energy \(E_{\text{sym}}(\rho^0)\).

In conventional BUU calculations, however, the smearing effect of the test particles introduces a corresponding scaling factor [44], so that \(F^v_{\text{eff}} \approx N_{\text{test}}E_{\text{sym}}\). Such scaling actually reduces drastically the isovector fluctuation variance produced by the UU collision term. In the following, we investigate how the collision term used in the BLOB approach differs from the UU treatment. Since the former is not an average contribution and it acts independently of the number of test particles, we expect a larger isovector fluctuation variance.

To prepare a transport calculation, the system is initialised with a Fermi-Dirac distribution at a temperature \(T = 3\) MeV; it is then sampled for several values of \(\rho^0\) and the potential, restricted to the only isovector contribution, is tested for a stiff and a soft density dependence of the symmetry energy for symmetric matter (see appendix B).

B. Isovector fluctuation variance and symmetry energy

From a set of calculations for different densities ranging from \(\rho^0 = 0.02\) to \(\rho^0 = 0.2\) fm\(^{-3}\) we obtain a numerical solution of the r.h.s. of Eq. (22) for SMF. We use \(N_{\text{test}} = 40\). We consider an equilibrium temperature extracted for each density bin from the slope of the Fermi-Dirac distribution evolved in time. The isovector variance \((\sigma_{\rho^0})^2\), calculated in cells of edge size \(l = 1\), \(l = 2.05\) and \(l = 3.55\) fm, is multiplied by \(N_{\text{test}}\), in order to extract \(F^v_{\text{eff}}\) and to compare it with the symmetry energy \(E_{\text{sym}}\). The comparison, shown in Fig. 2, is satisfactory and it is the closest in shape to \(E_{\text{sym}}\) for larger cells than \(l = 1\) fm but, however, the large scaling factor \(N_{\text{test}}\) has to be taken into account. The better agreement in larger cells reflects the decreasing importance of surface effects, so that the calculation gets close to the (volume) symmetry energy.

We notice that an equivalent calculation where the collision term is suppressed yields identical distributions; such collisionless calculation corresponds to switching off the collision term. The need of scaling by \(N_{\text{test}}\) to recover the expected fluctuation value reflects the fact that isovector fluctuations are not correctly implemented in

![FIG. 2](image_url)

**FIG. 2.** The effective symmetry energy, scaled by \(N_{\text{cost}}\), as extracted from SMF simulations, using Eq. (22), for nuclear matter at temperature \(T = 3\) MeV and at several density values. The different symbols correspond to the three edge sizes \(l\) of the cells over which the isovector variance is evaluated. Two parametrizations of the symmetry energy are considered in the calculations: asy-soft (left panel) and asy-stiff (right panel). In both panels, the dot-dashed line represents the analytical expression of the symmetry energy. For the asy-stiff case (right panel), an SMF calculation where the collision term is suppressed is also shown for the edge size \(l = 2.05\) fm (full violet line). Error bars indicate the standard deviation of the \(F^v_{\text{eff}}/N_{\text{cost}}\) distribution obtained considering several time instants within a large interval at equilibrium.
SMF. Indeed, much attention is paid in the model to a good reproduction of isoscalar fluctuations and amplification of mean-field unstable modes, by introducing an appropriate external field [47]. On the other hand, explicit fluctuation terms are not injected in the isovector channel in SMF. In this case, one just obtains the fluctuations related to the use of a finite number of test particles which, as far as the Fermi statistics is preserved, amount to the physical ones divided by $N_{\text{test}}$. These results completes the study of ref.[55] concerning SMF.

We now turn to BLOB calculations. Fig. 3 shows that the isovector variance in BLOB results larger than in SMF. Such difference is therefore the effect of the treatment of collisional correlations in BLOB, which displays a dependence with the system density. In particular, the low-density limit of the spectrum corresponds to a situation where the collision rate is vanishing. In this case, the BLOB procedure is practically ineffective (see also the discussion in Section V.A) and all approaches converge to the same isovector variance, just related to the finite number of test particles employed. At larger density than saturation ($\rho \geq 0.18$ fm$^{-3}$), BLOB displays a longer path to convergence which is due to the difficulty of relocating large portions of phase space in binary collisions without violating Pauli blocking.

Fig. 4 condenses and extends the information of Fig. 3 by displaying the density evolution of the isovector variance attained at equilibrium as evaluated in cells of different size $l$, for asy-stiff and asy-soft forms of the symmetry energy. The SMF data correspond to those analysed in Fig. 2. The BLOB spectra progressively deviate from SMF data for increasing density. Such deviation increases for larger cell sizes indicating that the isovector fluctuations are better built in large volumes [31]. This is related to the variety of configurations, concerning shape and extension of the nucleon wave packet, which occur in the implementation of the fluctuating collision integral. This introduces a smearing of fluctuations on a
scale comparable to the wave-packet extension in phase space. However, the gain in isovector variance exhibited by the BLOB approach, indicates that the dependence on \( N_{\text{test}} \) is partially reduced with respect to the SMF scheme.

C. Interference between mean-field propagation, collisional and numerical correlations

According to Eq. (9), the BLOB approach should introduce and revive fluctuations continuously. The agglomeration procedure employed in BLOB is actually able to construct agglomerates of test particles of the same isospin species and which are located around local density maxima in random selected phase-space cells: this technique should preserve at least partially the isovector correlations in the system, contrarily to the usual BUU technique which smears them out. This advance with respect to BUU is however not sufficient because of the concurrent effects associated with the mean-field dissipation. Indeed, fluctuations are propagated according to a total inverse relaxation time

\[
\frac{1}{\tau_k} = \frac{1}{\tau_k^{\text{coll}}} + \frac{1}{\tau_k^{\text{m.f.}}},
\]

so that, if the collisional rate is too small, they are damped by the mean-field dynamics before they can reach a sizeable amplitude.

Moreover, even in absence of any explicit fluctuation seed, the dynamics is actually affected by a numerical noise, due to the use of a finite number of test particles in the numerical resolution of the transport equations; such spurious contribution imposes the dependence of \((\sigma_\rho)^2\) on \( N_{\text{test}} \) [52]. If this latter effect may be negligible with respect to the large isoscalar fluctuations developing in presence of mean-field instabilities (see next Section), it becomes a highly interfering contribution for the isovector modes. In other words, the numerical noise leads to an effective diffusion coefficient \( D_k^{\text{noise}} = D_k + D_k^{\text{noise}} \). If a small number of test particles is considered, and two-body collisions are not so frequent, then \( D_k^{\text{noise}} \) prevails over \( D_k \), causing a deviation of the fluctuation amplitude from the correct value.

For these reasons, though in principle the fluctuation equilibrium value, as deduced from BLOB, should not depend on the details of the nucleon-nucleon cross section \( \sigma_{\text{NN}} \) and on the number of test particle employed, our results depend significantly on both ingredients.

Two ways can be tested to get a deeper insight into this problem: either the collision term should be considerably enhanced, or fluctuations generated by test particles should be prevented.

The first solution can be achieved by simply multiplying \( \sigma_{\text{NN}} \) by a large factor, with the drawback of then handling incorrect collision rates. Of course, this is not a problem if one is interested in equilibrated matter, as in the present case, but it would be crucial when dealing with non-equilibrium processes, such as nuclear reactions. Some tests in the first direction are proposed in Fig. 4, by employing a constant \( \sigma_{\text{NN}} \) with progressively larger values, showing that the isovector variance grows with the collision rate, as we expect on the basis of the arguments discussed above.

The second check would consist in employing the largest possible number of test particles per nucleon. In this case, the collisionless transport model would ideally correspond to the Vlasov approach and, when collisional correlations are introduced, interferences with spurious stochastic sources can be highly reduced. However, interference effects with the mean-field propagation can still be important, depending on the collision rate. As far as numerical complexity can be handled, Fig. 5, left, illustrates such situation: SMF calculations show a behaviour \( \propto 1/N_{\text{test}} \), independently on \( \sigma_{\text{NN}} \). On the other hand, in the BLOB case one observes that, especially in the largest cells, where fluctuations are more effective, the corresponding variance deviates more and more, for large test particle numbers, from the SMF results, reaching a kind of saturation value. The latter depends on the cell size, \( l \), and on the cross section employed (see also the discussion above). Fig. 5, right, shows the time evolution of the fluctuation variance. It appears that for a small number of test particles (up to 100) the variance oscillates

![FIG. 5. Left: The isovector variance, at equilibrium, as a function of the number of test particles, \( N_{\text{test}} \), as obtained in SMF simulations (open circles) and in BLOB calculations (open squares), using a constant \( \sigma_{\text{NN}}=50 \text{mb} \), for nuclear matter at density \( \rho=0.08 \text{ fm}^{-3} \) and temperature \( T=3 \text{ MeV} \). BLOB calculations are also shown for \( \sigma_{\text{NN}}=100 \text{mb} \) (green full circles). Cells of different size \( l \) are considered, as indicated on the figure. Dashed lines represent a fit of SMF simulations, assuming a trend proportional to the inverse of the test particle number. Right: Time evolution of the isovector variance, as obtained in a single event, for BLOB calculations with constant \( \sigma_{\text{NN}}=100 \text{mb} \) and \( l=2.05 \text{fm} \). The different curves correspond to different number of test particles employed in the simulations. The asy-stiff form of the symmetry energy is considered.](image-url)
around its initial value, which is essentially associated with the numerical noise and scales as $1/N_{\text{test}}$. Increasing the number of test particles, the numerical noise gets smaller and the BLOB fluctuation source prevails on it, building up a fluctuation variance which is larger than the initial value. However, since we are considering systems at low temperature, the number of nucleon-nucleon collisions is extremely low and insufficient to rapidly introduce a pattern of isovector correlations, unless one employs very high values for the cross section: the isovector variance shows in fact a very gentle growth.

In conclusion, the BLOB fluctuation source term works well in conditions where the collision rate is large enough, as compared to the mean-field propagation and to the spurious dissipative terms associated with the finite number of test particles. These conditions are likely reached in the first, non equilibrated stages of heavy ion collisions, but not necessarily for equilibrated nuclear matter at low temperature. In the latter case, the variance associated with the fluctuating collision integral can be recovered by artificially increasing the employed $\sigma_{\text{NN}}$. Indeed, as shown in Fig. 4 and Fig. 5, we observe that the fluctuation variance built by BLOB may deviate significantly from the SMF results, being up to a factor ten larger, especially when considering fluctuations in larger cells ($l \approx 2$ to 3 fm).

V. RESULTS ON ISOSCALAR FLUCTUATIONS

If fluctuation seeds are introduced in homogeneous neutral nuclear matter at low temperature, Landau zero-sound [61] collective modes should stand out and propagate in the system. In the present section we analyse whether the BLOB approach is able to develop, as aimed, isoscalar fluctuations of correct amplitude in nuclear matter spontaneously, and not from an external contribution, when the system is placed in a dynamically unstable region of the equation of state [62], like the spinodal zone. In this circumstance, as soon as fluctuation seeds are generated, unstable zero-sound waves should be amplified in time. In the opposite situation, in conditions of mechanical stability, undamped stable zero-sound waves propagate. Then, for stable configurations, the same arguments of Sec. IV hold and, in this case, the fluctuation variance is linked to matter incompressibility.

A. Sampling zero-sound propagation in mechanically stable and unstable nuclear matter

The propagation of fluctuations in nuclear matter can be described in a linear-response approximation [44] as far as deviations from the average dynamical path are small. In Eq. (16), by selecting isoscalar modes ($q \to s$, we drop the $s$ index in the following), and setting residual contributions to zero, we obtain a linearised Vlasov equation in terms of frequencies $\omega_k$ to describe stable matter with isoscalar contributions:

$$\omega_k f_k + \mathbf{k} \cdot \frac{p}{m} f_k - \frac{\partial f^0}{\partial \rho} \frac{\partial U_k}{\partial \rho} - \frac{\mathbf{k} \cdot \mathbf{p}}{m} \rho_k = 0 .$$

Different wave numbers $k$ are decoupled, each linked to a collective solution $f_k$ given by the Fourier-transformed equation of motion. By applying the self-consistency condition $\rho_k = (g/h^3) \int f_k(p)d\mathbf{p}$, we obtain the dispersion relation for the propagation of density waves in Fermi liquids at $T = 0$:

$$1 = \frac{g}{h^3} \frac{\partial U_k}{\partial \rho} \int \frac{\partial f^0}{\partial \omega} \frac{\mathbf{k} \cdot \mathbf{p}/m}{\omega_k + \mathbf{k} \cdot \mathbf{p}/m} d\mathbf{p} .$$

where $\omega_k$ and $-\omega_k$ are pair solutions due to the invariance $\mathbf{p} \leftrightarrow -\mathbf{p}$. As well documented in the literature, at $T = 0$ eigenmodes $f_k$ depend only on states near the Fermi level. Indeed, the momentum integral is restricted to the Fermi surface because $\partial_t f^0 \approx -\delta (\epsilon - \epsilon_F)$, being $\epsilon_F$ the Fermi energy. The dispersion relation reduces to an expression where solutions correspond to sound velocities $s = \omega_k/(k \nu_F)$ in units of Fermi velocity $\nu_F = p_F/m$. In this case, introducing the Landau parameter

$$F_0(k) = N_0 \partial_s U_k = (3/2)(\partial \rho/\epsilon_F) \partial_s U_k ,$$

where $N_0 = N(T = 0)$ is linked to the number of levels at Fermi energy $\epsilon_F$, the dispersion relation takes the form [63]:

$$1 + \frac{F_0}{F_0} = L(s) = \frac{s}{2} \ln \left( \frac{s + 1}{s - 1} \right) ,$$

where the Lindhard function, $L(s)$ has been introduced. In correspondence to the effective interaction employed, reflected in the potential shown in Fig. 6a, the Landau parameter is illustrated in Fig. 6b, while Fig. 6c presents the roots of the dispersion relation, corresponding to the effective interaction.

B. Warm systems and interaction range

Eq. (27) is only valid at zero temperature. When the temperature is significant, two-body collision rates become prominent and these mean-field dominated zero-sound waves are absorbed and taken over by hydrodynamical first-sound collective modes. Since our approach exploits two-body collisions to introduce fluctuations in a self-consistent mean field, we expect the possible occurrence of a zero-to-first-sound transition which, at variance with other Fermi liquids [64], should be even smeared out due to the small values taken by the Landau parameter $F_0$ in nuclear matter. It was found that, depending on how the system is prepared and on the type of collective motion, such transition should arise in a range of temperature from 4 to 5 MeV and occur as late as 200 fm/c [65, 66]. In practice, zero-sound modes associated to wave vectors $k$ characterise the system as long
The isoscalar mean-field potential as a function of the density. The dots indicate the two density values considered in SMF/BLOB simulations. (b) The Landau parameter $F_0$ as a function of the density. (c) the two-body collision frequency as a function of the density. (d) The chemical potential, divided by the Fermi energy, as a function of the unstable mode $k$.
is analysed in Fig. 8 for the two density choices. For the

is the modulus of a vector ranging from 1 to $t_{\text{max}} = L/l$ along each of the three spacial directions. Then the amplitude of the isoscalar fluctuation of a mode $k$ is obtained from the Fourier transform, $F_k$, of the space density

$$\sigma_k^2(t) = \langle |F_k(t)|^2 \rangle = \frac{1}{3L} \left\{ \sum_{n'} \rho_{n'}(t) \exp(ian \cdot n') \right\}^2$$

$$\propto \left\{ \left[ \sum_{n'} \rho_{n'}(t) \cos(an \cdot n') \right]^2 + \left[ \sum_{n'} \rho_{n'}(t) \sin(an \cdot n') \right]^2 \right\},$$

where $a = 2\pi L$ and the average is extended over all orientations of $k$.

The distribution of ratios $\bar{\sigma}_n^2(t) = \sigma_k^2(t)/\sigma_k^2(t = 0)$, averaged over several dynamical paths, is shown at different time intervals in Fig. 7 for the two density choices. It should be noticed that the initial fluctuation amplitude is due to the finite number of test particles employed in the calculations. However, as soon as the BLOB term starts to act, fluctuations of larger amplitude are built up (see also the discussion in Section V.A), and further amplified by the unstable mean-field. The system prepared at $\rho^0 = 0.053$ fm$^{-3}$, inside the spinodal region, exhibits a clear growth of instabilities as a function of time for some $k$ waves, while the system prepared at $\rho^0 = 0.14$ fm$^{-3}$, outside the spinodal region, presents an evolution of the response intensity corresponding to a more gentle growth in a Landau-damping regime. However, even in this latter case, fluctuations reach a significant amplitude, owing to the small compressibility value in the density region considered, but cluster formation is not observed.

Correspondingly, the early evolution in time of $\bar{\sigma}_n^2(t)$ is analysed in Fig. 8 for the two density choices. For the leading modes, one can consider a linear fit of the quantity plotted in Fig. 8a, in intervals ranging from around 20 fm/c to time instants close to saturation (see Eq. 19). The very initial path is excluded from the fit because, as previously mentioned, the fluctuation mechanism sets in spontaneously after that a sufficient number of collisions has occurred, and does not emerge from suited initial conditions. Differences from the ideal linear response in the growing side of single modes indicate a more complex behaviour, resulting from the coupling of different wavelengths and the tendency toward a chaotic evolution [71]; A SMF calculation is also presented for the unstable system, where the linear growth of the leading modes is initially comparable to the BLOB approach and deviates at later times. This behaviour is due to the efficiency of the collision term in the BLOB model in reviving fluctuations of correct amplitude, compared to SMF, where fluctuations are not introduced by the collision term. As a consequence, in SMF fluctuations decay by the combination of small wavelengths into larger ones, while in BLOB higher fluctuation amplitudes can be attained because of the combination of small wavelengths into larger ones, while in BLOB higher fluctuation amplitudes can be attained beyond threshold conditions.

leading modes, one can consider a linear fit of the quantity plotted in Fig. 8a, in intervals ranging from around 20 fm/c to time instants close to saturation (see Eq. 19). The very initial path is excluded from the fit because, as previously mentioned, the fluctuation mechanism sets in spontaneously after that a sufficient number of collisions has occurred, and does not emerge from suited initial conditions. Differences from the ideal linear response in the growing side of single modes indicate a more complex behaviour, resulting from the coupling of different wavelengths and the tendency toward a chaotic evolution [71]; A SMF calculation is also presented for the unstable system, where the linear growth of the leading modes is initially comparable to the BLOB approach and deviates at later times. This behaviour is due to the efficiency of the collision term in the BLOB model in reviving fluctuations of correct amplitude, compared to SMF, where fluctuations are not introduced by the collision term. As a consequence, in SMF fluctuations decay by the combination of small wavelengths into larger ones, while in BLOB higher fluctuation amplitudes can be attained beyond threshold conditions.
The range of the interaction, as an effect of the implemented surface term, would correspond to a Gaussian smearing width \( \sigma \). For comparison, a calculation in one-dimension within the approach of ref. [31] is also shown (green diamonds).

mode \( k \) as

\[
\Gamma_k = \frac{1}{2} \frac{\partial}{\partial t} \ln \langle \sigma_k^2(t) \rangle , \tag{35}
\]

where the average \( \langle \cdot \rangle \) is taken over several stochastic dynamical trajectories. Such analysis is presented in Fig. 9, where the numerical calculation, averaged over 100 events, is compared to the analytic result of Eq. (33). The range of the interaction, as an effect of the implemented surface term, would correspond to a Gaussian smearing of around \( \sigma = 0.8 \) fm to \( \sigma = 0.9 \) fm. We infer that BLOB reproduces consistently the expected dispersion relation within the uncertainties of the linear regression. Another calculation, also based on the same mean-field, but which employs the earlier approach of ref. [31], also solved in three dimensions but with fluctuations developing along one axis of configuration space, produces a similar result. While BLOB keeps the different unstable modes decoupled for a more extended interval of time during their early growth, also resulting into a larger ultraviolet cutoff, the other approach (green points) presents some alterations due to the combining of unstable modes, where small-wavelength \( (n > 7) \) are gradually absorbed by large-wavelength \( (n = 0, n = 1) \). The effect in this case is an increase of the growth rate for small \( k \) values and it signs the entrance of the chaotic behaviour which characterises larger times [72]. The largest \( k \) modes, corresponding to wavelengths which drop below the Gaussian smearing width \( \sigma \) are meaningless. As a final result of this study, the leading modes are found in a wavelength range from 8 to 9 fm, and for a growth time \( \tau_k \) of around 30 fm/c.

VI. CONNECTING NUCLEAR MATTER TO OPEN SYSTEMS

The aim of this work is studying the effect of isovector and isoscalar fluctuations. The ultimate purpose of the transport approaches discussed therein is describing the formation of nuclear fragments in a fermionic system and their properties through the combination of these two types of fluctuating modes, as will be detailed more diffusely in forthcoming works. In particular, isovector fluctuations, on top of other isospin transport effects, impose that the isospin content is distributed through a density-dependent process of distillation, supplemented by an isotopic variance. The onset of isoscalar modes is then responsible for breaking the uniformity of the density landscape and eventually partitioning it into nuclear fragments, where the isospin properties of the initial nesting sites are preserved. The isoscalar and isovector mechanisms should therefore be intimately connected in order to describe fragment formation.

A. Fragment formation: patterns and time scales

Qualitatively, we may underline some connection between the wavelengths involved in the dispersion relation analysed in Fig. 9, and fragment formation [73], considering that at the system density \( \rho_0 \) the leading modes correspond to fragments of mass \( A \approx \rho_0 \lambda^3 \); for the leading wavelengths, this corresponds to a distribution of sizes peaked around Neon. These results are also in agreement with other previous studies where quantum effects were taken into considerations explicitly [74–78] despite a more schematic treatment of fluctuations, or of the whole dynamics (2-dimension treatments, fluctuations propagated from an initial state, spherical geometries). In this respect, BLOB extends these previous attempts to a model that can be applied at the same time to nuclear matter and, rather successfully, to heavy-ion collisions in three dimensions and without any preliminary initialisation of fluctuation seeds [30, 79].

From the growth time of the leading modes in Fig. 9, we infer that the corresponding process of fragment formation would be rather short, progressing from when the system has been largely diluted. This suggests that the scenario studied in nuclear matter can be quite directly translated to the phenomenology of open systems [7]. As an example, Fig. 10 illustrates the correspondence between a portion of nuclear matter (simulated for \( T = 3 \) MeV and \( \rho_0 = 0.053 \) fm\(^{-3} \)) for an interaction defined

**FIG. 9.** BLOB calculations for nuclear matter at \( \rho_0 = 0.053 \) fm\(^{-3} \) and temperature \( T = 3 \) MeV: The growth rate \( \Gamma_k \), as extracted from the simulations (see Eq.(35)), is plotted as a function of the wave number \( k \) (full line with dots). Uncertainties are evaluated from the linear-response fit. The dashed lines correspond to analytical predictions, obtained solving Eq.(32) with different values of the width \( \sigma \) of the Gaussian smearing factor. For comparison, a calculation in one-dimension within the approach of ref. [31] is also shown (green diamonds).
kinematics of the process was also found to be rather explosive. The spinodal mechanism was therefore proposed as a suited description \[82, 83\]; BLOB has already been adapted successfully to nuclear collisions and tested over various systems which experience spinodal instability \[30, 79, 84\].

### B. Isospin content in fragments

Fig. 11 completes the survey, investigating the isospin content in potential ripples containing \(N'\) neutrons and \(Z'\) protons for the system \(^{136}\text{Xe} + ^{124}\text{Sn}\) at 32 AMeV. Distributions of isotopic variances are calculated for the most probable mass range around a forming Carbon and a forming Neon (two upper rows). The distributions are studied in an early time span (before that fragments are clearly formed, around 130fm/c) and in a late time interval (during fragment formation around 200fm/c). They are compared with the analytic distributions obtained at a temperature \(T = 5.5\) MeV, as extracted from the calculation, and at the local density \(\rho\). The isotopic variance (see Eq. (18)) can be studied as the probability of variation \(\delta\) around the mean value of \(N' - Z'\) and for a given \(A'\) yielding the distribution

\[
Y \approx \exp\left[-(\delta^2/A')C_{\text{sym}}(\rho)/T\right].
\]

The local density is evaluated either in the (denser) centroid of the potential ripples \(\rho_{\text{centroid}}\), or averaged all over the volume of the emerging fragments \(\bar{\rho}\), or, more significantly, corresponding to the matter contained in the volume of the potential ripples \(\rho_{\text{well}}\). We deduce that, as expected from the calculation in stable nuclear matter discussed above, the isotopic width results underestimated with respect to the analytic prediction of Eq. (18). The difference is still acceptable due to the following two effects. First of all, fluctuations are built out of equilibrium: this implies that the collision rate is higher, generally leading to larger variances. Secondly, in open systems, particle evaporation may contribute in widening the isotopic spectra.

The bottom row of Fig. 11 investigates the average isospin content measured in potential ripples in the corresponding early and late time intervals as a function of the \(\rho_{\text{well}}\). The mass \(A'\) grows with the density and the corresponding isospin content decreases, signing a process of isospin distillation.

### C. Extent of different clusterisation processes in heavy-ion collisions

The processes discussed in this work, related to phase-space fluctuations and mechanical instabilities, involve a rich phenomenology of phase transitions and thresholds between very different reaction mechanisms. They may therefore also present some similarities in their outcome with other rather different processes and, in some

![Density-landscape at several time instants for nuclear matter in a periodic box at \(\rho^0 = 0.053\) fm\(^{-3}\) and \(T = 3\) MeV (left) and in a hot open nuclear system formed in a head-on \(^{136}\text{Xe} + ^{124}\text{Sn}\) collision at 32 AMeV (right); arrows indicate the beam direction. Both simulations employ the BLOB approach with the same mean-field properties. The big arrow proposes an analogy between nuclear matter and the open system in correspondence with the arising of the spinodal instability.](image)

as in Eq. (B1) and a hot system formed in the collision \(^{136}\text{Xe} + ^{124}\text{Sn}\) at 32 AMeV for a central impact parameter \(b = 0\) (such system was studied in an experimental campaign \[80, 81\]). In particular, we observe some analogy between the early time when inhomogeneities emerge in nuclear matter (20fm/c) and when fragments start forming in an open system (around 100fm/c) right after accessing low-density spinodal conditions (around 80fm/c). In both systems, a spinodal signal stands out by exhibiting equal-size inhomogeneities in configuration space within a similar time scale \[30\], and it is smeared out by fragment recombination later on. At even later times, the evolution is different, in the box calculation clusters continue interacting with each other while in the open system they split apart.

Experimental investigations of heavy-ion collisions at Fermi energies already pointed out that the range of masses given by the dispersion relation of Fig. 9 is actually favoured in multifragmentation mechanisms; the

\[
\rho^0 = 0.053\text{fm}^{-3}, \ T = 3\text{MeV}
\]
situations, combine with them. For instance, the onset of instabilities of Rayleigh type is a common process in macroscopic hydrodynamic systems, like classical fluids with a non-negligible surface tension [85], which has also been proposed as a possible additional scenario for nuclear multifragmentation in heavy-ion collisions [86, 87], in some specific situations. Such process occurs in systems where a dilute core expands into a denser shell (Rayleigh-Taylor instability), or it acts on very deformed systems involving cohesional forces which respond to external perturbations (Plateau-Rayleigh instability). The system in such hydrodynamic scenario develops hole nucleation, evolving into a sponge-like or a filamented configuration, a dilute core expanding into a denser shell.

In practice, even though technically demanding, the BLOB approach constitutes a conceptually straightforward solution of the BLE in three dimensions. Through a simple renormalisation of the collision term, the Fermi statistics is in fact preserved for a long time and a correct isoscalar fluctuation amplitude is obtained independently of the ingredients of the numerical implementation (like the number of test particles), just associated with the collision rate and the growth time of the unstable modes. Also the fluctuation variance of isovector fluctuations which then relax into compact droplets. The mechanism is faster than ordinary fission and density variations of bound matter along the process do not need to be significant.

On the other hand, the spinodal process described above can only occur if the system traverses a specific region of the equation of state, characterised by negative incompressibility where nucleation progresses from a dilute phase, letting blobs of larger density gradually emerge. From a microscopic point of view, it is rather associated to the nuclear liquid-gas phase transition and it requires a time comparable to the equilibration time of the system in reactions at Fermi energies. We point out that, in simulations of heavy-ion collision, the BLOB approach is actually able to describe the interplay between spinodal processes and the above mentioned hydrodynamic effects [88].

Heavy-ion collisions and nuclear matter also involve processes of nuclear cluster formation, from light charge particles to heavier nuclear molecules, but those products emerge from an even different mechanisms [89], which would require the explicit inclusion of additional correlations in the hierarchy of Eq. (1). Light charged particles related to nuclear clustering have too small size, exceeding the ultraviolet cutoff of the dispersion relation, so that they can not belong to the unstable multipole modes which characterise spinodal fragmentation. Solutions for an explicit treatment of cluster formation are proposed in refs. [90–92]. Connections between nuclear clustering and (spinodal) multifragmentation might be proposed, considering that multifragmentation might act on defining nuclear sources with rather complex shape from which clustered structures might eventually emerge.

VII. CONCLUSIONS

This work presents crucial steps to validate BL transport models applied to a fermionic system, both in stable and mechanically unstable conditions, as far as the development of isoscalar and isovector fluctuations at various densities is concerned. In particular, the amplitude of fluctuations is investigated in relation with the corresponding properties of the nuclear effective interaction. A transport approach constructed by requiring to satisfy the dispersion relation of mean-field unstable modes proves to be suited for the description of nuclear multifragmentation.

In particular, the amplitude of fluctuations is investigated in relation with the corresponding properties of the nuclear effective interaction. A transport approach constructed by requiring to satisfy the dispersion relation of mean-field unstable modes proves to be suited for the description of nuclear multifragmentation.

In practice, even though technically demanding, the BLOB approach constitutes a conceptually straightforward solution of the BLE in three dimensions. Through a simple renormalisation of the collision term, the Fermi statistics is in fact preserved for a long time and a correct isoscalar fluctuation amplitude is obtained independently of the ingredients of the numerical implementation (like the number of test particles), just associated with the collision rate and the growth time of the unstable modes. Also the fluctuation variance of isovector fluctuations which then relax into compact droplets. The mechanism is faster than ordinary fission and density variations of bound matter along the process do not need to be significant.

On the other hand, the spinodal process described above can only occur if the system traverses a specific region of the equation of state, characterised by negative incompressibility where nucleation progresses from a dilute phase, letting blobs of larger density gradually emerge. From a microscopic point of view, it is rather associated to the nuclear liquid-gas phase transition and it requires a time comparable to the equilibration time of the system in reactions at Fermi energies. We point out that, in simulations of heavy-ion collision, the BLOB approach is actually able to describe the interplay between spinodal processes and the above mentioned hydrodynamic effects [88].

Heavy-ion collisions and nuclear matter also involve processes of nuclear cluster formation, from light charge particles to heavier nuclear molecules, but those products emerge from an even different mechanisms [89], which would require the explicit inclusion of additional correlations in the hierarchy of Eq. (1). Light charged particles related to nuclear clustering have too small size, exceeding the ultraviolet cutoff of the dispersion relation, so that they can not belong to the unstable multipole modes which characterise spinodal fragmentation. Solutions for an explicit treatment of cluster formation are proposed in refs. [90–92]. Connections between nuclear clustering and (spinodal) multifragmentation might be proposed, considering that multifragmentation might act on defining nuclear sources with rather complex shape from which clustered structures might eventually emerge.
observables are better treated than in conventional semi-classical approaches, even though the expected variance is still not achieved. Indeed, in the implementation of the fluctuating collision integral, different configurations, varying in shape and extension, are possible to represent the nucleon wave packet. This induces smearing effects on the fluctuation amplitude. Moreover, if the collision rate is very low, the characteristic time scales associated with the construction of collisional two-body correlations are larger than the typical mean-field time scale and the fluctuations are damped by the propagation in the stable mean-field. This explains why, even for equilibrated nuclear matter, the model yields a dependence of the isovector fluctuation amplitude on the nucleon-nucleon cross section. It is also observed that, if two-body collisions are too rare, the numerical noise dominates the dynamics and one obtains a fluctuation variance reduced by a factor \(1/N_{\text{test}}\) with respect to the expected value, as obtained in standard transport approaches where fluctuations are neglected [35]. On the other hand, if the collision rate is large enough, the fluctuation amplitude does not depend on the number of test particles employed in the simulations.

It is worth noting that the dynamical approach presented in this work does not imply any thermodynamic hypothesis (equilibration for instance) in the implementation of the fluctuation source, so that the characteristic thermodynamic features of multifragmentation, like the occurrence of a nuclear liquid-gas phase transition, are obtained as a result of the transport dynamics [30]: this finding makes the present dynamical description and alternative statistical approaches for multifragmentation mutually consistent. Finally, this approach can easily connect nuclear matter to heavy-ion collisions in the same framework.

### Appendix A: Exploiting fluctuations in BLOB: handling metrics and nucleon-nucleon collision statistics

In Sec. II C the BLOB scheme, Eq. (9), is introduced to generate stochastic dynamical paths in phase space. The system is sampled through the usual test-particle method, often adopted for the numerical resolution of transport equations [93] with the difference that, in the case of the BLOB implementation, the phase-space portions \(A\) and \(B\) involved in single two-body collisions are not two individual test particles but rather agglomerates of \(N_{\text{test}}\) test particles of equal isospin, where \(N_{\text{test}}\) is the number of test particles per nucleon used in the simulations. In a binary nucleon-nucleon collision, the initial states \(A\) and \(B\) are constructed by agglomeration around two phase-space sites, which are sorted at random, inside a phase-space cell of volume \(h^3\), according to the method proposed in ref. [30] and further improved in ref. [79]. At successive intervals of time, by scanning all phase space in search of collisions, all test-particle agglomerates are redefined accordingly in \(h^3\) cells, so as to continuously restore nucleon-nucleon correlations. Since test particles could be sorted again in new agglomerates to attempt new collisions in the same interval of time, the nucleon-nucleon cross section \(\sigma_{NN}\) contained in the transition rate \(W\) should be divided by \(N_{\text{test}}\):

\[
\sigma = \sigma_{NN}/N_{\text{test}}. \tag{A1}
\]

Boltzmann-Langevin solutions where an ensemble of \(N_{\text{test}}\) test particles are moved in one bunch and the nucleon-nucleon cross section is scaled by \(N_{\text{test}}\) where already followed in the early approach by Bauer and Bertsch [46], or in more recent implementations [94]. There is however a very fundamental difference: in the Bauer-and-Bertsch approach the Pauli-blocking term is not applied to the involved portions of phase space which are actually interested by the scattering at a given time \(t\), as imposed by Eq. (11), but it is applied only to the centroids of the two colliding packets. Such approximation makes the Pauli blocking satisfied only approximately, with the drawback of loosing the Fermi statistics [95]. In the direction of BLOB, to prevent the above problem, a first practical solution was proposed in Ref. [31]. Moreover, in BLOB, special attention is paid to the metrics when defining the test-particle agglomeration: the agglomerates are searched requiring that they are the most compact configurations in the phase space metrics which does neither violate Pauli blocking in the initial and in the final states, nor energy conservation in the scattering. For this purpose, when a collision is successful, its configuration is further optimised by modifying the shape and the width of the initial and final states [96]. Fig. 12 illustrates the paths of a collision configuration which by a procedure of successive modulations is brought to a situation which respects Pauli blocking strictly. If such modulation procedure results unsuccessful, the collision is rejected. The rate of rejections due to unsuccessful modulation of the collision configuration is close to zero in open systems (heavy-ion reactions) so that the correlation between attempted and effective collision number is identical if a UU or a BLOB collision term is applied, provided that the same nucleon-nucleon cross section is used. On the other hand, in uniform nuclear matter at equilibrium, where only nucleons close to the Fermi surface can be involved in two-body collisions, the occurrence of such rejections becomes not negligible when the temperature \(T\) considered is very low compared to the Fermi momentum. In this case, the exact correspondence between attempted and
effective collision rates in BUU (or SMF) and BLOB is lost.

A remarkable advantage of the renormalised form of the residual contribution in Eq. (9) is to connect directly the fluctuation variance to the physical properties of the system, regardless the test-particle number. Such aspect has a general relevance because it makes the dynamics independent from many aspects of the numerical implementation. The dependence on \( N_{\text{test}} \) persists on the other hand in the mean-field representation, therefore when the physical fluctuation amplitude is small, the global fluctuation phenomenology may suffer from noise effects produced by the use of a finite number of test particles in the numerical implementation of the transport equation. This remark should be kept in mind for the study of fluctuations of relatively small amplitude, like isovector fluctuations, as discussed in Sec. IV C.

Appendix B: Model parameters for nuclear matter

In this work, for comparison purposes, both BLOB and SMF models are prepared as relying on a strictly identical implementation of the mean field, so that they differ only for the residual contribution. A simplified Skyrme-like (SKMF\(^*\)) effective interaction \([58, 97]\), where momentum-dependent terms are omitted, is employed in the propagation of the one-body distribution function, corresponding to the following definition of the potential energy per nucleon:

\[
E_{\text{pot}}(\rho) = \frac{A}{2}u + \frac{B}{\sigma + 1}u^\sigma + \frac{C_{\text{surf}}}{\rho}\left(\nabla \rho\right)^2 + \frac{1}{2}C_{\text{sym}}(\rho)\beta^2,
\]

with \( u = \rho/\rho_{\text{sat}}, \) being \( \rho_{\text{sat}} \) the saturation density and \( \beta = (\rho_n - \rho_p)/\rho. \) This parameterization, with \( A = -356 \) MeV, \( B = 303 \) MeV and \( \sigma = 7/6, \) corresponds to a soft isoscalar equation of state with a compressibility modulus \( K = 200 \) MeV. An additional term as a function of the density-gradient introduces a finite range of the nuclear interaction and accounts for some contribution from the zero-point motion of nucleons \([97]\). \( C_{\text{surf}} \) is related to various properties of the interaction range: the surface energy of ground-state nuclei (the best fit imposing a value of \(-6/\rho_{\text{sat}} \) MeV fm\(^5\)), the surface tension (light-fragment emission, in comparison to available data is better described for a smaller range given by \(-7/\rho_{\text{sat}} \) MeV fm\(^5\) in BLOB), and the ultraviolet cutoff in the dispersion relation for wavelengths in the spinodal instability (larger spectrum for a smaller range) \([74]\). In this work, a value of \( C_{\text{surf}} = -7/\rho_0 \) MeV fm\(^5\) is chosen for the surface term. A linear (asy-stiff) density dependence of the potential part of the symmetry energy coefficient, \( E_{\text{sym}}^{\text{pot}} \), is obtained by setting \( C_{\text{sym}}(\rho) = \text{constant} = 32 \) MeV and a quadratic-like (asy-soft) dependence is obtained for \( C_{\text{sym}}(\rho) = \rho_{\text{sat}}(482 - 1638\rho) \) MeV \([98]\).

\( N_{\text{test}} = 40 \) test particles per nucleon are employed if not otherwise specified. In this work the collision term involving an isospin- and energy-dependent free nucleon-nucleon cross section with an upper cutoff at \( \sigma_{\text{NN}} = 0.16 \) fm.  

![Fig. 12](image1.png)

**Fig. 12.** (a) Schematic representation of the definition of test-particle agglomerates in their initial \((A,B)\) and final \((C,D)\) states in momentum space in a \( h^3 \) volume. (b) Convergence of a binary nucleon-nucleon collision configuration towards a situation where Pauli blocking is strictly satisfied. The path in the plane determined by the occupancy numbers, \( f_C \) and \( f_D \), of the final states collects the sequence of modulations in phase-space of the test-particle clouds where the occupancy of the destination regions is iteratively optimised. (c) Examples of possible shape modulations for the packets associated with nucleons in the final state.

![Fig. 13](image2.png)

**Fig. 13.** Energy distribution for \( \rho_0 = 0.08 \) (top) and \( 0.16 \) fm\(^{-3}\) (bottom), as obtained in SMF (dashed line) and BLOB (full line) calculations at \( t = 80 \) fm/c. The coloured band connects the Fermi-Dirac distributions corresponding to \( T = 3 \) and \( T = 5 \) MeV.
we adopt the quite short time interval of 2 fm/c to inject fluctuations. In unstable conditions, like the spinodal region studied in Sec. V, the choice of a short time interval as compared to the typical growth time of unstable modes leads to convergent results on isoscalar fluctuations. We note that the growth time of unstable modes amounts to about 30 fm/c, quite independently of the density conditions (see Sec. V C). Concerning isovector fluctuations, they are only induced by the finite number of test particles. Indeed, in the SMF model there are no explicit fluctuation terms injected in the isovector channel.

To simulate nuclear-matter, we prepare the system in a cubic periodic box of edge size $L = 39$ fm, and we subdivide it in a lattice of cubic cells of edge size $l$ where we calculate density variances. For the sake of simplicity, we consider symmetric nuclear matter, i.e. with equal number of neutrons and protons. We initially define the system by imposing a uniform-matter effective field $U_0(\rho)$ whose amplitude only depends on the density considered, and a corresponding effective Hamiltonian $\epsilon(\rho) = h_0(p) = p^2/(2m) + U_0(\rho)$. Accordingly, the phase-space distribution function $f_0(p) = \{1 + \exp[(p - \mu)/T]\}^{-1},$ not depending on configuration space (because the system is homogeneous), is the Fermi-Dirac equilibrium distribution at the temperature $T$ and chemical potential $\mu$.

The system is initialised with a Fermi-Dirac distribution at a temperature $T = 3$ MeV. As shown in Fig. 13, both SMF and BLOB transport dynamics succeed to preserve the initial distribution quite efficiently as a function of time, even though a flattening of the spectrum around an effective equilibrium temperature $T_{eq}$ should be accounted for, due to the fact that the Fermi statistics is not perfectly preserved. This temperature modification depends on the parameters of the calculation and is larger for larger densities.
