Abstract

In this paper, we consider optimal linear sensor fusion for obtaining a remote state estimate of a linear process based on the sensor data transmitted over lossy channels. There is no local observability guarantee for any of the sensors. It is assumed that the state of the linear process is collectively observable. We transform the problem of finding the optimal linear sensor fusion coefficients as a convex optimization problem which can be efficiently solved. Moreover, the closed-form expression is also derived for the optimal coefficients. Simulation results are presented to illustrate the performance of the developed algorithm.

Key words: State estimation, Kalman filter, sensor fusion, lossy channel, collective observability.

1 Introduction

Wireless sensor networks (WSNs) have been widely adopted in industrial processes, agricultural irrigation, smart grids, etc. Recently, due to the advances in wireless communication technologies, especially the advent of 5G era (Shaﬁ et al. (2017)), the spectrum of physical networks can be utilized more efﬁciently. Hence, more devices can be accommodated, which establishes the foundations for a large-scale Internet-of-Things (IoT) (Mekki et al. (2019)), ultra-dense networks (Wang et al. (2018)), etc.

In order to reliably operate a large-scale dynamic system, it is necessary to obtain an accurate real-time state estimate at each time step. For this purpose, preliminary works have investigated management of the channel resources (Eisen et al. (2019)) as well as design of the data aggregation (He et al. (2019)) from various sensors. In this paper, we focus on the fusion problem of data from multiple sensors observing a physical process in a distributed manner.

The techniques in sensor fusion were developed for practical needs in state estimation or hypothesis testing problems. Some earlier works focused on estimating static variables based on fusion of raw measurements. For example, decentralized state estimation was investigated by Xiao et al. (2008) and Behbahani et al. (2012), where a static unknown variable is estimated over networked channels, and the power allocation is optimized. Moreover, linear fusion has also been investigated in the decision fusion of hypothesis testing problems, e.g., spectrum sensing in cognitive radio (CR) network (Quan et al. (2009)).

Later, sensor fusion has been extended to state estimation of dynamic systems. Channel activation over a graph topology as well as sensor selection problem for remote estimation has been considered by Yang et al. (2015).

Aside from fusing the raw measurements, an alternative approach is to fuse the pre-processed data. The motivation is to save the communication resources. Linear compression of the sensor data before transmission is proposed by Zhang et al. (2003). Along this direction, smart sensors are employed to recursively extract information from the raw observations of dynamic systems.

The foundation of optimal linear fusion for smart sensors is laid by Sun and Deng (2004). Later works by Chen...
extend it to cases with channel failures or bandwidth constraints. To avoid high computational complexity, Wu et al. (2019) proposed an efficient algorithm for linear state fusion with scalar fusion coefficients. However, all these works assumed local observability of the entire process.

For example, when a large-scale dynamic system is monitored by a sensor network with each sensor observing certain sub-components of the system state, it is no longer feasible to estimate the system state locally. This collectively observable scenario has been addressed by Liu et al. (2017), where the centralized Kalman filter can be recovered by a linear combination of the local estimations on the observable subspace of each sensor. The subspace decomposition methods for state estimation is also investigated by Yu et al. (2019). Meanwhile, He et al. (2018) considered a distributed state estimation problem with graph topology, and covariance intersection (CI) fusion strategy is adopted to bound the estimation error. A more recent result on distributed estimation for WSN is proposed by Talebi and Werner (2019), where the optimal performance of a centralized Kalman filter is recovered through average consensus algorithms on the local state estimates and the local covariance information from the population of sensors with collective observability.

In this work, we consider linear state fusion over lossy networks with collective observability. With Kalman decomposition, the observable subspace of each sensor is identified. Compared with Liu et al. (2017), local estimates on the observable subspace of the sensors are transmitted to the remote state estimator through unreliable channels, and the optimal fusion coefficients are determined online. Several challenges emerge in our problem setup:

1. When collective observability is assumed, a global state estimate is infeasible at each sensor locally. As a result, it is necessary to propose a framework where smart sensors can pre-process their raw measurements effectively before transmitting over unreliable channels, and the remote state estimator is capable of recovering a state estimate of the entire system;

2. Due to the lack of local observability, each sensor is merely capable of obtaining a “reduced-order” information on the system state, which causes the singularity of the collective covariance matrix, hence results in Sun and Deng (2004); Chen et al. (2014) are not applicable. Alternative approaches are required to compute the optimal fusion coefficients;

3. For linear state fusion, it is desirable to obtain a closed-form solution of the optimal fusion coefficients in order to analyze the performance and the variation of optimal coefficients given different system parameters.

To cope with these difficulties, we have made the follow-

ing contributions:

1. To perform sensor fusion with collective observability, we adopt Kalman decomposition and subspace projection to extract informative data from the observation of each sensor, which generalize previous works on linear fusion based on smart sensors by Sun and Deng (2004), Chen et al. (2014) with local observability;

2. For online implementation of the linear sensor fusion over lossy channels, we transform the original optimization problem for calculating the optimal coefficients for unbiased linear state fusion as a linear programming (Theorem 1), which features a complexity of $O(n^3N^2.5)$, where $n$ is the dimension of the state of the dynamic process and $N$ is the number of sensors. The complexity of our solution is comparable to $O(n^3N^3)$ in locally observable scenarios considered by Sun and Deng (2004); Chen et al. (2014). Besides, this approach avoids the computation of matrix inversions. The stability of the fusion estimation is shown in Proposition 1;

3. In order to obtain a closed-form expression for the optimal fusion coefficients, we draw an analogy with our problem and the minimum-variance unbiased estimate of an unknown parameter. According to Gauss-Markov theorem with singular covariance by Albert (1973), the closed-form optimal fusion coefficient is obtained (Theorem 2).

The remainder of this paper is organized as follows. In Section II, preliminary results on state estimation over a communication network is given, and the optimal unbiased linear state fusion with collective observability is posed as an optimization problem. Section III transforms it as a linear programming (LP), and shows the stability of the proposed fusion scheme. Section IV gives the closed-form fusion coefficients. Numerical results are given in Section V to illustrate the performance, and conclusions are drawn in Section VI.

Notations:

Denote the space of $n \times n$ positive semi-definite matrices as $\mathbb{S}_+^n$, and the space of $n \times m$ real matrix as $\mathbb{R}^{n \times m}$. For any singular $M \in \mathbb{R}^{m \times n}$, its Moore-Penrose pseudo-inverse is denoted as $M^+ \in \mathbb{R}^{n \times m}$. An identity matrix in $\mathbb{R}^{n \times n}$ is denoted as $I_n$. We denote a block diagonal matrix with diagonal elements $D_1, D_2, \ldots, D_l$ as $\text{Diag}(D_1, D_2, \ldots, D_l)$. An indicator function is defined as $\delta_{kj} = 1$ if $k = j$ and $\delta_{kj} = 0$ otherwise. Given an operator $\mathcal{T} : X \to X$, the operation of applying it recursively is denoted as $T^m = \mathcal{T} \circ \mathcal{T} \circ \cdots \circ \mathcal{T}$.

In order to clarify the meanings of different variables in this paper, we have summarized them in a table in Appendix A.
2 Preliminaries

In this paper, we consider a group of N different smart sensors observing a linear process and forwarding their local state estimates to a remote state estimator through multiple independent lossy channels separately (Fig. 1). The transmitted packets will be dropped with a certain probability, and the packet dropout for each channel follows an independent Bernoulli process.

At the other side of the channels, in order to obtain a global state estimate incorporating the received data, the remote state estimator employs a linear fusion scheme.

Fig. 1. Remote state estimation of a linear process over multiple independent lossy channels.

2.1 Process and sensor models

The process dynamic is given by

\[ x_{k+1} = Ax_k + w_k, \]

(1)

and each sensor takes its measurement independently with the following observation equation

\[ y^{(i)}_k = C_ix_k + v^{(i)}_k. \]

(2)

In (1) and (2), the state variable is \( x_k \in \mathbb{R}^n \), and the observation of the state at time \( k \) by sensor \( i \) is \( y^{(i)}_k \in \mathbb{R}^{m_i} \). Assume the initial state variable \( x_0 \in \mathbb{R}^n \) follows Gaussian distribution \( \mathcal{N}(\bar{x}_0, \Sigma_0) \) with \( \Sigma_0 \geq 0 \). The Gaussian white noise in the system dynamics is \( w_k \sim \mathcal{N}(0, Q) \) with \( Q \geq 0 \) and \( \mathbb{E}[w_kw'_j] = 0 \) for any \( k \neq j \). The observation noise is \( v^{(i)}_k \sim \mathcal{N}(0, R_i) \) with \( R_i > 0 \) and \( \mathbb{E}[v^{(i)}_k v^{(j)}'_i] = 0 \) for any \( k \neq j \) and \( i = 1, 2, \ldots, N \). It is assumed that \( w_k \) and \( v_k \) are uncorrelated. Besides, the initial state variable \( x_0 \) is independent of \( w_k \). The observation noise process \( v^{(i)}_k \) from different sensors are uncorrelated as well.

Assumption 1 Assume \( Q > 0 \) and the system is collectively observable, i.e., \( (A, [C'_1 C'_2 \ldots C'_N]) \) is observable.

Remark 1 Note that the assumption \( Q > 0 \) is slightly stronger than the conventional assumption of controllability of \( (A, \sqrt{Q}) \). This is to ensure that whenever the original state variable is projected onto the observable subspace of sensor \( i \), which generally has a dimension smaller than \( n \), controllability will still hold for the subsystem.

For each sensor \( i \), it will first employ Kalman decomposition on \( (A,C_i) \), and then the Kalman filter is adopted to obtain an optimal linear estimate of the state variable \( x_k \) on the observable subspace of \( (A,C_i) \). Denote the local state variable in the observable subspace of sensor \( i \) as \( \chi^{(i)}_k \in \mathbb{R}^{n_i} \), where \( n_i = \text{rank}[C'_i A'C'_i A'^2C'_i \ldots A'^{n_i-1}C'_i] \). According to Kalman decomposition, there exists an orthogonal coordinate transformation \( T_i = [V_i,\bar{\Sigma}_V_i] \in \mathbb{R}^{n \times n} \) such that \( T_i^t T_i = I_n \). By defining \( \chi^{(i)}_k := T_ix_k \) through a change of basis, an equivalent dynamic model of the linear process (1) is

\[ \chi^{(i)}_{k+1} = T_iAT_i'\chi^{(i)}_k + T_iw_k = \begin{bmatrix} A_i,\bar{\Sigma}_V_i & A_i,\bar{\Sigma}_V_i \\ O & A_i,\bar{\Sigma}_V_i \end{bmatrix} \chi^{(i)}_k + T_iw_k, \]

(3)

where \( i = 1, 2, \ldots, N \).

The locally observable state at sensor \( i \) can then be expressed as \( \chi^{(i, o)}_k := V'_i,\bar{\Sigma}_V_i x_k \in \mathbb{R}^{n_i} \) and its corresponding process noise is \( \tilde{w}^{(i, o)}_k := V'_i,\bar{\Sigma}_V_i w_k \). Thus, its dynamic model is

\[ \chi^{(i, o)}_{k+1} = A_i,\bar{\Sigma}_V_i \chi^{(i, o)}_k + \tilde{w}^{(i, o)}_k, \quad i = 1, 2, \ldots, N, \]

(4)

with the Gaussian white noise \( \tilde{w}^{(i, o)}_k \sim \mathcal{N}(0, Q_i) \), where \( Q_i = V'_i,\bar{\Sigma}_V_i QV'_i,\bar{\Sigma}_V_i \). The initial state variable follows \( \chi^{(i, o)}_0 \sim \mathcal{N}(\bar{\chi}^{(i, o)}_0, \bar{\Pi}^{(i, o)}_0) \), where \( \bar{\Pi}^{(i, o)}_0 \geq 0 \).

The equivalent observation equation is

\[ y^{(i)}_k = C_ix_k + v^{(i)}_k = C_iT_i^t \chi^{(i, o)}_k + v^{(i, o)}_k = \bar{C}_i \chi^{(i, o)}_k + v^{(i, o)}_k, \]

(5)

where \( \bar{C}_i := C_iV_i,\bar{\Sigma}_V_i \), and \( i = 1, 2, \ldots, N \).

Remark 2 In the transformation matrix \( T_i = [V_i,\bar{\Sigma}_V_i]^t \), the basis \( V_i,\bar{\Sigma}_V_i \in \mathbb{R}^{n_i \times n_i,\bar{\Sigma}} \) consists of \( n_i \) column vectors forming an orthonormal basis of the unobservable subspace of \( (A,C_i) \) while \( V_i,\bar{\Sigma}_V_i \in \mathbb{R}^{n \times n_i,\bar{\Sigma}} \) consists of orthonormal basis vectors of the observable subspace, which are linearly independent of the basis of unobservable subspace. Thus, by definition of Kalman decomposition, the pair \( (A_i,\bar{\Sigma}_V_i) \) is observable for any sensor \( i = 1, 2, \ldots, N \).

In order for each sensor to locally obtain a state estimate, a Kalman filter is implemented for estimating \( \chi^{(i, o)}_k \). For
Lemma 1. With sensor information set the remote state estimator based on the received information by sensor \( \hat{x}_{k} \) recursive update functions to obtain a local state estimate \( \hat{x}_{k}^{i} \).

\[
\begin{align*}
\hat{x}_{k|k-1}^{i} &= A_{i,o}^{i} \hat{x}_{k-1}^{i}, \\
P_{k|k-1}^{i} &= h_{i}(P_{k-1|k-1}^{i}), \\
K_{k}^{i} &= P_{k|k-1}^{i} C_{i}^{T} (C_{i} P_{k|k-1}^{i} C_{i}^{T} + R_{i})^{-1}, \\
\hat{x}_{k}^{i} &= \hat{x}_{k|k-1}^{i} + K_{k}^{i} (y_{k} - \hat{C}_{i} \hat{x}_{k|k-1}^{i}), \\
P_{k}^{i} &= g_{i}(P_{k|k-1}^{i}),
\end{align*}
\]

where \( h_{i} \) and \( g_{i} : S_{+}^{n} \rightarrow S_{+}^{n} \) are defined as follows:

\[
\begin{align*}
h_{i}(X) &= A_{i,o}^{i} X A_{i,o}^{T} + \hat{Q}_{i,o}, \\
g_{i}(X) &= X - X C_{i}^{T} (C_{i} X C_{i}^{T} + R_{i})^{-1} C_{i} X.
\end{align*}
\]

The recursion starts from \( \hat{x}_{0}^{i} = \chi_{0} \) and \( P_{0}^{i} = \Pi_{0}^{i} \geq 0 \), and the convergence result will be shown in Lemma 1.

### 2.2 Communication over independent lossy channels

Denote by \( \lambda_{i} \in (0, 1] \) the packet arrival rate associated with sensor \( i \). For the packet containing \( \hat{x}_{k}^{i} \) transmitted by sensor \( i \) at time \( k \), the arrival indicator is defined as

\[
\gamma_{k}^{(i)} = \begin{cases} 1, & \text{\( \hat{x}_{k}^{i} \) arrives at the remote state estimator;} \\ 0, & \text{Otherwise.} \end{cases}
\]

with \( \mathbb{P} (\gamma_{k}^{(i)} = 1) = \lambda_{i} \).

### 2.3 Sensor fusion at the remote state estimator

Define the “holding time” of each sensor as the number of consecutive time steps from the moment it receives its latest data packet to the current time \( k \), as expressed by

\[
\tau_{k}^{(i)} := k - t_{k}^{(i)},
\]

where \( t_{k}^{(i)} := \max \{ t \leq k : \gamma_{t}^{(i)} = 1 \} \).

Before we go into the details of the fusion methods, it is necessary to calculate the individual state estimates at the remote state estimator based on the received information set \( I_{k}^{(i)} \). Denote the remote state estimate in the observable subspace of sensor \( i \) as \( \chi_{k}^{(i,o)} \), then

\[
\begin{align*}
\chi_{k}^{(i,o)} &= \mathbb{E}[\chi_{k}^{(i,o)} | I_{k}^{(i)}] = \mathbb{E}[\chi_{k}^{(i,o)} | \{ \chi_{t}^{(i)} \}_{t=0}^{k}] \\
\chi_{k}^{(i,o)} &= \mathbb{E} \left[ A_{i,o}^{k} \chi_{k-\tau_{k}^{(i)}}^{(i,o)} + \sum_{t=0}^{\tau_{k}^{(i)}-1} A_{i,o}^{t} \chi_{k-1-t}^{(i,o)} \left| \chi_{k}^{(i,o)} \right. \right] \\
\chi_{k}^{(i,o)} &= A_{i,o}^{k} \chi_{k-\tau_{k}^{(i)}}^{(i,o)}.
\end{align*}
\]

Next, we project these individual estimates \( \chi_{k}^{(i,o)} \) back into the original space of state variables \( x_{k} \). In particular, we fill the unobservable modes with zeros, then the projection is given by \( \hat{x}_{k}^{(i,o)} = T_{1}^{T} [O \chi_{k}^{(i,o)}]' = V_{i,o}^{T} \chi_{k}^{(i,o)} \in \mathbb{R}^{n} \).

We adopt a linear fusion scheme such that the local state estimates from different sensors are incorporated into an unbiased estimate of the state \( x_{k} \in \mathbb{R}^{n} \) at the remote state estimator, as follows.

\[
\hat{x}_{k} = \sum_{i=1}^{N_{k}} W_{k}^{(i)} x_{k}^{(i)} = \sum_{i=1}^{N_{k}} W_{k}^{(i)} V_{i,o}^{T} \chi_{k}^{(i,o)},
\]

where we choose the coefficient matrix \( W_{k}^{(i)} \) at each time \( k \in \mathbb{N}_{+} \) to ensure that \( \sum_{i=1}^{N_{k}} W_{k}^{(i)} V_{i,o} V_{i,o}' = I_{(n)} \). This constraint gives an unbiased linear fusion. Moreover, we assume the packet dropout rate and the process dynamics satisfies the following assumption.

**Assumption 2**

\[
\left( 1 - \min_{1 \leq i \leq N_{k}} \lambda_{i} \right) \rho^{2}(A) < 1.
\]

Assumption 2 originates from [Sinopoli et al. (2004)](https://example.com), which ensures the stability of remote state estimation over a lossy channel.

### 2.4 Error covariance of the fused state estimate

Denote \( P_{k} \) as the estimation error covariance of \( \hat{x}_{k} \), which is defined by

\[
P_{k} = \mathbb{E}[e_{k} e_{k}'],
\]

where \( e_{k} := x_{k} - \hat{x}_{k} \) is the error of the remote state estimate.

It is desirable to obtain a closed-form expression of \( P_{k} \) based on the linear fusion scheme (12). We firstly establish the convergence of the local Kalman filter by verifying the controllability of \( (A_{i,o}, \sqrt{Q_{i,o}}) \) and the observability of \( (A_{i,o}, \hat{C}_{i}) \) ([Kailath et al. (2000)](https://example.com)).
Lemma 1 Based on Assumption 1, the pair \((A_{i,o}, \sqrt{Q_{i,o}})\) is controllable and \((A_{i,o}, \hat{C}_i)\) is observable for any \(i\). As a result, the estimation error covariance \(P_{k+1}^{(i,o)}\) of the local Kalman filter (6) converges exponentially to the steady-state error covariance \(P^{(i,o)} > 0\).

PROOF. We show the controllability of \(\left( A_{i,o}, \sqrt{Q_{i,o}} \right) \) first. According to Assumption 1, \( Q > 0 \). It remains to verify that \( Q_{i,o} := V_{i,o}^T Q V_{i,o} \in \mathbb{R}^{n_{i,o} \times n_{i,o}} \) is positive definite.

Given the fact that \( T_i T'_i = I \) for \( T_i = \left[ V_{i,0} V_{i,1} \right] \), it is straightforward to obtain that \( V_{i,1}^T V_{i,0} = I_{n_{i,o}} \) and \( V_{i,0}^T V_{i,0} = I_{n_{i,o}} \). Thus, \( V_{i,0} = n_{i,o} \). Now we take an arbitrary but fixed zero vector \( x_{i,o} \in \mathbb{R}^{n_{i,o}} \). Since \( \| V_{i,o} x_{i,o} \|_2^2 = x_{i,o}^T V_{i,o} x_{i,o} = \| x_{i,o} \|_2^2 > 0 \), a higher-dimensional non-zero vector can be obtained as \( V_{i,o} x_{i,o} \in \mathbb{R}^{n_{i,o}} \). As a result, given \( Q > 0 \), we can obtain by definition of a positive definite matrix that \( V_{i,o}^T V_{i,o} Q V_{i,o} x_{i,o} > 0 \) for any fixed \( x_{i,o} \in \mathbb{R}^{n_{i,o}} \). Therefore, it is verified that \( V_{i,o}^T Q V_{i,o} > 0 \).

Based on Popov-Belovich-Hautus (PBH) test, the controllability of \( \left( A_{i,o}, \sqrt{Q_{i,o}} \right) \) is equivalent to

\[
\text{rank} \left[ A_{i,o} - \lambda I \sqrt{Q_{i,o}} \right] = n_{i,o}, \quad \forall \lambda \in \mathbb{R}.
\]

We can then get \( n \geq \text{rank} \left[ A_{i,o} - \lambda I \sqrt{Q_{i,o}} \right] \geq \sqrt{Q_{i,o}} = n_{i,o}, \quad \forall \lambda \in \mathbb{R} \), which indicates that \( \left( A_{i,o}, \sqrt{Q_{i,o}} \right) \) is controllable.

The pair \( \left( A_{i,o}, \hat{C}_i \right) \) is observable due to the properties of Kalman decomposition. Hence, the controllability of \( \left( A_{i,o}, \sqrt{Q_{i,o}} \right) \) as well as the observability of \( \left( A_{i,o}, \hat{C}_i \right) \) has been verified successfully.

Next, it comes to the convergence property of the local Kalman filters (6) given the above results. From [Kailath et al. 2000], the controllability and observability shown above ensure the convergence of the local Kalman filter. Specifically, there is a unique fixed-point \( P_{k+1}^{(i,o)} > 0 \) for the Riccati equation \( X = h_i \circ \tilde{g}_i(X) \), which corresponds to the steady-state prediction error. Then, the steady-state estimation error is \( \tilde{P}^{(i,o)} = \tilde{g}_i(P^{(i,o)}) \).

As \( R_i > 0 \) for any \( i \), based on the information form of a Kalman filter and matrix inversion lemma, it can be obtained that

\[
\tilde{P}^{(i,o)} = \tilde{g}_i(P^{(i,o)}) = \left[ I + P^{(i,o)} \hat{C}_i R_i^{-1} \hat{C}_i^T \right]^{-1} P^{(i,o)}.
\]

As the steady-state prediction error \( P^{(i,o)} > 0 \), we can obtain that \( \tilde{P}^{(i,o)} > 0 \).}

From Lemma 1, we conclude that the optimal Kalman gain \( K_k^{(i)} \) also converges to a constant value \( K_k^{*} = P^{(i,o)} \hat{C}_i R_i^{-1} \hat{C}_i^T \). For simplicity of analysis, we assume the local Kalman filters at the sensors have been operating for an adequately long time such that each has converged to its steady-state at \( k = 0 \).

As overlaps may exist among the observable subspaces of different sensors, the local state estimates obtained by each sensor may correlate with each other. Denote the error of local state estimator \( i \) at time step \( k \) is \( \xi_k^{(i,o)} = \hat{x}_k^{(i,o)} - \hat{x}_k^{(i,o)} \in \mathbb{R}^{n_{i,o}} \). Thus, it is also necessary to analyze the convergence of the cross-covariances between the estimation errors \( \xi_k^{(i)} \) and \( \xi_k^{(j)} \) with \( i \neq j \).

**Lemma 2** For each pair of different local state estimators \( i, j \in \{ 1, 2, \ldots, N \} \) \((i \neq j)\), the recursive update of cross-correlation matrix \( \Gamma_{ij}^{(k)} := \text{E}[\xi_k^{(i)} \xi_k^{(j)}'] \in \mathbb{R}^{n_{i,o} \times n_{j,o}} \) is

\[
\Gamma_{ij}^{(k+1)} = \mathcal{T}_{ij}(\Gamma_{ij}^{(k)}),
\]

where the mapping \( \mathcal{T}_{ij} : \mathbb{R}^{n_{i,o} \times n_{j,o}} \rightarrow \mathbb{R}^{n_{i,o} \times n_{j,o}} \) is given by \( \mathcal{T}_{ij}(X) = (I - K_k^{(i)} \hat{C}_i) h_{ij}(X)(I - K_k^{(j)} \hat{C}_j)' \), with \( h_{ij} : \mathbb{R}^{n_{i,o} \times n_{j,o}} \rightarrow \mathbb{R}^{n_{i,o} \times n_{j,o}} \) defined as \( h_{ij}(X) := A_{i,o} X A_{j,o}' + V_{i,o} Q V_{j,o} \). As \( k \rightarrow \infty \), when the local Kalman filters converge to their steady states, the cross-correlation matrix also converges to a fixed point of the mapping \( \mathcal{T}_{ij} \), denoted by \( \Gamma_{ij} \), i.e., \( \lim_{k \rightarrow \infty} \Gamma_{ij}^{(k)} = \Gamma_{ij} \).

**PROOF.** First, we show the update function (14). According to the system model (1), (4) and the update functions for the Kalman filter (6), the estimation error at the local state estimator \( i \) can be expressed as

\[
\xi_k^{(i)} = \chi_k^{(i,o)} - \hat{x}_k^{(i,o)} = (I - K_k^{(i)} \hat{C}_i) A_{i,o} \xi_{k-1}^{(i)} + (I - K_k^{(i)} \hat{C}_i) \tilde{w}_{k-1}^{(i,o)} - K_k^{(i)} \hat{C}_i^{(i)}.
\]

Then the cross-correlation at time step \( k \) can be ex-
pressed as
\[
\Gamma_k^{ij} = (I - K_i^* \tilde{C}_i) h_{ij}(\Gamma_{k-1}^{ij}) (I - K_j^* \tilde{C}_j)',
\]
\[
= (I - K_i^* \tilde{C}_i)(A_{i,o} \Gamma_{k-1}^{ij} A'_{j,o} + V_{i,o} Q V_{j,o})(I - K_j^* \tilde{C}_j)',
\]
\[
= T_{ij} (\Gamma_{k-1}^{ij}).
\]  

(15)

Now, we pick two different initial values \(\Gamma_{0}^{ij}\) and \(\tilde{\Gamma}_{0}^{ij}\) for the cross-covariance between sensor \(i\) and \(j\). It can be obtained that
\[
\begin{align*}
\left\| \Gamma_k^{ij} - \tilde{\Gamma}_k^{ij} \right\| &= \left\| T_{ij} (\Gamma_{k-1}^{ij}) - T_{ij} (\tilde{\Gamma}_{k-1}^{ij}) \right\| \\
&= \left\| (A_{i,o} - K_i^* \tilde{C}_i A_{i,o}) (\Gamma_0^{ij} - \tilde{\Gamma}_0^{ij}) (A_{j,o} - K_j^* \tilde{C}_j A_{j,o}) \right\| \\
&= \ldots \\
&\leq \left\| (A_{i,o} - K_i^* \tilde{C}_i A_{i,o}) \right\| \cdot \left\| \Gamma_0^{ij} - \tilde{\Gamma}_0^{ij} \right\| .
\end{align*}
\]

According to Corollary 5.6.14 in [Horn and Johnson (1990)], for a matrix norm \(\|\cdot\|\) and an arbitrary square matrix \(X \in \mathbb{R}^{n \times n}\), there is \(\rho(X) = \lim_{k \to \infty} \|X^k\|^{\frac{1}{k}}\). In other words, for any \(\epsilon > 0\), there exists a \(\tilde{K}_0 > 0\) such that
\[
\|X^k\|^{\frac{1}{k}} - \rho(X) < \epsilon\quad \text{for all } k > \tilde{K}_0,
\]
which is equivalent to that for any \(k > K_0\),
\[
(\rho(X) - \epsilon)^k < \|X^k\| < (\rho(X) + \epsilon)^k. \tag{16}
\]

Take \(\epsilon := \min\{1 - \rho(A_{i,o} - K_i^* \tilde{C}_i A_{i,o}), 1 - \rho(A_{j,o} - K_j^* \tilde{C}_j A_{j,o})\} / 2\),
\(\rho(A_{i,o} - K_i^* \tilde{C}_i A_{i,o}), \rho(A_{j,o} - K_j^* \tilde{C}_j A_{j,o})\} / 2\), there is
\[
\begin{align*}
\left\| \Gamma_k^{ij} - \tilde{\Gamma}_k^{ij} \right\| &\leq \left\| (A_{i,o} - K_i^* \tilde{C}_i A_{i,o}) + \epsilon \right\| \cdot \left\| \Gamma_0^{ij} - \tilde{\Gamma}_0^{ij} \right\| \\
&\leq \left\| (A_{j,o} - K_j^* \tilde{C}_j A_{j,o}) + \epsilon \right\|, \quad \forall k > K_0.
\end{align*}
\]

Since by Kalman decomposition that \((A_{i,o}, \tilde{C}_i)\) is observable for all \(i\), under the steady-state optimal Kalman gain \(K_i^*\), we must have \(A_{i,o} - K_i^* \tilde{C}_i A_{i,o}\) stable, i.e., \(\rho(A_{i,o} - K_i^* \tilde{C}_i A_{i,o}) < 1\). Based on the chosen \(\epsilon\), there is also \(\rho(A_{i,o} - K_i^* \tilde{C}_i A_{i,o}) + \epsilon < 1\) and \(\rho(A_{j,o} - K_j^* \tilde{C}_j A_{j,o}) + \epsilon < 1\). As a result, we have \(\lim_{k \to \infty} \left\| \Gamma_k^{ij} - \tilde{\Gamma}_0^{ij} \right\| = 0\) for any initial values \(\Gamma_0^{ij}, \tilde{\Gamma}_0^{ij} \in \mathbb{R}^{n_{i,o} \times n_{j,o}}\).

Thus, we can conclude that the sequence \(\{\Gamma_k^{ij}\}_{k \geq 0}\) converges. Its limit \(\Gamma_{ij} \in \mathbb{R}^{n_{i,o} \times n_{j,o}}\) is the steady-state cross-covariance between sensor \(i\) and \(j\).

Denote the individual estimation error corresponding to each sensor \(i\) as \(e_k^{(i,o)} := x_k^{(i,o)} - \hat{x}_k^{(i,o)}\), and the associated error covariance matrix is
\[
P_k^{(ii)} = E[e_k^{(i,o)} e_k^{(i,o)'}] = h_k^{(i)} (P_k^{(i,o)}), \tag{17}
\]
which only depends on the “holding time” \(\tau_k^{(i)}\) of state estimator \(i = 1, 2, \ldots, N\).

The cross correlation matrix \(P_k^{(ij)} := E[e_k^{(i,o)} e_k^{(j,o)'})\] can be expressed as
\[
P_k^{(ij)} = E[e_k^{(i,o)} e_k^{(j,o)'})\]  
\[
= E[(x_k^{(i,o)} - \hat{x}_k^{(i,o)})(x_k^{(j,o)} - \hat{x}_k^{(j,o)})']
\]
\[
= E[(A_{i,o} \hat{x}_k^{(i,o)}) + \sum_{t=0}^{\tau_k^{(i)} - 1} A_{i,o} v_{i,o}^{(t)} (k-t-1) - A_{i,o} \hat{x}_k^{(i,o)} + \tau_k^{(i)}}
\]
\[
= E[(A_{j,o} \hat{x}_k^{(j,o)}) + \sum_{t=0}^{\tau_k^{(j)} - 1} A_{j,o} v_{j,o}^{(t)} (k-t-1) - A_{j,o} \hat{x}_k^{(j,o)} + \tau_k^{(j)}]
\]
\[
= A_{i,o} \Gamma_{ij} A_{j,o}' + \sum_{t=0}^{\tau_k^{(i)} - 1} A_{i,o} V_{i,o}^{t} A_{j,o}'
\]
\[
\tag{18}
\]

where the third equation is based on (4) and (11), the fifth equation holds as the Kalman filter (6) reaches steady state. This expression of \(P_k^{(ij)}\) depends on the holding time \(\tau_k^{(i)}\) and \(\tau_k^{(j)}\), and it holds for any \(i \neq j, i, j \in \{1, 2, \ldots, N\}\).

Denote the stacked fusion-coefficient matrix by \(W_k := [W_k^{(1)}, W_k^{(2)}, \ldots, W_k^{(N)}] \in \mathbb{R}^{n \times n}\) and \(V_0 := [V_{1,o} V_{1,o}', V_{2,o} V_{2,o}', \ldots, V_{N,o} V_{N,o}'] \in \mathbb{R}^{n \times n}\). Suppose the fusion coefficients are chosen appropriately such that
\[
\sum_{i=1}^{N} W_k^{(i)} V_{i,o} V_{i,o}' = W_k' V_o = I_{(n)}, \quad i.e., \quad \text{it provides an unbiased linear fusion. Then, the error covariance of the fusion estimation \(\hat{x}_k\) is thus}
\]
\[
P_k = E[e_k e_k' = \sum_{i=1}^{N} \sum_{j=1}^{N} W_k^{(i)} V_{i,o} W_k^{(j)} = W_k' \Sigma W_k,
\]
\[
\tag{19}
\]
in which the covariance matrix $\Sigma \in \mathbb{R}^{nN \times nN}$ is

$$\Sigma := \begin{bmatrix}
V_{1,o}P_{1}^{(11)}V_{1,o}' & V_{1,o}P_{1}^{(12)}V_{2,o}' & \cdots & V_{1,o}P_{1}^{(1N)}V_{N,o}' \\
V_{2,o}P_{2}^{(21)}V_{1,o}' & V_{2,o}P_{2}^{(22)}V_{2,o}' & \cdots & V_{2,o}P_{2}^{(2N)}V_{N,o}' \\
\vdots & \vdots & \ddots & \vdots \\
V_{N,o}P_{N}^{(N1)}V_{1,o}' & V_{N,o}P_{N}^{(N2)}V_{2,o}' & \cdots & V_{N,o}P_{N}^{(NN)}V_{N,o}'
\end{bmatrix}.$$  

(20)

2.5 Problem formulation

The problem of optimal linear fusion at the remote state estimator is stated as an optimization problem which minimizes the estimation error (19) by designing the fusion coefficients.

**Problem 1 (Unbiased linear state fusion)**

$$\min_{W_{k} \in \mathbb{R}^{nN \times nN}} \text{tr}(P_{k}),$$

s.t. $W_{k}'V_{o} = I_{n}$,

where $\text{tr}(P_{k}) = \text{tr}(W_{k}'\Sigma W_{k})$ according to (19).

3 Main results

We transform Problem 1 as a linear programming (LP), for which efficient algorithms exist.

3.1 Optimal linear fusion coefficients

First, we show the positive semi-definiteness of the matrix $\Sigma \in \mathbb{R}^{nN \times nN}$.

**Lemma 3** The matrix $\Sigma \in \mathbb{R}^{nN \times nN}$ in (20) is symmetric and $\Sigma \succeq 0$.

See Appendix B for proof.

In order to efficiently calculate the optimal fusion coefficients and to show the stability of the optimal linear fusion estimation, it is helpful to reformulate Problem 1. In order to do so, we introduce a new auxiliary variable and relax the constraints. The relaxed version of the original sensor fusion problem is given as follows.

**Problem 2 (Relaxed optimization problem)**

$$\min_{W_{k} \in \mathbb{R}^{nN \times nN}} \text{tr}(\Sigma X_{k}),$$

(21)

s.t. $W_{k}'V_{o} = I_{n}$ and $X_{k} \succeq W_{k}W_{k}'$.

It can be verified that Problem 2, as a relaxed problem, has no loss of optimality compared to the original Problem 1 on linear fusion. This result is stated in the following lemma, of which the proof establishes the necessity for the optimal solution pair to take equality in the constraint $X_{k} \succeq W_{k}W_{k}'$.

**Lemma 4** The optimal solution to Problem 2 coincides with the optimal solution to Problem 1.

See Appendix C for proof.

With help from Lemma 4, we are able to build the bridge for the equivalence between Problem 1 and a linear programming.

**Problem 3 (Transformed linear programming)**

$$\max_{W_{k} \in \mathbb{R}^{nN \times nN}, \Lambda_{1} \in \mathbb{R}^{nN \times nN}} \frac{1}{2} \text{tr}(\Lambda_{1}),$$

s.t. $W_{k}'V_{o} = I_{n}$ and $2\Sigma W_{k} = V_{o}\Lambda_{1}$.

**Theorem 1** The Problem 1 for finding the optimal fusion coefficients can be solved through the linear programming in Problem 3.

See Appendix D for proof.

Based on the complexity of linear programming as analyzed by [Vaidya 1989], Problem 3 can be solved in polynomial time $O(n^{2.5}N^{2})$. Hence, with Theorem 1, efficient algorithms exist for calculating the optimal fusion coefficients.

3.2 Stability of the remote state estimate

The stability of this remote fusion estimation is given in the following proposition.

**Proposition 1** Denote as $P_{k}^{*}$ the error covariance of the remote state estimate under the optimal fusion coefficients $W_{k}^{*}$ given by the solution to Problem 1 at time $k$. Then,

$$\lim_{k \to \infty} \text{tr} \left( \mathbb{E}[P_{k}^{*}] \right) < \infty.$$

(23)

See Appendix E for proof.

3.3 Closed-form optimal fusion coefficients by Gauss-Markov theorem

In Problem 3, we have formulated the problem of finding the unbiased linear state fusion coefficients as a linear programming (LP), which can be solved efficiently. Meanwhile, we are interested in obtaining a closed-form expression of the optimal fusion coefficients.
The classical parameter estimation problem given a noisy linear observation is analyzed by Albert [1973], where the covariance matrix of the observation noise is possibly singular. The explicit parameter estimation problem is formulated as follows.

Consider observations of the form
\[ z = Hx + v, \]
where \( H \in \mathbb{R}^{n \times p} \) is the observation matrix, and the vector \( x \in \mathbb{R}^p \) is a constant but unknown vector to be estimated. The zero-mean observation noise \( v \in \mathbb{R}^n \) has a singular covariance matrix \( V \in \mathbb{R}^{n \times n} \) with \( V \geq 0 \).

Now, we plan to find a linear estimate of the parameter \( x \) based on the noisy observation \( z \in \mathbb{R}^n \), i.e., to find the appropriate gain \( K \in \mathbb{R}^{p \times n} \) such that the estimate \( \hat{x} \in \mathbb{R}^n \) is
\[ \hat{x} = Kz. \]

We hope to find an unbiased estimate which minimizes the estimation error, hence this can be formulated as a constrained optimization problem.

The objective can be expressed as
\[
\mathbb{E}[\| \hat{x} - x \|^2] = \mathbb{E}[\| Kz - x \|^2] = \mathbb{E}[\| (KH - I)x + Kv \|^2] = \mathbb{E}[\| (KH - I)x \|^2] + \text{tr}(KVK^\top).
\]

In order for the state estimate to be unbiased, it is necessary to have \( \mathbb{E}[\hat{x} - x] = 0 \), i.e., \( KH = I \), and the objective function becomes \( \text{tr}(KVK^\top) \). According to Luenserger [1997], the constrained optimization problem is given as follows.

**Problem 4 (Minimum-variance unbiased estimate)**

\[
\min_{K \in \mathbb{R}^{p \times n}} \text{tr}(KVK^\top), \\
\text{s.t. } KH = I.
\]

Due to the singularity of the covariance matrix \( V \), the closed-form solution is obtained based on the results on Gauss-Markov estimate by Albert [1973], of which the main result is stated in the following lemma.

**Lemma 5 (MVUE with singular covariances)**

When the covariance \( V \in \mathbb{R}^{n \times n} \) is a singular matrix, the optimal solution to Problem 4 is
\[
K^* = H^\top[I - (LVL)^\top LV],
\]
where \( L := I - HH^\top \).

The structural similarity between the fusion estimation in Problem 1 and MVUE in Problem 4 motivates us to find an optimal linear fusion coefficient in closed-form.

**Theorem 2 (Closed-form solution to Problem 1)**
The optimal fusion coefficients in the unbiased linear state fusion in Problem 1 can be expressed as
\[
W_k^* = [I_{(nN)} - (M\Sigma M)^\top M\Sigma]V_o^\dagger,
\]
where \( M := I_{(nN)} - V_oV_o^\dagger \).

**PROOF.** Based on the comparison between Problem 1 and Problem 4, the result follows directly from Lemma 5.

4 Simulation

In this section, we consider a linearized model of inverted pendulum Messner et al. [1999] to verify the performance of the proposed unbiased linear fusion scheme. The following parameters are chosen:

- Mass of the cart \( M = 0.5 \text{ Kg} \);
- Mass of the pendulum \( m = 0.2 \text{ Kg} \);
- Coefficient of friction for cart \( b = 0.1 \text{ N/m/s} \);
- Length to pendulum center of mass \( l = 0.1 \text{ m} \);
- Moment of inertia of the pendulum \( J = 1 \text{ Kg.m}^2 \).

We denote the cart’s displacement as \( x \) and the pendulum angle as \( \phi \), i.e., the deviation of the pendulum’s position from equilibrium. The following continuous-time dynamic equation is obtained,

\[
\begin{bmatrix}
\dot{x} \\
\dot{\phi}
\end{bmatrix} = \begin{bmatrix}
0 & 1 & 0 & 0 \\
0 & -\frac{(J+mI^2)b}{p} & \frac{m^2g^2}{x^2} & 0 \\
0 & 0 & 0 & 1 \\
0 & -\frac{mlb}{p} & \frac{mgl(M+m)}{p} & 0
\end{bmatrix} \begin{bmatrix}
x \\
x \dot{x} \\
\phi \\
\dot{\phi}
\end{bmatrix} + \begin{bmatrix}
0 \\
\frac{J+mI^2}{p} \\
0 \\
\frac{ml}{p}
\end{bmatrix} u,
\]

where \( p := J(M + m) + M ml^2 \) and \( u \) is the external force.

To discretize the system dynamics, we apply zero-order holding (ZOH) with sampling time \( T_s = 0.001 \text{s} \) and obtain the discrete-time linear dynamic model as \( X_{k+1} = AX_k + Bu_k \), where \( X_k := [x_k \ 0 \ 0 \ 0] \) is the state variable, and \( u_k \) is the control input.

In this simulation example, we assume that a random perturbation force is imposed on the cart. Specifically, we model the control input as a Gaussian white noise \( u_k \sim \mathcal{N}(0, \sigma^2) \).
\[ N(0, \sigma^2) \] with \( \sigma^2 = 10 \). Define \( Q := E[Bu_ku_k'B'] = \sigma^2BB' \ge 0 \), then the dynamics of the linear process becomes
\[ X_{k+1} = AX_k + w_k, \tag{28} \]
where the Gaussian white noise \( w_k := Bu_k \sim N(0, Q) \) and \( E[w_kw_k'] = 0 \) for any \( k \neq j \).

Different sensing technologies are employed to measure the states of the inverted pendulum, e.g., infrared rays and mechanical sensors, etc. Suppose the measurement of each sensor is an independent Gaussian noise, and the error covariance matrices of the observations noise are
\[ R_1 = 0.04, \quad R_2 = \text{Diag}(0.02, 0.01), \quad R_3 = 0.16, \quad R_4 = 0.01, \quad R_5 = \text{Diag}(0.04, 0.01), \quad R_6 = 0.35, \quad R_7 = 0.02, \quad R_8 = 0.25, \quad R_9 = \text{Diag}(0.01, 0.03), \quad R_{10} = 0.09. \]

The packet arrival rates of the communication channels for these sensors are: \( [\lambda_1, \lambda_2, \ldots, \lambda_{10}] = [0.5, 0.6, 0.7, 0.6, 0.7, 0.5, 0.8, 0.5, 0.7, 0.6] \).

Hence, each sensor is only capable of observing a certain “sub-component” of the system state, whereas the remote state estimator can fuse the local information linearly to obtain a stable global state estimate.

It can be verified that Assumption 2 is satisfied, i.e., \( (1 - \min_i \lambda_i) \rho^2(A) = 0.5 \times 1.0004^2 < 1 \). The process is simulated for 50 sample trajectories, and we obtain the 2-norm \( \|e_k\| \) of the fusion estimation error averaged over all sample paths. The results are shown in Fig. 2, where the centralized Kalman filter with perfect channels is the benchmark.

Fig. 2. Numerical simulation of the state estimation error.

Fig. 3. Error of fusion estimation at the observable subspace of each sensor.

The simulation result indicates that the fusion estimation has achieved a better performance than the estimate generated based only on the observations by some individual sensors; e.g., sensor 1, sensor 2 or sensor 8 as plotted in Fig. 2, which illustrates the effectiveness of the proposed linear fusion scheme. As mentioned before, the optimal fusion coefficient can be solved in polynomial time \( O(n^5N^{2.5}) \). Therefore, linear fusion can effectively and efficiently integrate information from different sensors. Next, we pay attention to the quality of fusion estimation on the observable subspace of each sensor, as shown in Fig. 3.

As observed from Fig. 3, the optimal linear fusion does not necessarily improve the estimation performance in every subspace of the state space. However, since this fusion estimation achieves a better accuracy in the state estimate globally, a tradeoff is achieved among different sensors when calculating the fusion estimation at the remote state estimator. For example, according to the Kalman decomposition (3), sensor 3 and 7 are observing unstable modes of the dynamic system, thus the-

\[ e_k = \begin{bmatrix} 1 & 0 & 0 & 0 \end{bmatrix}, \quad C_2 = \begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix}, \quad C_3 = \begin{bmatrix} 0 & 0 & 0 & 0 \end{bmatrix}, \quad C_4 = \begin{bmatrix} 0 & 0 & 0 & 0 \end{bmatrix}, \quad C_5 = \begin{bmatrix} 0 & 0 & 0 & 0 \end{bmatrix}, \quad C_6 = \begin{bmatrix} 0 & 0 & 0 & 0 \end{bmatrix}, \quad C_7 = \begin{bmatrix} 0 & 0 & 0 & 0 \end{bmatrix}, \quad C_8 = \begin{bmatrix} 0 & 0 & 0 & 0 \end{bmatrix}, \quad C_9 = \begin{bmatrix} 0 & 0 & 0 & 0 \end{bmatrix}, \quad C_{10} = \begin{bmatrix} 0 & 0 & 0 & 0 \end{bmatrix}. \]

and the error covariance matrices of the observations noise are
\[ R_1 = 0.04, \quad R_2 = \text{Diag}(0.02, 0.01), \quad R_3 = 0.16, \quad R_4 = 0.01, \quad R_5 = \text{Diag}(0.04, 0.01), \quad R_6 = 0.35, \quad R_7 = 0.02, \quad R_8 = 0.25, \quad R_9 = \text{Diag}(0.01, 0.03), \quad R_{10} = 0.09. \]

The packet arrival rates of the communication channels for these sensors are: \( [\lambda_1, \lambda_2, \ldots, \lambda_{10}] = [0.5, 0.6, 0.7, 0.6, 0.7, 0.5, 0.8, 0.5, 0.7, 0.6] \).

Hence, each sensor is only capable of observing a certain “sub-component” of the system state, whereas the remote state estimator can fuse the local information linearly to obtain a stable global state estimate.

It can be verified that Assumption 2 is satisfied, i.e., \( (1 - \min_i \lambda_i) \rho^2(A) = 0.5 \times 1.0004^2 < 1 \). The process is simulated for 50 sample trajectories, and we obtain the 2-norm \( \|e_k\| \) of the fusion estimation error averaged over all sample paths. The results are shown in Fig. 2, where the centralized Kalman filter with perfect channels is the benchmark.
provenments on the estimation errors in their corresponding observable subspaces are more crucial. Hence, more weights are placed on them while performing linear fusion. On the other hand, sensor 1 and 6 are observing stable modes of the dynamics, thus information from these sensors may be sacrificed during linear fusion.

5 Conclusion

In this paper, we consider an unbiased linear state fusion problem where local observability is not guaranteed for each sensor and the communication channels are lossy. More specifically, each sensor generates an optimal state estimate with a local Kalman filter on its observable subspace, which is then forwarded through lossy channels to the remote state estimator for linear fusion. We propose a networked sensor fusion scheme under collectively observability assumption. The optimal linear fusion coefficients are found through a linear programming. Moreover, the closed-forms expressions of the coefficients are obtained. In the future, globally optimal state fusion scheme as well as sensor fusion in presence of data-injection attacks or eavesdroppers can be considered.

### A Summary of Variable Notations

| Variables | Meanings |
|-----------|----------|
| \( x_k \) | State variable of the linear process |
| \( w_k \) | Gaussian i.i.d. white noise in the dynamics |
| \( Q \) | Variance of \( w_k \) |
| \( y^{(i)}_k \) | Observation by sensor \( i \) |
| \( v^{(i)}_k \) | Gaussian i.i.d. white observation noise at sensor \( i \) |
| \( R_i \) | Variance of \( v^{(i)}_k \) |
| \( \chi^{(1,o)}_k \) | Projected state variable \( x_k \) on the observable subspace of smart sensor \( i \) |
| \( \chi^{(1)}_k = [\chi^{(1)}_k \, \chi^{(1,o)}_k] \) | Equivalent expression of state \( x_k \) on a new basis |
| \( A_{i,o} \) | System matrix on the observable subspace of smart sensor \( i \) |
| \( \tilde{w}^{(1,o)}_k \) | The projection of \( w_k \) on the observable subspace of smart sensor \( i \) |
| \( \tilde{Q}_{i,o} \) | Variance of \( \tilde{w}^{(1,o)}_k \) |
| \( \hat{\chi}^{s,(i)}_k \) | The estimate of state \( \chi^{(1,o)}_k \) given by the local Kalman filter at sensor \( i \) |
| \( \tilde{E}^{s,(i)}_k \) | The error of state estimate \( \hat{\chi}^{s,(i)}_k \) |
| \( \tilde{\chi}^{s,(i)}_{k|k-1} \) | The prediction of \( \chi^{(1,o)}_k \) at time \( k \) |
| \( P^{s,(i)}_{k|k-1} \) | The error covariance associated with the prediction \( \tilde{\chi}^{s,(i)}_{k|k-1} \) |
| \( P^{s,(i,o)}_k \) | The steady-state value of \( P^{s,(i)}_{k|k-1} \) |
| \( T^{(i,o)}_k \) | The steady-state value of \( P^{s,(i,o)}_k \) |
| \( \tilde{\chi}^{(1,o)}_k \) | The remote version of the state estimate \( \hat{\chi}^{s,(i)}_k \) |
| \( \tilde{E}^{(i,o)}_k \) | The error of state estimate \( \tilde{\chi}^{(1,o)}_k \) |
| \( P^{(i,o)}_{k} \) | The error covariance of state estimate \( \tilde{\chi}^{(1,o)}_k \) |
| \( P^{(i)}_{k} \) | The cross-covariance of the error of state estimate \( \hat{\chi}^{(1,o)}_k \) and \( \chi^{(1,o)}_k \) |
| \( \tilde{x}^{(i)}_k \) | The projection of \( \tilde{\chi}^{(1,o)}_k \) back to the original state space with zero-padding on the unobservable modes |
| \( \tilde{x}_k \) | The linear fusion estimation of state variable \( x_k \) |
| \( P_k \) | The error covariance associated with the fusion estimation \( \tilde{x}_k \) |
| \( V_{i,o} \) | The basis matrix for the observable subspace of sensor \( i \) |
| \( W^{(i)}_k \) | The linear fusion coefficients for weighting the state estimate in the observable subspace of sensor \( i \) |
B Proof of Lemma 3

**Proof.** Denote \( \mathcal{E}_k = [\mathcal{E}_k^{(1,o)}, \mathcal{E}_k^{(2,o)}, \ldots, \mathcal{E}_k^{(N,o)}]' \), \( P_k = [p_k^{(ij)}]_{i,j} \in \{0,1\}^n \) and \( \Sigma = V P_k V' \), where \( P_k := \mathbb{E}[\mathcal{E}_k \mathcal{E}_k'] \geq 0 \). By definition, it is known that \( p_k^{(ij)} := \mathbb{E}[\mathcal{E}_k^{(i,o)} \mathcal{E}_k^{(i',o)}]' \) is symmetric for any \( k \in \mathbb{N} \) and \( i \). Then, it can be directly obtained that each diagonal block \( V_i o p_k^{(ij)} V_i o \in \mathbb{R}^{n \times n} \) in the matrix \( \Sigma \) is symmetric. Hence, it remains to show that \( V_i o p_k^{(ij)} V_j V_i o = (V_j o p_k^{(ij)} V_i o)' \) holds for any off-diagonal elements \( i \neq j \), i.e., \( P_k^{(ij)} = P_k^{(ji)} \). According to Assumption 1 and (18), given that \( Q \) is symmetric, it suffices to show \( \Gamma_{ji} = \Gamma_{ij} \).

According to Lemma 2, it can be concluded that \( \Gamma_{ij} \) and \( \Gamma_{ji} \) are limits of the sequences \( \{ \Gamma_{ij}^k \}_{k \geq 0} \) and \( \{ \Gamma_{ji}^k \}_{k \geq 0} \) generated by recursively adopting the operators \( \Gamma_{ij}^k \) and \( \Gamma_{ji}^k \) separately. For arbitrary initial values \( \Gamma_{ij}^0 \in \mathbb{R}^{n_i \times n_j} \) and \( \Gamma_{ji}^0 \in \mathbb{R}^{n_j \times n_i} \), with similar arguments as in the proof of Lemma 2, we can obtain that

\[
\begin{align*}
&\left\| \Gamma_{ij}^k - \Gamma_{ji}^k \right\| \leq \left\| (A_{i,o} - K_i^* \hat{C}_i A_{i,o})^k \right\| \cdot \left\| \Gamma_{ij}^0 - \Gamma_{ji}^0 \right\|,
&\left\| (A_{j,o} - K_j^* \hat{C}_j A_{j,o})^k \right\| \leq \rho(A_{i,o} - K_i^* \hat{C}_i A_{i,o}) + \epsilon^k \cdot \left\| \Gamma_{ij}^0 - \Gamma_{ji}^0 \right\|,
&\left\| (A_{j,o} - K_j^* \hat{C}_j A_{j,o}) + \epsilon^k \right\| \leq \rho(A_{i,o} - K_i^* \hat{C}_i A_{i,o}) + \epsilon < 1,
\end{align*}
\]

where the last inequality is based on (16), and \( 0 < \rho(A_{i,o} - K_i^* \hat{C}_i A_{i,o}) + \epsilon < 1 \) and \( 0 < \rho(A_{j,o} - K_j^* \hat{C}_j A_{j,o}) + \epsilon < 1 \).

Hence, for any initial values \( \Gamma_{ij}^0 \) and \( \Gamma_{ji}^0 \), it can be concluded that \( 0 \leq \left\| \Gamma_{ij} - \Gamma_{ji} \right\| = \lim_{k \to \infty} \left\| \Gamma_{ij}^k - \Gamma_{ji}^k \right\| = 0 \), i.e., \( \Gamma_{ij} = \Gamma_{ji} \).

Therefore, the symmetric matrix \( \Sigma = VP_k V' \geq 0 \).

C Proof of Lemma 4

**Proof.** As \( X_k \geq W_k W_k' \geq 0 \), there is \( X_k - W_k W_k' \geq 0 \). For any pair of optimal solution \( (W_k^*, X_k^*) \), we can construct an auxiliary variable pair \( (W_k^*, X_k^*) \) such that \( X_k^* = W_k^* W_k'^* \). Hence, the constraints are still satisfied. Moreover, the value of the objective function in Problem 2 achieved under the auxiliary variable pair is

\[
\begin{align*}
\frac{\partial}{\partial \mathbf{W}_k} L(\mathbf{W}_k, \mathbf{X}_k, \Lambda_1, \Lambda_2) &= 0; \\
\frac{\partial}{\partial \mathbf{X}_k} L(\mathbf{W}_k, \mathbf{X}_k, \Lambda_1, \Lambda_2) &= 0; \\
\mathbf{W}_o V_o = I_{(n)}; \\
\mathbf{X}_k &\geq \mathbf{W}_k \mathbf{W}_k'; \\
\Lambda_2 &\geq 0; \\
\text{tr} (\Lambda_2 (\mathbf{X}_k - \mathbf{W}_k \mathbf{W}_k')) &= 0.
\end{align*}
\]

Through manipulating the KKT conditions, we obtain that

\[
\Lambda_2 = \Sigma; \quad 2\Sigma \mathbf{W}_k = \mathbf{V}_o \Lambda_1'; \quad \mathbf{W}_k' \mathbf{V}_o = I_{(n)}.
\]
Hence, the objective of the dual problem of Problem 2 will be
\[
\max_{\Lambda_1, \Lambda_2} \min_{W_k, X_k} L(W_k, X_k, \Lambda_1, \Lambda_2) \\
= \max_{\Lambda_1, \Lambda_2} \text{tr} (\Lambda_1^t W_k' W_k) - \text{tr} (\Lambda_1^t W_k V_o) \\
= \max_{\Lambda_1, \Lambda_2} \frac{1}{2} \text{tr} (V_o \Lambda_1^t W_k' W_k) = \max_{\Lambda_1} \frac{1}{2} \text{tr} (A_1).
\]

Thus, the dual of Problem 2 is Problem 3. It remains to check the strong duality.

From Problem 2, the objective \( \text{tr} (\Sigma X_k) \) and the constraint \( W_k' V_o = I(n) \) are linear, while the matrix inequality constraint \( X_k \succeq W_k W_k' \) can be equivalently expressed as
\[
\begin{bmatrix} I(n) & W_k' \\ W_k & X_k \end{bmatrix} \succeq 0,
\]
which is a convex constraint.

For a variable \( W_k \) satisfying \( W_k' V_o = I(n) \), if we pick \( X_k = W_k W_k' + \epsilon I(n,N) \) with \( \epsilon > 0 \), the Slater’s condition hold, i.e., \( W_k' V_o = I(n) \) and \( X_k \succ W_k W_k' \) are satisfied at the same time. Therefore, strong duality is verified, hence Problem 1 is equivalent to Problem 3. \( \blacksquare \)

E \ Proof of Proposition 1

PROOF. As shown in Theorem 1, the optimal solution to Problem 1 is equivalent to Problem 2. Denote its optimal solution as \((W_k^*, X_k^*)\), then for any pair of feasible variables \((W_k, X_k)\), it can be obtained that for any \( X_k \) the error covariance \( P_k^* \) under optimal fusion coefficients satisfies
\[
\text{tr} E[P_k^*] = \text{tr} (\Sigma X_k^*) \leq \text{tr} (\Sigma X_k) \leq \text{tr} (\Sigma X_k^*).
\]

Hence, it suffices to show that \( \text{tr} (\Sigma X_k) < \infty \).

Based on Assumption 1, the linear process is collectively observable by the \( N \) sensors. Hence, we have rank \([V_{1,o}, V_{2,o}, \ldots, V_{n,o}] = n \), as shown below by contradiction.

Assume that rank \([V_{1,o}, V_{2,o}, \ldots, V_{n,o}] < n \), then there exists a non-zero vector \( v \in \mathbb{R}^{\sum_{i=1}^{N} n_i,o} \setminus \{0\} \) such that \([V_{1,o}, V_{2,o}, \ldots, V_{n,o}] v = 0 \in \mathbb{R}^n \). As \( v \neq 0 \), there exists a sensor \( i_0 \) with \( V_{i_0,o} v_i = 0 \) for a non-zero \( v_i \in \mathbb{R}^{n_i,o} \setminus \{0\} \), hence rank \( V_{i_0,o} < n_{i_0,o} \), which contradicts with \( V_{i_0,o}' V_{i_0,o} = I(n_{i_0,o}) \) given by Kalman decomposition. Consequently, we have rank \([V_{1,o}, V_{2,o}, \ldots, V_{N,o}] = n \).

The rank of matrix \( V_o \in \mathbb{R}^{N \times n} \) satisfies
\[
n \geq \text{rank} V_o \geq \text{rank} (\text{Diag}(V_1', V_2', \ldots, V_N')) \cdot V_o \] 
\[
= \text{rank} [V_{1,o}, V_{2,o}, \ldots, V_{N,o}] = n,
\]
i.e., the matrix \( V_o \) is of full row rank. Thus, the constraint \( W_k' V_o = I(n) \) is feasible.

Now, we arbitrarily pick and fix a \( W \) satisfying \( W V_o = I(n) \). Based on Schur decomposition, we can obtain that \( W W' \leq m I(n,N) \) where \( m > \sigma^2_{\text{max}}(W) \), i.e., the square of the maximum singular value of \( W \). We choose \( X = m \cdot I(n,N) \), then the pair \((W, X)\) is feasible in (21) at any time \( k \).

According to (E.1), it can be concluded that
\[
\text{tr} E[P_k^*] = \text{tr} (\Sigma X_k) \leq m \cdot \text{tr} (\Sigma) \\
= m \cdot E \left[ \sum_{i=1}^{N} \text{tr} \left( V_{i,o}' V_{i,o} P^{(i)}(i) \right) \right] \\
\leq m \cdot \sum_{i=1}^{N} n_{i,o} \cdot \left\{ \text{tr} \left( \frac{V_{i,o}' Q V_{i,o}}{1 - \rho^2 (A_{i,o})} \right) + \text{tr} \left( \frac{V_{i,o}' Q V_{i,o}}{1 - \rho^2 (A_{i,o})} \right) \right\}
\]
\[
< \infty.
\]

The last inequality holds according to Assumption 2, as
\[
E[\rho^{2k(i)}(A_{i,o})] = \sum_{k=0}^{\infty} \rho^{2k} \cdot A_{i,o} \cdot \lambda_i (1 - \lambda_i)^k \\
= \sum_{k=0}^{\infty} \rho^{2k} \cdot A_{i,o} \cdot \lambda_i (1 - \lambda_i)^k \\
< \infty.
\]

Therefore, the remote state estimate is stable. \( \blacksquare \)
