Acute effects of consumption of energy drinks on intraocular pressure and blood pressure

Background: Energy drinks contain a wide variety of ingredients including caffeine, for which there have been conflicting reports regarding its effects on intraocular pressure (IOP) and blood pressure. The aim of this study was to investigate the acute effects of an energy drink (Red Bull®) on the IOP and blood pressure of healthy young adults.

Methods: Thirty healthy university students of either gender, aged 18–30 (mean 23.20 ± 2.81) years were randomly selected to participate in this study. The subjects were randomly divided into two groups (experimental and control) and were asked to abstain from caffeine for 48 hours prior to and during the study. Baseline IOP and blood pressure were measured. The experimental group (n = 15) consumed one can of the energy drink (containing 85 mg of caffeine in 250 mL) and measurements were repeated at 30, 60, and 90 minutes, while the control group drank 250 mL of water and were tested over the same time period.

Results: When compared with baseline, a significant decrease (P < 0.05) in mean IOP at 60 and 90 minutes was observed in the experimental group. There was no corresponding change in systolic or diastolic blood pressure.

Conclusion: Our results suggest that energy drinks (ie, Red Bull) produce a significant reduction in IOP but have no effect on blood pressure. These findings may be interpreted as reflecting the effect of the combination of caffeine and taurine in the Red Bull energy drink. This effect may result from the known hypotensive effect of taurine, and warrants further study.

Keywords: acute effect, intraocular pressure, blood pressure, glaucoma, caffeine, taurine

Introduction

Energy drinks (eg, Power Horse®, Red Bull®, and Rox®) are caffeinated beverages designed primarily to increase the consumer’s physical endurance. Companies that market these products usually target young adults. A survey of energy drink consumption by young people revealed that 51% reported consuming at least one energy drink per month.¹

These beverages contain many ingredients, including caffeine (80–500 mg) and an amino acid derivative called taurine (1000–2000 mg). Sugar, vitamins, and other nutritional supplements may also be included.² Researchers have studied caffeine and taurine, and shown that they are the most physiologically active ingredients in energy drinks.³

It should be noted that, although energy drinks have been sold worldwide for more than a decade, only a few published studies have examined their effects on health and well-being. Steinke and Lanfear⁴ investigated the effects of energy drink consumption on hemodynamic and electrocardiogram (ECG) parameters in healthy young adults,
and reported a significantly increased heart rate and blood pressure within 4 hours. On the first day, baseline measurements of blood pressure, heart rate, and ECG were taken. The participants then drank two cans of an energy drink containing caffeine 80 mg and taurine 1000 mg. Blood pressure, heart rate, and ECG measurements were repeated at 30 minutes, and at hours 1, 2, 3, and 4 after consumption. This continued for the next 5 days, then the same procedures used on the first day were repeated on day 7. Within 4 hours of energy drink consumption, maximum systolic blood pressure increased by 7.9% on day 1 and by 9.6% on day 7, and within 2 hours of energy drink consumption, diastolic blood pressure increased by 7% and 7.8% on days 1 and 7, respectively. It was also found that heart rate increased by 7.8% on day 1 and by 1% on day 7. No significant ECG changes were observed.

In another study, the influence of a multicomponent energy drink and its individual ingredients on the heart was compared. Red Bull containing both taurine and caffeine, a similar drink containing caffeine but no taurine, and a placebo drink without taurine or caffeine, were ingested by subjects in a double-blind, crossover study. Stroke volume was significantly increased in the Red Bull group, along with an increase in the diastolic intake velocity (related to ventricular function of the heart). The same observation was made in the caffeine group, but without any increase in the diastolic intake velocity, indicating that the combination of taurine and caffeine produced a different result from that of the individual ingredients.

So far, no data are available for the effect of energy drinks on IOP. However, many of the ingredients have been studied individually. Caffeine (a methylxanthine derivative) has been shown to influence IOP levels in subjects without and with glaucoma. With few exceptions, most studies show that caffeine ingestion from drinks such as coffee causes negligible changes in IOP. In addition, Chen et al investigating the ability of taurine or taurine-like substances to prevent and treat retinal ganglion cell damage in glaucoma, demonstrated that taurine has the potential to protect retinal ganglion cells against hypoxic damage in vivo by preventing mitochondrial dysfunction.

Primary open-angle glaucoma is a major cause of blindness worldwide. It is characterized by progressive optic nerve deterioration ultimately leading to blindness if untreated. Little is known of its etiology, but an important established risk factor for the development and progression of primary open-angle glaucoma is elevated IOP. Elevated blood pressure is the single most important predictor of hypertension. Hypertension is an important public health problem worldwide, and one of the leading causes of disability or death, due to stroke, heart attack, and kidney failure.

Because the Sub-Saharan Africans are more predisposed to glaucoma and hypertension, and because these conditions may be modulated by lifestyle factors, efforts to identify activities that may influence IOP and blood pressure levels may be promising in developing primary prevention strategies for these conditions. We therefore carried out this study to determine the acute effect of drinking a can of Red Bull, which includes taurine and caffeine, on IOP and blood pressure.

Methods
Participants
The participants for the study were students from the University of Cape Coast in Ghana. They were selected at random as the first 50 patients who answered a letter asking if they would volunteer to participate in a study. Thirty students of either gender, aged 18–30 years, were entered into the study. The subjects were randomly divided into two groups. There were 15 subjects (seven females and eight males) in the experimental group and 15 subjects (seven females and eight males) in the control group. The mean age in the experimental and control group was 23.47 ± 3.16 years and 23.00 ± 2.54 years, respectively. After fully explaining the purpose of the study, written informed consent was obtained from the subjects. In order to be eligible to participate...
in the study, subjects also had to meet a set of inclusion criteria obtained by a complete ophthalmic examination and a questionnaire, ie, absence of any ocular disease, IOP < 22 mmHg, blood pressure < 120/80 mmHg, absence of systemic diseases (including hypertension, diabetes, or vascular disease), evidence of abstinence from caffeine or caffeine beverages, and abstinence from use of any systemic drugs and/or alcohol. Any subject who stated that they had a family or personal history of glaucoma was excluded.

**Instruments**

IOP was measured by Goldmann applanation tonometry, and brachial artery systemic blood pressure was assessed by automated sphygmomanometer (Tyco Wall sphygmomanometer, Welch Allyn, Skaneateles Falls, NY).

**Procedure**

The study protocol was approved by the Department of Optometry, University of Cape Coast, Ghana. The study was conducted according to the tenets of the Declaration of Helsinki regarding scientific research on human subjects. Subjects abstained from caffeine for 48 hours prior to and during the study. Baseline IOP and systolic and diastolic blood pressures were measured. The experimental group consumed one can of Red Bull (equivalent to 85 mg caffeine in 250 mL beverage). IOP and blood pressure measurements were repeated 30, 60, and 90 minutes after ingestion. As a control, 15 of the subjects were required to consume 250 mL of water, and IOP was measured over the same period.

All participants had a best corrected visual acuity of 6/9 or better in both eyes and had no ocular pathology. Using a Goldmann applanation tonometer, IOP was measured for the right eye only between noon and 2 pm to minimize the influence of diurnal variations in IOP. A group of three consecutive readings with variation of less than 3 mmHg was considered to be an acceptable result and averaged for analysis. One member of the investigative team administered the treatment. This information was not revealed to the examiner measuring the IOP until the end of the investigation. IOP was measured at specific time intervals. The interval between each time period was used to weigh subjects. The scale was calibrated to zero before use.

Sequential examination of arterial blood pressure was also performed at the same time intervals. Three consecutive blood pressure readings, separated by at least 5-minute intervals, were obtained from both arms, with participants in a seated position. The higher mean value in either arm was used in the analysis.

**Statistical analysis**

The results for all subjects at each time point, for each group, were combined and presented as the means (±standard deviation), to allow for statistical comparison. The absence of any difference between all the measured variables was tested using the independent t-test. The pre-test and post-test data were analyzed using a paired-sample t-test. An alpha level of 0.05 was used to determine statistical significance using the SPSS program for Windows, (v 16; SPSS Inc, Chicago, IL).

**Results**

We found a high correlation between the measured outcomes for the right and left eye (Pearson’s correlation coefficient; r = 0.87 [data not presented]), indicating a symmetry in data collected from both eyes independently. Therefore, the analyses which follow are limited to the right eye. The mean values and standard deviations of all the measured variables in the pre-tests and post-tests are shown in Tables 1, 2, and 3. There was no significant difference (independent sample t-test, P < 0.05) between the experimental and control group with respect to baseline parameters of age, weight, IOP, systolic blood pressure, and diastolic blood pressure, although the mean IOP of the control group was proportionally higher than in the experimental group.

**Intraocular pressure changes**

An IOP increase of ≥2 mmHg was only observed in two subjects. Eleven subjects had a decrease in IOP of ≥2 mmHg, while there was no change in IOP in four subjects.

**Control group**

An IOP increase of 1 mmHg was observed in three subjects at 30 minutes after ingestion of 250 mL of water and this was sustained for 60 minutes. With the exception of four

| Table 1 Descriptive statistics (mean ± standard deviation) for the measured variables of the two groups |
|-----------------------------------------------|
| Group     | Age (years) | Weight (kg) | Baseline | 30 minutes | 60 minutes | 90 minutes |
|-----------|-------------|-------------|----------|------------|------------|------------|
| Experimental | 23.47 ± 3.16 | 60.67 ± 8.0 | 14.60 ± 2.50 | 14.00 ± 2.24 | 13.07 ± 2.58 | 12.87 ± 2.59 |
| Control   | 23.00 ± 2.54 | 63.47 ± 12.67 | 15.87 ± 3.40 | 15.67 ± 3.75 | 15.40 ± 3.48 | 15.67 ± 3.52 |
| P-value   | 0.612       | 0.475       | 0.255     | 0.151      | 0.46        | 0.19       |
subjects who had a decrease in IOP of 1 mmHg and one subject who had an IOP decrease of 4 mmHg, there was no change in IOP observed in the seven subjects of the control group post ingestion.

**Experimental group**

Figure 1 and Tables 4 and 5 present the results for analyses of the pre-test and post-test data by the paired samples t-test. Ingestion of Red Bull Energy produced an immediate and sustained reduction in IOP in both eyes. Compared with baseline, mean IOP for the experimental group decreased significantly at 60 and 90 minutes (by 1.53 ± 1.96 mmHg and 1.73 ± 1.90 mmHg, respectively, \( P < 0.05 \)). Repeated measurement of IOP in the 15 control subjects did not produce any significant change in IOP from baseline at any of the time points measured (two-tailed, paired t-test, \( P > 0.05 \)).

**Blood pressure**

The results of the paired samples t-test to determine the effect of Red Bull on systolic blood pressure and diastolic pressure are presented in Tables 6–9.

**Subgroup analysis**

After consumption of the energy drink, a diastolic blood pressure increase of ≥2 mmHg was observed in six subjects, four subjects had a decrease in diastolic blood pressure of <2 mmHg, while no change was observed in five subjects. A systolic blood pressure increase of ≥2 mmHg was observed in five subjects after consumption of the energy drink, while three subjects had a decrease in systolic blood pressure, but this was less than 2 mmHg. There was no apparent change in systolic blood pressure in seven subjects.

**Group analysis**

After consumption of the energy drink, there was a non-significant \( (P = 0.72) \) mean increase in diastolic blood pressure from baseline at 30 minutes, and at 90 minutes from baseline there was a borderline significant increase \( (P = 0.054) \) in diastolic blood pressure. There was no statistically significant difference from baseline in systolic blood pressure at 30 minutes \( (P = 0.719) \), 60 minutes \( (P = 1.00) \), and 90 minutes \( (P = 1.00) \). For the controls, a significant decrease in mean systolic blood pressure from baseline was observed at 60 minutes but not at 30 minutes. No significant change in diastolic blood pressure was detected at any of the time points. Figures 2 and 3 present the graphs for mean changes in systolic blood pressure and diastolic blood pressure, respectively, for the experimental and control groups.

**Discussion**

Energy drinks are beverages frequently purported to improve cognitive function and concentration. However, because they contain high amounts of caffeine, which have been shown to influence IOP and blood pressure levels, we examined its effect on these parameters in normal subjects.

Available evidence suggests that caffeinated beverages have different effects on IOP in different groups of individuals. For patients with glaucoma or ocular hypertension, IOP increased significantly,\(^{1,12}\) while in normal subjects, IOP either increased, sometimes transiently,\(^{5,7,11–13}\) or no change in IOP was found.\(^{8–10,31,32}\) Chandrasekaran et al\(^{31}\) found no relationship between IOP and coffee intake in normal subjects. Adams and Brubaker\(^{31}\) investigated the effect of orally administered coffee (containing caffeine 400 mg) on aqueous humor flow in healthy human subjects, and found that caffeine consumption had no effect on aqueous humor formation. In addition, they reported that they did not observe any statistically significant difference in IOP measured before and after coffee intake. In another study, Ozkan et al\(^{32}\) found no significant increase in mean IOP in healthy volunteers after oral administration of caffeine 300 mg. In contrast, a study by Ajayi and Ulkwade,\(^{4}\) which included only Nigerian

| Group     | Baseline | 30 minutes | 60 minutes | 90 minutes |
|-----------|----------|------------|------------|------------|
| Experimental | 70.00 ± 9.26 | 70.67 ± 7.99 | 70.67 ± 7.07 | 74.00 ± 11.21 |
| Control   | 71.33 ± 10.60 | 72.00 ± 7.75 | 71.33 ± 6.40  | 72.00 ± 7.75  |
| \(P\)-value | 0.716     | 0.646      | 0.788      | 0.574      |
subjects, reported a significant transient mean IOP increase of 4 mmHg after coffee intake in normal subjects.

Our findings did not support any of the earlier findings because IOP decreased significantly in the experimental group compared with the control group at 60 and 90 minutes after ingestion of Red Bull. Nevertheless, our finding is similar to that of Kang et al, who reported an inverse association between consumption of an average-sized cup of tea and the risk of primary open-angle glaucoma in a prospective cohort study of 79,120 women and 42,050 normal subjects.

The two main active ingredients in Red Bull energy drink are caffeine and taurine. The hypotensive effects of taurine on blood pressure have already been demonstrated. However, it would appear that most studies have focused mainly on the ergogenic effects of energy drinks, thus hardly any study in the existing literature has examined the effects on IOP of these compounds combined in an energy drink. On the other hand, with regard to the controversial reports about the effects of caffeine on IOP, it is unclear whether the combination of caffeine and taurine in energy drinks will have a hypotensive or hypertensive effect on IOP. Theoretically, our results can be considered as a possible way to explain the dominant hypotensive effect on IOP of taurine over caffeine when they are combined together. Unfortunately we did not investigate this phenomenon. Furthermore, because this was the first study to examine the effects of an energy drink on IOP, these results must be interpreted cautiously and confirmed by future studies.

We did not find any significant changes in either systolic blood pressure or diastolic blood pressure after consumption of the energy drink. However, there was a significant reduction in mean systolic blood pressure in control subjects at 60 minutes. This finding is noteworthy, given the controversy concerning the effect of drinking water on blood pressure. The effect of energy drinks on blood pressure is also controversial. It was reported in one study that consumption of an energy drink increases blood pressure, but no change in blood pressure was found in another study, which is the same as for our study. We found that, although systolic blood pressure fluctuated slightly and the diastolic pressure rose monotonically by 4 mmHg at 90 minutes, these findings were not statistically significant. Given that we have found no increase in IOP and corresponding blood pressure after the ingestion of a caffeinated energy drink, our results indirectly corroborate those of Ajayi and Ukwade, suggesting that an increase in blood pressure due to ingestion of caffeine may contribute to the increase in IOP. In their investigation, they found that the blood pressure increase occurs much earlier than the IOP increase.

The mechanism by which caffeine may influence IOP is also controversial. One investigator proposed that caffeine, as a phosphodiesterase inhibitor, may increase intracellular cyclic AMP, stimulating the production of aqueous humor by the ciliary body. Conversely, another investigator hypothesized that caffeine may reduce outflow by decreasing the tone of smooth muscles via adenosine receptor blockade, leading to closure of trabecular pores in the aqueous outflow path. However, Kurata et al, using beagle dogs, showed that caffeine increases IOP possibly by increasing aqueous humor formation, and not by inhibiting aqueous drainage through the trabecular meshwork. Nonetheless, Adams and Brubaker reported no significant difference in aqueous flow measured hourly for up to 4 hours after administration of caffeine. Our results do not argue directly for or against any of these proposed mechanisms. We can only assume that there was an interaction between the activities of caffeine and taurine in the energy drink to cause a significant reduction in IOP. These findings could stimulate further research on this subject.

Although controversial, the expected mild IOP effect of drinking water was not apparent in our study, and would suggest two possible causes. Either our tonometric procedure incorrectly assessed the IOP, or the small fluid challenge volume of 250 mL used as a control, coupled with inherent biological factors which we were unable to account for, influenced our results. In considering the first possibility, we examined the IOP outcomes for each subject. A group of three consecutive readings with a variation of less than 3 mmHg was considered acceptable and averaged for analysis. We found that, in almost all cases, there was a reproducible trend of IOP results in each eye and a similar trend in both eyes (Pearson’s correlation coefficient, r = 0.87), thus justifying the validity and reliability of our tonometric procedure. Goldmann applanation tonometry has an intraobserver reliability of 1.7 mmHg and an interobserver variability of 0.4 mmHg. However, its accuracy can be affected by other inherent biological factors, such as corneal biomechanics and axial length,36,37 which we were not able to account for. Nonetheless, the finding in our study that drinking water was not associated with increased IOP is similar to that found previously by Hsin et al.38

In summary, we found that consumption of an energy drink may decrease IOP without changing systemic blood pressure in normal subjects. We hypothesize that this result is a reflection of the effect of the caffeine and taurine combination in energy drinks. Further studies are warranted to explore the biological basis of this hypothesis.
