(Dated: October 28, 2015)

Background: The Doppler broadening of $\gamma$-ray peaks due to nuclear recoil from $\beta$-delayed nucleon emission can be used to measure the energies of the nucleons. This method has never been tested using $\beta$-delayed proton emission or applied to a recoil heavier than $A = 10$.

Purpose: To test and apply this Doppler broadening method using $\gamma$-ray peaks from the $^{26}$P($\beta\gamma$) $^{25}$Al decay sequence.

Methods: A fast beam of $^{26}$P was implanted into a planar Ge detector, which was used as a $^{26}$P $\beta$-decay trigger. The SeGA array of high-purity Ge detectors was used to detect $\gamma$ rays from the $^{26}$P($\beta\gamma$) $^{25}$Al decay sequence.

Results: Radiative Doppler broadening in $\beta$-delayed proton-$\gamma$ decay was observed for the first time. The Doppler broadening analysis method was verified using the 1613 keV $\gamma$-ray line for which the proton energies were previously known. The 1776 keV $\gamma$ ray de-exciting the 2720 keV $^{25}$Al level was observed in $^{26}$P($\beta\gamma$) $^{25}$Al decay for the first time and used to determine that the center-of-mass energy of the proton emission feeding the 2720-keV level is $5.1 \pm 1.0$ (stat.) $\pm 0.6$ (syst.) MeV, corresponding to a $^{26}$Si excitation energy of $13.3 \pm 1.0$ (stat.) $\pm 0.6$ (syst.) MeV for the proton-emitting level.

Conclusions: The Doppler broadening method has been demonstrated to provide practical measurements of the energies for $\beta$-delayed nucleon emissions populating excited states of nuclear recoils at least as heavy as $A = 25$.

Away from the valley of $\beta$ stability on the chart of nuclides, the nucleon-emission energy thresholds tend to become lower until they cross zero at the drip lines. Concurrently, the $\beta$-decay $Q$ values tend to become larger. Combining these trends creates a large probability for $\beta$-delayed particle emission near the drip lines [1]. Considering ongoing advancements in rare-isotope beam production techniques it is, therefore, becoming increasingly important to develop experimental methods to measure $\beta$-delayed particle emissions. On the proton-rich side of the valley of $\beta$ stability it is relatively straightforward to measure these emissions directly because the particles are usually charged [2]. However, on the neutron-rich side the detection of uncharged $\beta$-delayed neutrons is much more challenging [3]. Experimental data on these neutrons are necessary to solve long-standing problems in nuclear structure, nuclear astrophysics, and nuclear energy. Considering the complex decay schemes involved and the modest neutron-energy resolution of existing techniques, the development of complementary experimental tools for the study of $\beta$-delayed neutrons is particularly valuable [4].

When $\beta$-delayed particle emissions populate excited states a $\beta$-particle-$\gamma$ decay sequence can occur. The emitted particle causes the residual nucleus to recoil with a velocity that depends on the center-of-mass (c. m.) energy for the particle emission. This velocity can be mea-

sured using the Doppler shift of the γ ray providing a measure of the c. m. decay energy. For an ensemble of isotropic, uncorrelated decays in free space, the Doppler shift is manifested as a uniformly broadened peak in the γ-ray energy spectrum and the degree of broadening can be used to determine the recoil velocity. If the decay occurs in a medium then the recoiling nucleus may slow down before it emits the γ ray; in this case knowledge of the lifetime of the γ-decaying state and the the stopping power can be used to reconstruct the initial recoil velocity. A detailed formalism for the analysis of this kind of Doppler broadening has been presented in Ref. [5].

The Doppler broadening of γ-ray lines produced by the decays of excited states populated in β-delayed nucleon emission has only been reported in one very light system: the β-delayed neutron emission of 11Li. The application of this method to higher-mass systems is more challenging because the recoil velocities are smaller. Therefore, it is important to test this technique and improve the precision so it can be applied to nuclides with the highest masses possible [5].

In the present work, the use of this Doppler-broadening method in the highest-mass system yet is experimentally demonstrated: the β-delayed proton decay of 26P to 25Al. By using a charged-particle emission for the first time, it was possible to test and verify the Doppler broadening analysis technique for a 26P(βpγ)25Al γ-ray transition associated with two well-known proton energies and a well-known lifetime that could be used as constraints. The technique was then applied to measure an unknown proton energy using a newly-discovered 26P(βpγ)25Al γ-ray line and determine the excitation energy of the proton-emitting 26Si state.

The 26P β-decay experiment has already been described in Ref. [10], which focused on a 26Si excited state of astrophysical interest. Briefly, 26P activity of up to 100 decays per second was produced by the in-flight method at the National Superconducting Cyclotron Laboratory using a 75-pnA, 150-MeV/u 36Ar primary beam and a 9Be production target. The 26P beam was purified using the A1900 fragment separator [11] and a radio-frequency fragment separator [12] before being implanted into a planar germanium double-sided strip detector (GeDSSD) [13], which was used to detect the signals from charged particles including β particles. Beam particles were identified by combining the time of flight from a thin scintillator at the A1900 focal plane to two downstream Si detectors with the energy loss in those Si detectors. The average 26P-beam purity was 74 % with 18 % contamination by 24Al and small fractions of lighter ions. The GeDSSD was surrounded by the SeGA array [14] of high-purity germanium detectors, which was used to detect γ rays. The NSCL digital data acquisition [15, 16] was employed.

Signals from the GeDSSD were used to indicate when a 26P β decay took place. The SeGA array was used to detect β-delayed γ rays in coincidence with these signals within a 1.2-μs timing gate. The SeGA spectra were gain-matched run by run using well-known room-background activity detected in the γ-ray singles spectrum at 1400.8 keV (from 40K decay) and 2614.5 keV (from 208Tl decay). The sum of the gain-matched scintillator-gated SeGA spectra is plotted in Fig. 1.

TABLE I. 26P(βpγ)25Al γ rays observed in the present work. The measured γ-ray energies are reported in the first column with their statistical uncertainties only; the global systematic uncertainty is 0.5 keV. An asterisk denotes γ rays observed for the first time in 26P β decay. The γ-ray intensity per 26P decay is reported in the second column, where the intensity of the 1613-keV line from Ref. [17] was used for normalization. The third column lists γ rays observed in coincidence.

| Energy (keV) | Intensity (%) | γ-ray coincidences |
|-------------|---------------|--------------------|
| 451.9(3)    | 2.0(3)        | 493, 844, 930, 1383, 1776 |

| 843.5(3)    | 0.8(2)        | 452, 493, 944 |
| 930.4(5)*   | 0.09(5)       | 452, 944 |
| 944.4(2)    | 1.2(1)        | 844, 930, 1776 |
| 1338.0(2)   | 0.8(1)        | 452 |
| 1613.1(3)   | 2.2(2)        | |
| 1775.5(3)*  | 1.2(1)        | 452, 493, 944 |
| 1790.2(3)   | 0.8(3)        | |

In the 26P β-delayed γ-ray spectrum (Fig. 1), peaks were observed at 452, 493, 844, 930, 944, 1338, 1613, 1776, and 1970 keV (Table I) and attributed to 25Al γ decays produced by the 26P(βpγ)25Al decay sequence. 25Al peaks were initially identified by searching for the γ rays previously observed from this decay [17]. New peaks at 930 and 1776 keV were identified to be candidate 25Al γ-ray lines by comparing to the energies of known 25Al γ-ray transitions from Ref. [18]. Coincidences linking several of these γ rays in cascades were also observed (Table II).

Exponentially modified Gaussian (EMG) response functions were used to fit the peaks of interest. The parameters describing the width of the Gaussian component and the decay of the exponential component were determined as a function of energy by fitting narrow, isolated peaks. Peak centroids and integrals were extracted from the fits, accounting for Doppler broadening when necessary, as described below.

A linear energy-calibration function was created using well-known 24Mg γ-ray energies from β decay of the 24Al beam contaminant [19]. The calibration was verified to have an accuracy of 0.5 keV using well-known room background peaks in the γ-ray singles spectrum. The γ-ray energies are reported in Table II. The 844-keV peak contains a small contribution from an unresolved 26P(βpγ)26Si line at nearly the same energy. In this case, we report the energy of the combined peak. The energies are all consistent with previously reported values when known [18].

The efficiency of SeGA was found by comparing GEANT4 Monte Carlo simulations [20] to data taken offline using an absolutely calibrated 154,155Eu source and
FIG. 1. (Color online) $^{26}$P $\beta$-delayed $\gamma$-ray spectrum. All $\gamma$-ray peaks attributed to the $^{26}$P($\beta^+\gamma$)$^{25}$Al decay are labeled by their energy in keV (black). Other peaks are labeled by the $\gamma$-ray emitting nuclide, with escape peaks denoted by an asterisk (gray). Selected regions are shown in more detail in Figs. 3 and 5.

the relative intensities of the $^{24}$Mg lines from online data. Intensities were found by normalizing to the 1613-keV $\gamma$-ray, which is known to have an absolute intensity of $2.2 \pm 0.2\%$ [17] based on the proton feeding of the 1613-keV excited state (Table I). The intensity of the 844-keV peak and its uncertainty were determined by combining the acquired $^{26}$Si data set with sd-shell model calculations [21, 22] to predict, and subtract, the small contribution of $0.33 \pm 0.17\%$ from the $^{26}$P($\beta\gamma$)$^{26}$Si line.

| 2720*                            | 1.1(1)                           |              |

Doppler broadening was clearly observed in two $\gamma$-ray lines from the $\beta$-delayed proton emission of $^{26}$P to the 1613-keV and 2720-keV excited states of $^{25}$Al. The 1613-keV state de-excites by emitting a 1613-keV $\gamma$ ray (Fig. 4). The 2720-keV excited state de-excites predominantly by emitting a 1776-keV $\gamma$ ray (Fig. 5). Due to the proportionality of the Doppler shift on $\gamma$-ray energy, we were not sensitive to the Doppler broadening of the lines at 1338 keV and below. Due to the proximity of the intense 1797-keV $^{26}$Si peak to the 1790-keV $^{25}$Al peak, it was not possible to study the broadening of the 1790-keV peak precisely.

To analyze the Doppler-broadened peaks we used the method described in Ref. [5]. A fit function was created that was based on linear combinations of boxcar step functions convoluted with the detector response function. The width of each step function describes the difference between the Doppler shift for $\gamma$-rays emitted by nuclei recoiling directly toward versus away from the detector at a particular speed. Determining the step-function width enabled a calculation of the $^{25}$Al recoil speed at the time the $\gamma$ rays were emitted. The half-life of the $^{25}$Al excited state was incorporated by utilizing the exponential decay equation and the stopping power for Al ions in Ge [23] to model the deceleration of the recoiling nucleus. The variety of possible recoil speeds introduced by incorporat-
FIG. 2. $^{25}$Al level scheme from $^{26}$P($\beta\gamma$)$^{25}$Al decay deduced from the present work. The $\gamma$-ray transitions observed are denoted by arrows with thicknesses proportional to their intensities and labeled by $\gamma$-ray energy in keV. The $\beta p$ feeding of the different excited states is depicted by the arrows on the right, which are labeled by the intensities. The single asterisk denotes a value adopted from Ref. [17]. The double asterisks denotes the upper limit of the $\beta$ feeding of the 452-keV state at the 95% confidence level.

The $\gamma$-ray scheme was modeled with a straight line. The $\gamma$-ray line intensities and centroids were used to constrain the fit (Fig. 3).

The $\gamma$-ray scheme was modeled with a straight line. The $\gamma$-ray line intensities and centroids were used to constrain the fit (Fig. 3).

FIG. 3. (Color online) $^{26}$P $\beta$-delayed $\gamma$-ray spectrum in the region of the $^{25}$Al peak at 1613 keV. The peak at 1613 keV is broader than the neighboring $^{26}$Al peak at 1622 keV. The solid blue (gray) line is the overall fit including Doppler broadening and the dotted red (gray) line represents the Compton scattering background. Below the data and fit, the individual peak components are shown. The 1611-keV $^{25}$Mg, 1613-keV $^{25}$Al, and 1622-keV $^{26}$Al $\gamma$-ray lines are represented by the dot-double-dashed green (gray), dashed gold (gray) and dot-dashed light blue (gray) lines, respectively.

The 1613-keV peak was initially assumed to be a narrow line without any Doppler broadening, yielding a $\chi^2$ per degree of freedom of 138/27 corresponding to a $p$ value of 0.0001. This was clear evidence that the 1613-keV peak is not narrow.

A more detailed fit was then performed, which incorporated the Doppler broadening due to the proton emission, including the 12(2)-fs half-life [18]. There are two different excited states above the proton threshold in $^{26}$Si that emit protons populating the 1613-keV excited state of $^{25}$Al, which undergoes a $\gamma$-ray transition to the ground state [17]. The c. m. energies of the two protons are 2288(3) keV and 5893(4) keV and they have a relative intensity of $I_{2288}/I_{5893} = 2.0$ (Fig. 4) [17]. The fit function was constructed to be a linear combination of these two components. The improvement of the fit after including Doppler broadening with these known values was visually clear (Fig. 3) and is reflected in the improvement in the $\chi^2$ per degree of freedom to 31.5/27 corresponding to a $p$ value of 0.25. This confirmed the Doppler broadening of this line as well as the accuracy of the Doppler broadening analysis technique [5] and encouraged a measurement of an unknown proton energy using this method.

The 1613-keV peak was initially assumed to be a narrow line without any Doppler broadening, yielding a $\chi^2$ per degree of freedom of 138/27 corresponding to a $p$ value of 0.0001. This was clear evidence that the 1613-keV peak is not narrow.

A more detailed fit was then performed, which incorporated the Doppler broadening due to the proton emission, including the 12(2)-fs half-life [18]. There are two different excited states above the proton threshold in $^{26}$Si that emit protons populating the 1613-keV excited state of $^{25}$Al, which undergoes a $\gamma$-ray transition to the ground state [17]. The c. m. energies of the two protons are 2288(3) keV and 5893(4) keV and they have a relative intensity of $I_{2288}/I_{5893} = 2.0$ (Fig. 4) [17]. The fit function was constructed to be a linear combination of these two components. The improvement of the fit after including Doppler broadening with these known values was visually clear (Fig. 3) and is reflected in the improvement in the $\chi^2$ per degree of freedom to 31.5/27 corresponding to a $p$ value of 0.25. This confirmed the Doppler broadening of this line as well as the accuracy of the Doppler broadening analysis technique [5] and encouraged a measurement of an unknown proton energy using this method.

We observed the previously known 1776-keV $\gamma$-ray transition from the 2720-keV excited state of $^{25}$Al for the first time in $^{26}$P $\beta$ decay (Fig. 5). The c. m. proton energy feeding the 2720 keV excited state was unknown, enabling the application of the Doppler broadening method to measure the proton energy and identify the proton emitting state of $^{26}$Si.

In the fit of the 1776-keV region, the continuous Compton scattering component of the background was modeled
life of the 2720-keV state included by incorporating the 20(14)-fs \([18]\) half-life using the three known proton energies \([17]\) feeding it and expected to be Doppler broadened; its shape was constrained on the shoulder of the strong 1797-keV \(^{26}\)Si state, causing two different \(^{25}\)Al recoil velocities following proton emission.

![FIG. 4. The previously known decay scheme for the \(^{26}\)P \(\beta\)-delayed proton emission to the 1613-keV excited state of \(^{25}\)Al \([17]\). Two proton-unbound \(^{26}\)Si states feed the 1613-keV \(^{25}\)Al excited state, causing two different \(^{25}\)Al recoil velocities following proton emission.](image)

to be linear. Since there were other peaks in the region, it was necessary to include these peaks in the fit function to provide an accurate representation of the background underneath the 1776-keV peak. The 1790-keV \(^{25}\)Al peak on the shoulder of the strong 1797-keV \(^{26}\)Si line was modeled to be Doppler broadened; its shape was constrained using the three known proton energies \([17]\) feeding it and the known half-life \([18]\).

The 1776-keV peak was modeled with Doppler broadening included by incorporating the 201(14)-fs \([18]\) half-life of the 2720-keV \(^{25}\)Al state and treating the recoil velocity as an unknown. We found no evidence for multiple proton energies feeding the 2720-keV excited state of \(^{25}\)Al at our level of sensitivity. The hypothesized initial \(^{25}\)Al kinetic energy was varied in the fit from 100 to 325 keV in 15-keV steps. The best fit and \(\chi^2\) value was found for each of these energies. The optimal \(^{25}\)Al initial kinetic energy was determined to be 195 \(\pm^{41}_{50}\) (stat.) ± 18 (syst.) keV by finding the minimum value of \(\chi^2\). This energy corresponds to a c. m. proton energy of 5.1 ± 1.0 (stat.) ± 0.6 (syst.) MeV and a proton-emitting \(^{26}\)Si level at an excitation energy of 13.3 ± 1.0 (stat.) ± 0.6 (syst.) MeV. Systematic uncertainties for the proton energy were derived from the uncertainties in the shape parameters of the response function, uncertainties in the stopping power, and uncertainties in the background. A summary of the uncertainties can be found in Table III, which shows that the stopping power contributes the dominant systematic uncertainty. The only proton unbound state of \(^{26}\)Si that is consistent with our measured proton energy is the isobaric analog state (IAS) of \(^{26}\)P at 13,015(4) MeV (the only known excited state above 10.8 MeV), which is also known to be strongly populated in \(^{26}\)P \(\beta\) decay \([17]\).

In conclusion, radiative Doppler broadening in \(\beta\)-delayed proton-\(\gamma\) decay has been observed for the first time. The \(^{26}\)P(\(\beta\)\(p\gamma\))\(^{25}\)Al charged-particle emission decay enabled a test of the Doppler broadening analysis technique outlined in Ref. \([5]\), which was found to provide a good constrained fit of the broadened 1613-keV \(\gamma\)-ray line. A new \(^{26}\)P(\(\beta\)\(\gamma\)) line was discovered at 1776 keV and the Doppler broadening technique was successfully applied to determine the unknown proton energy for this case, yielding the excitation energy of the proton-emitting \(^{26}\)Si state. To our knowledge, the \(A = 25\) daughter is the heaviest \(\beta\) delayed nucleon emission recoil to which this technique has been applied so far. This confirms that Doppler broadening is a promising complementary tool for the interpretation of \(\beta\)-delayed particle emission data in general and we anticipate that it will be particularly useful in the context of \(\beta\)-delayed neutron emission measurements \([4]\).
