COMBINATORICS OF CYCLIC SHIFTS IN PLACTIC, HYPOPLACTIC, SYLVESTER, BAXTER, AND RELATED MONOIDS

ALAN J. CAIN AND ANTÓNIO MALheiro

Abstract. The cyclic shift graph of a monoid is the graph whose vertices are elements of the monoid and whose edges link elements that differ by a cyclic shift. This paper examines the cyclic shift graphs of ‘plactic-like’ monoids, whose elements can be viewed as combinatorial objects of some type: aside from the plactic monoid itself (the monoid of Young tableaux), examples include the hypoplactic monoid (quasi-ribbon tableaux), the sylvester monoid (binary search trees), the stalactic monoid (stalactic tableaux), the taiga monoid (binary search trees with multiplicities), and the Baxter monoid (pairs of twin binary search trees). It was already known that for many of these monoids, connected components of the cyclic shift graph consist of elements that have the same evaluation (that is, contain the same number of each generating symbol). This paper focuses on the maximum diameter of a connected component of the cyclic shift graph of these monoids in the rank-$n$ case. For the hypoplactic monoid, this is $n - 1$; for the sylvester and taiga monoids, at least $n - 1$ and at most $n$; for the stalactic monoid, $3$ (except for ranks $1$ and $2$, when it is respectively $0$ and $1$); for the plactic monoid, at least $n - 1$ and at most $2n - 3$. The current state of knowledge, including new and previously-known results, is summarized in a table.

For both authors, this work was partially supported by the Fundação para a Ciência e a Tecnologia (Portuguese Foundation for Science and Technology) through the project UID/MAT/00297/2013 (Centro de Matemática e Aplicações) and the project PTDC/MHC-FIL/2583/2014.
1. Introduction

In a monoid $M$, two elements $s$ and $t$ are related by a cyclic shift, denoted $s \sim t$, if and only if there exist $x, y \in M$ such that $s = xy$ and $t = yx$. In the plactic monoid (the monoid of Young tableaux, here denoted $\text{plac}$), elements that have the same evaluation (that is, elements that contain the same number of each generating symbol) can be obtained from each other by iterated application of cyclic shifts [LS81, § 4]. Furthermore, in the plactic monoid of rank $n$ (denoted $\text{plac}_n$), it is known that $2^n - 2$ applications of cyclic shifts are sufficient [CM13, Theorem 17].

To restate these results in a new form, define the cyclic shift graph $K(M)$ of a monoid $M$ to be the undirected graph with vertex set $M$ and, for all $s, t \in M$, an edge between $s$ and $t$ if and only if $s \sim t$. Connected components of $K(M)$ are $\sim^*$-classes (where $\sim^*$ is the reflexive and transitive closure of $\sim$), since they consist of elements that are related by iterated cyclic shifts. Thus the results discussed above say that each connected component of $K(\text{plac})$ consists of precisely the elements with a given evaluation, and that the diameter of a connected component of $K(\text{plac}_n)$ is at most $2n - 2$. Note that there is no bound on the number of elements in a connected component, despite there being a bound on diameters that is dependent only on the rank.

This paper studies the cyclic shift graph for analogues of the plactic monoid in which other combinatorial objects have the role that Young tableaux play for the plactic monoid. For each monoid there are two central questions, motivated by the results for the plactic monoid: (i) whether connected components consist of precisely the elements with a given evaluation; (ii) what the maximum diameter of a connected component is in the rank $n$ case.

The monoids considered are the plactic monoid, which is celebrated for its ubiquity, arising in such diverse contexts as symmetric functions [Mac08], representation theory and algebraic combinatorics [Ful97, Lot02], and musical theory [Jed11]; the hypoplactic monoid, whose elements are quasi-ribbon tableaux and which arises in the theory of quasi-symmetric functions [KT97, KT99, Nov00]; the sylvester monoid, whose elements are binary search trees [HNT05]; the taiga monoid, whose elements are binary search trees with multiplicities [Pri13]; the stalactic monoid, whose elements are stalactic tableaux [HNT07, Pri13]; and the Baxter monoid, whose elements are pairs of twin binary search trees [Gir11, Gir12], and which is linked to the
COMBINATORICS OF CYCLIC SHIFTS

Table 1. Monoids and corresponding combinatorial objects.

| Monoid   | Sym. | Combinatorial object                        | See |
|----------|------|---------------------------------------------|-----|
| Plactic  | plac | Young tableau                               | § 4 |
| Hypoplactic | hypo | Quasi-ribbon tableau                        | § 5 |
| Sylvester | sylv | Binary search tree                          | § 6 |
| Stalactic | stal | Stalactic tableau                           | § 7 |
| Taiga    | taig | Binary search tree with multiplicities      | § 8 |
| Baxter   | baxt | Pair of twin binary search trees            | § 9 |

theory of Baxter permutations. (See Table 1) Each of these monoids arises by factoring the free monoid $\mathcal{A}^*$ over the ordered alphabet $\mathcal{A} = \{1 < 2 < \ldots\}$ by a congruence $\equiv$ that can be defined in two equivalent ways:

C1 *Insertion.* $\equiv$ relates those words that yield the same combinatorial object as the result of some insertion algorithm.

C2 *Defining relations.* $\equiv$ is defined to be the congruence generated by some set of defining relations $\mathcal{R}$.

Each of these monoids also has a rank-$n$ version (where $n \in \mathbb{N}$), which arises by factoring the free monoid $\mathcal{A}_n^*$ over the finite ordered alphabet $\mathcal{A}_n = \{1 < 2 < \ldots < n\}$ by the natural restriction of $\equiv$. Each of these monoids is discussed in its own section, and the equivalent definitions will be recalled at the start of the relevant section. For the present, note that these monoids are *multihomogeneous*: if two words over $\mathcal{A}^*$ represent the same element of the monoid (that is, are related by $\equiv$) then they have the same evaluation (that is, they contain the same number of each symbol in $\mathcal{A}$ and, in particular, have the same length). Thus it is sensible to consider the evaluation of an element of the monoid to be the evaluation of any word that represents it. The relation $\equiv_{ev}$ holds between elements that have the same evaluation; clearly $\equiv_{ev}$ is an equivalence relation and $\equiv_{ev}$-classes are finite.

This paper shows that in the cyclic shift graph of the hypoplactic, sylvester, and taiga monoids, each connected component does consist of precisely those elements with a given evaluation. In the case of the stalactic monoid, an alternative characterization is given when two elements lie in the same connected component. (The result for the sylvester monoid was previously proved in a different way by the present authors [CM15, Theorem 3.4].)

Furthermore, just as for the rank-$n$ plactic monoid, there is a bound on the maximum diameters of connected components in the cyclic shift graphs of the rank-$n$ hypoplactic, sylvester, and taiga monoids, and this bound is only dependent on $n$. It is worth emphasizing how remarkable this is: although there is no global bound on the number of elements in a component (or, equivalently, which have the same evaluation), any two elements in the same component are related by a number of cyclic shifts that is dependent only on $n$. Table 2 shows the current state of knowledge for all the monoids considered in this paper. All the exact values and bounds shown in this table are new results (although the upper bound of $2n - 3$ in the case of the plactic monoid follows by a minor modification of the reasoning that yields the Choffrut–Mercas bound of $2n - 2$).
Table 2. Maximum diameter of a connected component of cyclic shift graph for rank-$n$ monoids.

| Monoid  | $\sim = \equiv_{ev}$ | Known value | Conjecture | Lower | Upper |
|---------|-----------------------|-------------|------------|-------|-------|
| plac$_n$ | Y                     | ?           | $n - 1$    | $n - 1$ | $2n - 3$ |
| hypo$_n$ | Y                     | $n - 1$     | --         | --     | --     |
| sylv$_n$ | Y                     | ?           | $n - 1$    | $n - 1$ | $n$    |
| stal$_n$ | N                     | \begin{align*} n - 1 & \text{ if } n < 3 \\ 3 & \text{ if } n \geq 3 \end{align*} | -- | -- | -- |
| taig$_n$ | Y                     | ?           | $n - 1$    | $n - 1$ | $n$    |
| baxt$_n$ | N                     | ?           | --         | --     | --     |

Experimentation using the computer algebra software Sage [S+16] strongly suggests that in the cases of the rank-$n$ plactic, sylvester, and taiga monoids, the maximum diameter of a connected component is $n - 1$.

Also, although the monoids considered are all multihomogeneous, Section 3 exhibits a rank 4 multihomogeneous monoid for which there is no bound on the diameter of connected components in its cyclic shift graph. Thus, the bound on diameters is not a general property of multihomogeneous monoids: rather, it seems to dependent on the underlying combinatorial objects. This also is of interest because cyclic shifts are a possible generalization of conjugacy from groups to monoids; thus the combinatorial objects are here linked closely to the algebraic structure of the monoid.

[The results in this article have already been announced in the conference paper [CM17].]

2. Preliminaries

2.1. Alphabets and words. This subsection recalls some terminology and fixes notation for presentations. For background on the free monoid, see [How95]; for semigroup presentations, see [Hig91, Rus95].

For any alphabet $X$, the free monoid (that is, the set of all words, including the empty word) on the alphabet $X$ is denoted $X^*$. The empty word is denoted $\varepsilon$. For any $u \in X^*$, the length of $u$ is denoted $|u|$, and, for any $x \in X$, the number of times the symbol $x$ appears in $u$ is denoted $|u|_x$.

The evaluation (also called the content) of a word $u \in X^*$, denoted $ev(u)$, is the $|X|$-tuple of non-negative integers, indexed by $X$, whose $x$-th element is $|u|_x$; thus this tuple describes the number of each symbol in $X$ that appears in $u$. If two words $u, v \in X^*$ have the same evaluation, this is denoted $u \equiv_{ev} v$. Notice that $\equiv_{ev}$ is an equivalence relation (and indeed a congruence). Note further that there are clearly only finitely many words with a given evaluation, and so $\equiv_{ev}$-classes are finite.

When $X$ represents a generating set for a monoid $M$, every element of $X^*$ can be interpreted either as a word or as an element of $M$. For words $u, v \in X^*$, write $u = v$ to indicate that $u$ and $v$ are equal as words and
$u \equiv_M v$ to denote that $u$ and $v$ represent the same element of the monoid $M$. A presentation is a pair $\langle X | \mathcal{R} \rangle$ where $\mathcal{R}$ is a binary relation on $X^*$, which defines [any monoid isomorphic to] $X^*/\mathcal{R}^\#$, where $\mathcal{R}^\#$ denotes the congruence generated by $\mathcal{R}$.

The presentation $\langle X | \mathcal{R} \rangle$ is homogeneous (respectively, multihomogeneous) if for every $(u, v) \in \mathcal{R}$ we have $|u| = |v|$ (respectively, $u \equiv_{ev} v$). That is, in a homogeneous presentation, defining relations preserve length of words; in a multihomogenous presentation, defining relations preserve evaluations. A monoid is homogeneous (respectively, multihomogeneous) if it admits a homogeneous (respectively, multihomogeneous) presentation. Suppose $M$ is a monoid, the first $n$ natural numbers, viewed as an alphabet), $A^*$ is standard if for every $u \equiv_{ev}$ $123 \ldots |u|$. That is, $u$ is standard if it contains each symbol in $\{1, \ldots, |u|\}$ exactly once.

Throughout the paper, $A$ denotes the infinite ordered alphabet $\{1 < 2 < \ldots\}$ (that is, the set of natural numbers, viewed as an alphabet), $A_n$ the finite ordered alphabet $\{1 < 2 < \ldots < n\}$ (that is, the first $n$ natural numbers, viewed as an alphabet). A word $u \in A_n^*$ is standard if it contains each symbol in $\{1, \ldots, |u|\}$ exactly once.

This paper is mainly concerned with ‘plactic-like’ monoids, whose elements can be identified with some kind of combinatorial object. Each such monoid $M$ has an associated insertion algorithm, which takes a combinatorial object of the relevant type and a letter of the alphabet $A$ and computes a new combinatorial object. Thus one can compute from a word $u \in A_n^*$ a combinatorial object $P_M(u)$ of the type associated to $M$ by starting with the empty combinatorial object and inserting the symbols of $u$ one-by-one using the appropriate insertion algorithm and proceeding through the word $u$ either left-to-right or right-to-left. (The procedure is slightly different for the Baxter monoid: this will be discussed in Section 9.) One then defines a relation $\equiv_M$ as the kernel of the map $u \mapsto P_M(u)$. In each case, the relation $\equiv_M$ is a congruence, and $M$ is the factor monoid $A^n/\equiv_M$; the rank-$n$ analogue is the factor monoid $A^n_*/\equiv_M$, where $\equiv_M$ is naturally restricted to $A^n_* \times A^n_*$. Since each element of $M$ is an equivalence class of words that give the same combinatorial object, elements of $M$ can be identified with the corresponding combinatorial objects.

Each of the combinatorial objects and insertion algorithms considered in this paper is such that the number of each symbol from $A$ in the word $u$ is the same as the number of symbols $A$ in the object $P_M(u)$. It follows that each of the corresponding monoids is multihomogeneous, and it makes sense to define an element of a rank-$n$ monoid to be standard if it is represented by a standard word (and thus only by standard words).

2.3. Cyclic shifts. Recall that two elements $s, t \in M$ are related by a cyclic shift, denoted $s \sim t$, if and only if there exist $x, y \in M$ such that $s = xy$ and $t = yx$. If $X$ represents a generating set for $M$, then $s \sim t$ if and only if there exist $u, v \in X^*$ such that $uv$ represents $s$ and $vu$ represents $t$. Notice that
the relation ∼ is reflexive (because it is possible that x or y in the definition of ∼ can be the identity) and symmetric. For $k \in \mathbb{N}$, let $\sim^k$ be the k-fold composition of the relation $\sim$: that is,

$$\sim^k = \sim \circ \sim \circ \ldots \circ \sim.$$ 

Note that $\sim^*$, the transitive closure of $\sim$, is $\bigcup_{k=1}^{\infty} \sim^k$. Note further that $\sim^k \subseteq \sim^{k+1}$ since $\sim$ is reflexive. Thus $\sim^k$ relates elements of $M$ that differ by at most $k$ cyclic shifts.

The following result is immediate from the definition of $\sim$:

**Lemma 2.1.** In any multihomogeneous monoid, $\sim^* \subseteq \equiv_{ev}$.

For any monoid $M$, define the cyclic shift graph $K(M)$ to be the undirected graph with vertex set $M$ and, for all $s, t \in M$, an edge between $s$ and $t$ if and only if $s \sim t$. (See [Har69] for graph-theoretical definitions and terminology.) Two elements $s, t \in M$ are a distance at most $k$ apart in $K(M)$ if and only if $s \sim^k t$. Connected components of $K(M)$ are $\sim^*$-classes, since they consist of elements that are related by iterated cyclic shifts. The connected component of $K(M)$ containing an element $s \in M$ is denoted $K(M, s)$. If $M$ is multihomogenous, $\sim^* \subseteq \equiv_{ev}$, and thus connected components of $K(M)$ are finite. Since $\sim$ is reflexive, there is a loop at every vertex of $K(M)$. Throughout the paper, illustrations of graphs $K(M)$ will, for clarity, omit these loops.

### 2.4. Cocharge sequences

This subsection introduces ‘cocharge sequences’, which will be used in several places to establish lower bounds on the maximum diameters of connected components of the cyclic shift graphs of finite-rank monoids.

Let $u \in A^*$ be a standard word. The cocharge sequence of $u$, denoted cocharge(seq)(u), is a sequence (of length $|u|$) calculated from $u$ as follows:

1. Draw a circle, place a point * somewhere on its circumference, and, starting from *, write $u$ anticlockwise around the circle.
2. Label the symbol 1 with 0.
3. Iteratively, after labelling some $i$ with $k$, proceed clockwise from $i$ to the symbol $i + 1$:
   - if the symbol $i + 1$ is reached before *, label $i + 1$ by $k + 1$;
   - if the symbol $i + 1$ is reached after *, label $i + 1$ by $k$.
4. The sequence cocharge(seq)(u) is the sequence whose $i$-th term is the label of $i$.

Note that at steps 2 and 3, the symbols 1 and $i + 1$ are known to be in $u$ because $u$ is a standard word.
For example, for the word 1246375, the labelling process gives:

![Diagram of labelling process]

and it follows that $\text{cochseq}(u) = (0, 0, 0, 1, 1, 2, 2)$. Notice that the first term of a cocharge sequence is always 0, and that each term in the sequence is either the same as its predecessor or greater by 1. Thus the $i$-th term in the sequence always lies in the set $\{0, 1, \ldots, i - 1\}$.

The usual notion of cocharge is obtained by summing the cocharge sequence (see [Lot02, § 5.6]). Note, however, that cocharge is defined for all words, whereas this section defines the cocharge sequence only for standard words.

**Lemma 2.2.**

1. Let $u \in A^*$ and $a \in A_n \setminus \{1\}$ be such that $ua$ is a standard word. Then $\text{cochseq}(ua)$ is obtained from $\text{cochseq}(au)$ by adding 1 to the $a$-th component.

2. Let $xy \in A^*$ be a standard word such that $x$ does not contain the symbol 1. Then $\text{cochseq}(yx)$ is obtained from $\text{cochseq}(xy)$ by adding 1 to the $a$-th component for each symbol $a$ that appears in $x$.

3. Let $xy \in A^*$ be a standard word such that $y$ does not contain the symbol 1. Then $\text{cochseq}(yx)$ is obtained from $\text{cochseq}(xy)$ by subtracting 1 from the $a$-th component for each symbol $a$ that appears in $y$.

**Proof.** Consider how $a$ is labelled during the calculation of cocharge $\text{cochseq}(ua)$ and $\text{cochseq}(au)$:

![Diagram of labelling processes for Lemma 2.2]

In the calculation of cocharge $\text{cochseq}(ua)$, the symbol $a - 1$ receives a label $k$, and then $a$ is reached after $*$ is passed; hence $a$ also receives the label $k$. (If a symbol $a + 1$ is present, it receives the label $a + 1$.) In the calculation of cocharge $\text{cochseq}(au)$, the symbols $1, \ldots, a - 1$ receive the same labels as they do in the calculation of cocharge $\text{cochseq}(ua)$, but after labelling $a - 1$ by $k$ the symbol $a$ is reached before $*$ is passed; hence $a$ receives the label $k + 1$ (and if a symbol $a + 1$ is present, it also receives the label $k + 1$ since it is reached after $*$ is passed); after this point, labelling proceeds in the same way. Parts 2) and 3) are now immediate consequences of part 1).
3. General multihomogeneous monoids

In order to set in context the results below on the diameters of connected components of cyclic shift graphs, this section gives an example of a multihomogeneous monoid for which the connected components of the cyclic shift graph have unbounded diameter. This shows that the results for the ‘plactic-like’ monoids discussed in the rest of the paper are not simply consequences of some more general result that holds for all multihomogeneous monoids.

Example 3.1. Let \( M \) be the monoid defined by the presentation
\[
(a, b, x, y \mid (bxy, xyb), (byx, yxb), (axyb, byxa)).
\]
Notice that \( M \) is multihomogeneous. Let \( \alpha \in \mathbb{N} \). Then
\[
a(xy)^\alpha b \equiv_M axyb(xy)^{\alpha-1} \\
\equiv_M byxa(xy)^{\alpha-1} \\
\sim yxa(xy)^{\alpha-1}b \\
\equiv_M yxa(xy)^{\alpha-2} \\
\equiv_M yxbxya(xy)^{\alpha-2} \\
\equiv_M b(yx)^2a(xy)^{\alpha-2} \\
\sim (yx)^2a(xy)^{\alpha-2}b \\
\vdots \\
\sim b(yx)^\alpha a
\]
Thus the elements \( a(xy)^\alpha b \) and \( b(yx)^\alpha a \) lie in the same connected component of \( K(M) \). The aim is now to prove that the distance between \( a(xy)^\alpha b \) and \( b(yx)^\alpha a \) in \( K(M) \) is at least \( \alpha \). This necessitates defining an invariant, reminiscent of cocharge, but tailored specifically to the monoid \( M \).

Let \( L = \{ u \in \{a, b, xy, yx\}^* : |u|^a = |u|^b = 1 \} \). Define a map \( \mu : L \rightarrow \mathbb{N} \cup \{0\} \), where \( \mu(u) \) is calculated as follows:

1. Draw a circle, place a point \( * \) somewhere on its circumference, and write \( u \) anticlockwise around the circle.
2. Temporarily ignoring the symbol \( b \), let \( k(u) \) be the number of consecutive cyclic factors \( xy \) following \( a \). (Equivalently, let \( k(u) \) be the number of consecutive words \( xy \) (ignoring \( b \)) following the symbol \( a \), proceeding anticlockwise around the circle.)
3. Let \( \mu(u) \) be \( k(u) \) if starting from \( a \) and proceeding anticlockwise, one encounters \( b \) before *, and otherwise let \( \mu(u) \) be \( k(u) + 1 \).

It is now necessary to show that \( \mu(\cdot) \) is invariant under applications of defining relations. Clearly, the set \( L \) is closed under applying defining relations. Further, applying a defining relation \( (bxy, xyb) \) or \( (byx, yxb) \) does not alter \( k(\cdot) \), and does not alter the relative positions of \( a, b, \) and \( * \). So applying these defining relations does not alter \( \mu(\cdot) \). So suppose that \( u, v \in L \) differ by a single application of a defining relation \( (axyb, byxa) \). Interchanging \( u \) and \( v \) if necessary, suppose \( u = paxybq \) and \( v = pbxyaq \). Let \( m \in \mathbb{N} \cup \{0\} \) be maximal such that \( (xy)^m \) is a prefix of \( qp \); thus either \( qp = (xy)^m \) or
$qp = (xy)^m yxw$ for some $w \in \{xy, yx\}^*$. Applying the procedure above to $u$ and $v$, one sees that $k(u) = m + 1 = k(v) + 1$, but $b$ is encountered before $*$ for $u$ but not for $v$; hence $\mu(u) = k(u) = k(v) + 1 = \mu(v)$.

Thus if two words in $L$ represent the same element of $M$, they have the same image under $\mu$. If $u, v \in L$ are such that $u \sim v$, then $k(u) = k(v)$, since applying $\sim$ does not alter the number of cyclic factors $xy$ following $a$. Thus $\mu(u)$ and $\mu(v)$ differ by at most one. Hence, since $\mu(a(xy)^\alpha b) = \alpha$ and $\mu(b(yx)^\alpha a) = 1$, it follows that $a(xy)^\alpha b$ and $b(yx)^\alpha a$ are a distance at least $\alpha - 1$ apart in $K(M)$.

Since $\alpha$ was arbitrary, this shows that there is no bound on the diameters of connected components in $K(M)$.

4. Plactic monoid

This section recalls the essential facts about the plactic monoid; for proofs and further reading, see [Lot02, Ch. 5].

A Young tableau is an array with rows left aligned and of non-increasing length from top to bottom, filled with symbols from $A$ so that the entries in each row are non-decreasing from left to right, and the entries in each column are [strictly] increasing from top to bottom. An example of a Young tableau is

\[
\begin{array}{cccc}
1 & 2 & 2 & 4 \\
2 & 3 & 5 \\
4 & 4 \\
5 & 6 \\
\end{array}
\]

(4.1)

The associated insertion algorithm is as follows:

**Algorithm 4.1** (Schensted’s algorithm).

*Input:* A Young tableau $T$ and a symbol $a \in A$.

*Output:* A Young tableau $T \leftarrow a$.

*Method:*

1. If $a$ is greater than or equal to every entry in the topmost row of $T$, add $a$ as an entry at the rightmost end of $T$ and output the resulting tableau.

2. Otherwise, let $z$ be the leftmost entry in the top row of $T$ that is strictly greater than $a$. Replace $z$ by $a$ in the topmost row and recursively insert $z$ into the tableau formed by the rows of $T$ below the topmost. (Note that the recursion may end with an insertion into an ‘empty row’ below the existing rows of $T$.)

Thus one can compute, for any word $u = u_1 \cdots u_k \in A^*$, a Young tableau $P_{\text{plac}}(u)$ by starting with an empty tableau and successively inserting the symbols of $u$, proceeding left-to-right through the word. Define the relation $\equiv_{\text{plac}}$ by

$u \equiv_{\text{plac}} v \iff P_{\text{plac}}(u) = P_{\text{plac}}(v)$

for all $u, v \in A^*$. The relation $\equiv_{\text{plac}}$ is a congruence, and the plactic monoid, denoted $\text{plac}$, is the factor monoid $A^*/\equiv_{\text{plac}}$; the plactic monoid of rank $n$, denoted $\text{plac}_n$, is the factor monoid $A^*_n/\equiv_{\text{plac}}$ (with the natural restriction...
of \(\equiv_{\text{plac}}\). Each element \([u]_{\equiv_{\text{plac}}}\) (where \(u \in \mathcal{A}^*\)) can be identified with the Young tableau \(P_{\text{plac}}(u)\).

The monoid \(\text{plac}\) is presented by \(\langle \mathcal{A} | R_{\text{plac}} \rangle\), where

\[
R_{\text{plac}} = \{ (acb, cab) : a, b, c \in \mathcal{A}, a \leq b < c \} \\
\cup \{ (bac, bca) : a, b, c \in \mathcal{A}, a < b \leq c \};
\]

the defining relations in \(R_{\text{plac}}\) are often called the Knuth relations \([\text{Lot02, §5.2}]\). The monoid \(\text{plac}_n\) is presented by \(\langle \mathcal{A}_n | R_{\text{plac}} \rangle\), where the set of defining relations \(R_{\text{plac}}\) is naturally restricted to \(\mathcal{A}_n^* \times \mathcal{A}_n^*\). Notice in particular that \(\text{plac}\) and \(\text{plac}_n\) are multihomogeneous.

Lascoux & Schützenberger proved that if two elements of \(\text{plac}\) have the same evaluation, then it is possible to transform one to the other using cyclic shifts \([\text{LS81, §4}]\). In the terms of this paper, they proved that \(\equiv_{\text{ev}} \subseteq \sim^*\) in \(\text{plac}\). Since the opposite inclusion holds in general, it follows that \(\equiv_{\text{ev}} = \sim^*\) in \(\text{plac}\). Thus connected components of the cyclic shift graph \(K(\text{plac})\) are \(\equiv_{\text{ev}}\)-classes.

Choffrut & Mercas showed that if two elements of \(\text{plac}_n\) have the same evaluation, then it is possible to transform one to the other using at most \(2n - 2\) cyclic shifts \([\text{CM13, Theorem 17}]\). Thus the maximum diameter of a connected component of \(K(\text{plac}_n)\) is at most \(2n - 2\).

This section gives a lower bound on the maximum diameter of a connected component of \(K(\text{plac}_n)\), makes a slight improvement on the upper bound of Choffrut & Mercas, and conjecture the exact value on the basis of experimentation using computer algebra software.

Establish the lower bound requires the use of cocharge sequences (defined in Subsection 2.4 above). It is first of all necessary to show that cocharge sequences are well-defined on standard elements of \(\text{plac}\):

**Proposition 4.2.** Let \(w, w' \in \mathcal{A}^*\) be standard words such that \(w \equiv_{\text{plac}} w'\). Then \(\text{cochseq}(w) = \text{cochseq}(w')\).

**Proof.** It suffices to prove the result when \(w\) and \(w'\) differ by a single application of a defining relation. Assume that \(w\) and \(w'\) differ by an application of a defining relation \((acb, cab) \in R_{\text{plac}}\) where \(a \leq b < c\). So \(w = pacbq\) and \(w' = pcabq\), where \(p, q \in \mathcal{A}_n^*\) and \(a, b, c \in \mathcal{A}_n\) with \(a \leq b < c\). Since \(w\) and \(w'\) are standard words, \(a < b\).

Consider how labels are assigned to the symbols \(a, b,\) and \(c\) when calculating \(\text{cochseq}(w)\) as described in Subsection 2.4:

\[
\begin{array}{c}
* \\
\downarrow \\
\begin{array}{c}
a \\
\sim \\
c \\
b
\end{array}
\end{array}
\]

Among these three symbols, \(a\) will receive a label first, then \(b\), then \(c\). Thus, after \(a\), the labelling process will pass \(*\) at least once to visit \(b\) and only then visit \(c\). Thus interchanging \(a\) and \(c\) does not alter the resulting labelling. Hence \(\text{cochseq}(w) = \text{cochseq}(w')\). Similar reasoning shows that if \(w\) and \(w'\) differ by an application of a defining relation \((bac, bca) \in R_{\text{plac}}\), then \(\text{cochseq}(w) = \text{cochseq}(w')\). \(\square\)
For any standard tableau \( T \) in \( \text{plac} \), define \( \text{cochseq}(T) \) to be \( \text{cochseq}(u) \) for any standard word \( u \in A^* \) such that \( T = P(u) \). By Proposition 4.2, \( \text{cochseq}(T) \) is well-defined.

**Proposition 4.3.** (1) Connected components of \( K(\text{plac}) \) coincide with \( \equiv_{ev} \)-classes of \( \text{plac} \).

(2) Let \( k_n \) be the maximum diameter of a connected component of \( K(\text{plac}_n) \).

Then \( n - 1 \leq k_n \leq 2n - 3 \).

**Proof.** The first part is the result of Lascoux & Ščutzenberger [LS81 § 4], restated in the terms used of this paper. It remains to prove the second part.

To establish the lower bound on \( k_n \), it is necessary to exhibit a pair of elements of \( \text{plac}_n \) that lie in the same connected component of \( K(\text{plac}_n) \) but are a distance at least \( n - 1 \) apart.

Let \( t = 12\cdots(n-1)n \) and \( u = n(n-1)\cdots21 \), and let

\[
T = P_{\text{plac}}(t) = \begin{array}{cccc}
1 & 2 & \cdots & n
\end{array} \quad \text{and} \quad U = P_{\text{plac}}(u) = \begin{array}{c}
1 \\
2 \\
n
\end{array}
\]

Since \( T \equiv_{ev} U \), the elements \( T \) and \( U \) are in the same connected component of \( K(\text{plac}_n) \). Let \( T = T_0, T_1, \ldots, T_{m-1}, T_m = U \) be a path in \( K(\text{plac}_n) \) from \( T \) to \( U \). Then

\[
T = T_0 \sim T_1 \sim \ldots \sim T_{m-1} \sim T_m = U.
\]

Thus for \( i = 0, \ldots, m - 1 \), there are words \( u_i, v_i \in A_n^* \) such that \( T_i = P_{\text{plac}}(u_i) \) and \( T_{i+1} = P_{\text{plac}}(v_i u_i) \). For each \( i \), at least one of \( u_i \) and \( v_i \) does not contain the symbol 1, and by parts 2) and 3) ofLemma 2.2, \( \text{cochseq}(T_i) \) and \( \text{cochseq}(T_{i+1}) \) differ by adding 1 to certain components or subtracting 1 from certain components. Hence corresponding components of \( \text{cochseq}(T) \) and \( \text{cochseq}(U) \) differ by at most \( m \). Since \( \text{cochseq}(T) = (0, 0, \ldots, 0, 0) \) and \( \text{cochseq}(U) = (0, 1, \ldots, n-2, n-1) \), it follows that \( m \geq n - 1 \). Hence \( T \) and \( U \) are a distance at least \( n - 1 \) apart in \( K(\text{plac}_n) \).

To establish the upper bound for \( k_n \), we proceed as follows. Let \( T, U \in \text{plac}_n \) be such that \( T \equiv_{ev} U \). Let \( R \) be the unique tableau of row shape such that \( T \equiv_{ev} R \equiv_{ev} U \). By [CM13] Proof of Theorem 17], \( T \sim^{n-1} R \) and \( U \sim^{n-1} R \). Thus there exist \( T', U' \in \text{plac}_n \) such that \( T \sim^{n-2} T' \) and \( U \sim^{n-2} U' \), and \( T' \sim R \sim U' \). Since there is only one word \( w \in A_n^* \) that represents the row \( R \), it follows that there are words \( t \) and \( u \) that are cyclic shift of \( w \) with \( T' = P_{\text{plac}}(t) \) and \( U' = P_{\text{plac}}(u) \). Since \( t \) and \( u \) are both cyclic shifts of \( w \), they are cyclic shifts of each other and so \( T' \sim U' \). Hence \( T \sim 2n-3 \).

Experimentation using the computer algebra software Sage [S+16] suggests the following conjecture on maximum diameters of connected components of \( K(\text{plac}_n) \); see Figure 1.

**Conjecture 4.4.** The maximum diameter of a connected component of \( K(\text{plac}_n) \) is \( n - 1 \).
5. Hypoplactic monoid

Following the course of the previous section, only the essential facts about the hypoplactic monoid are recalled here; for proofs and further reading, see [Nov00].
A quasi-ribbon tableau is a finite array of symbols from $A$, with rows non-decreasing from left to right and columns strictly increasing from top to bottom, that does not contain any $2 \times 2$ subarray (that is, of the form $\begin{bmatrix} 1 & 1 \\ 2 & 2 \end{bmatrix}$). An example of a quasi-ribbon tableau is:

\begin{equation}
\begin{array}{cccc}
1 & 1 & 2 \\
3 & 4 & 4 \\
5 & 6 & 6
\end{array}
\end{equation}

Notice that the same symbol cannot appear in two different rows of a quasi-ribbon tableau.

The insertion algorithm is as follows:

**Algorithm 5.1** ([KT97, § 7.2]).

**Input:** A quasi-ribbon tableau $T$ and a symbol $a \in A$.

**Output:** A quasi-ribbon tableau $T \leftarrow a$.

**Method:** If there is no entry in $T$ that is less than or equal to $a$, output the quasi-ribbon tableau obtained by creating a new entry $a$ and attaching (by its top-left-most entry) the quasi-ribbon tableau $T$ to the bottom of $a$.

If there is no entry in $T$ that is greater than $a$, output the quasi-ribbon tableau obtained by creating a new entry $a$ and attaching (by its bottom-right-most entry) the quasi-ribbon tableau $T$ to the left of $a$.

Otherwise, let $x$ and $z$ be the adjacent entries of the quasi-ribbon tableau $T$ such that $x \leq a < z$. (Equivalently, let $x$ be the right-most and bottom-most entry of $T$ that is less than or equal to $a$, and let $z$ be the left-most and top-most entry that is greater than $a$. Note that $x$ and $z$ could be either horizontally or vertically adjacent.) Take the part of $T$ from the top left down to and including $x$, put a new entry $a$ to the right of $x$ and attach the remaining part of $T$ (from $z$ onwards to the bottom right) to the bottom of the new entry $a$, as illustrated here:

\begin{align*}
\begin{array}{ccc}
\hline
x & a \\
\hline
\end{array}
& \quad [\text{where } x \text{ and } z \text{ are vertically adjacent}] \\
\begin{array}{ccc}
\hline
x & a \\
\hline
\end{array}
& \quad [\text{where } x \text{ and } z \text{ are horizontally adjacent}]
\end{align*}

Output the resulting quasi-ribbon tableau.

Thus one can compute, for any word $u \in A^*$, a quasi-ribbon tableau $P_{\text{hypo}}(u)$ by starting with an empty quasi-ribbon tableau and successively inserting the symbols of $u$, proceeding left-to-right through the word. Define the relation $\equiv_{\text{hypo}}$ by

$$u \equiv_{\text{hypo}} v \iff P_{\text{hypo}}(u) = P_{\text{hypo}}(v)$$

for all $u, v \in A^*$. The relation $\equiv_{\text{hypo}}$ is a congruence, and the hypoplactic monoid, denoted hypo, is the factor monoid $A^*/\equiv_{\text{hypo}}$; the hypoplactic monoid of rank $n$, denoted hypo$_n$, is the factor monoid $A_n^*/\equiv_{\text{hypo}}$ (with the
Each element \([u] \equiv_{\text{hypo}}\) (where \(u \in A^*\)) can be identified with the quasi-ribbon tableau \(P_{\text{hypo}}(u)\). For two quasi-ribbon tableaux \(T\) and \(U\), denote the product of \(T\) and \(U\) in \(\text{hypo}\) by \(T \circ U\).

The monoid \(\text{hypo}\) is presented by \(\langle A \mid \mathcal{R}_{\text{hypo}} \rangle\), where \(\mathcal{R}_{\text{hypo}} = \mathcal{R}_{\text{plac}} \cup \{ (cadb, acbd) : a \leq b < c \leq d \} \cup \{ (bdac, dbca) : a < b \leq c < d \}\); see [Nov00, § 4.1] or [KT97, § 4.8]. The monoid \(\text{hypo}_n\) is presented by \(\langle A_n \mid \mathcal{R}_{\text{hypo}} \rangle\), where the set of defining relations \(\mathcal{R}_{\text{hypo}}\) is naturally restricted to \(A_n^* \times A_n^*\). Notice that \(\text{hypo}\) and \(\text{hypo}_n\) are multihomogeneous.

It seems that cyclic shifts of elements of \(\text{hypo}\) have not been explicitly discussed in the existing literature. However, it is clear from the defining relations that \(\text{hypo}\) is a quotient of \(\text{plac}\) under the natural homomorphism. If two elements are \(\sim\)-related in \(\text{plac}\), they are \(\sim\)-related in \(\text{hypo}\). Furthermore, since an element of \(\text{plac}\) and its image in \(\text{hypo}\) have the same evaluation, and since connected components of \(K(\text{plac})\) coincide with \(\equiv_{ev}\)-classes, it follows that connected components of \(K(\text{hypo})\) also coincide with \(\equiv_{ev}\)-classes. That is, \(\sim^* = \equiv_{ev}\) in \(\text{hypo}\).

In contrast to \(K(\text{plac}_n)\), it is possible to give an exact value for the maximum diameter of a connected component in \(K(\text{hypo}_n)\): the aim is to prove that it is \(n - 1\). The proof that it cannot be smaller than \(n - 1\) is similar to the proof of the lower bound in Proposition 4.3. Again, cocharge sequences are the key:

**Proposition 5.2.** Let \(u, v \in A^*\) be standard words such that \(u \equiv_{\text{hypo}} v\). Then \(\text{cochseq}(u) = \text{cochseq}(v)\).

**Proof.** It suffices to prove the result when \(u\) and \(v\) differ by a single application of a defining relation. Assume that \(u\) and \(v\) differ by an application of a defining relation \((cadb, acbd) \in \mathcal{R}_{\text{hypo}} \setminus \mathcal{R}_{\text{plac}}\) where \(a \leq b < c \leq d\). The reasoning for defining relations of the form \((bdac, dbca)\) is similar, and for defining relations in \(\mathcal{R}_{\text{plac}}\), one can proceed in the same way as in the proof of Proposition 4.2. So \(u = pcadbq\) and \(v = pacbdq\), where \(p, q \in A_n^*\) and \(a, b, c, d \in A_n\) with \(a \leq b < c \leq d\). Since \(u\) and \(v\) are standard words, \(a < b\) and \(c < d\).

Consider how labels are assigned to the symbols \(a\), \(b\), \(c\), and \(d\) when calculating \(\text{cochseq}(w)\) as described in Subsection 2.4.

\[
\begin{array}{c}
* \\
\circ \\
\nearrow \searrow \\
\check{a} \quad \check{c} \\
da \quad b
\end{array}
\]

Among these four symbols, \(a\) will receive a label first, then \(b\), then \(c\), then \(d\). Thus, after \(a\), the labelling process will pass \(\ast\) at least once to visit \(b\) and (perhaps after passing \(\ast\) more times) only then visit \(c\). After visiting \(b\), it must visit \(c\) first and thus must pass \(\ast\) at least once before visiting \(d\). Thus interchanging \(a\) and \(c\) and interchanging \(b\) and \(d\) does not alter the resulting labelling. Hence \(\text{cochseq}(u) = \text{cochseq}(v)\). \(\square\)
For any standard quasi-ribbon tableau $T$ in hypo, define $\text{cochseq}(T)$ to be $\text{cochseq}(u)$ for any standard word $u \in A^*$ such that $T = P_{\text{hypo}}(u)$. By Proposition 5.2, $\text{cochseq}(T)$ is well-defined.

**Lemma 5.3.** There is a connected component in $K(\text{hypo}_n)$ with diameter at least $n - 1$.

**Proof.** To prove this result, it suffices to exhibit two elements that lie in the same connected component of $K(\text{hypo}_n)$, but that are a distance strictly at least $n - 1$ apart. Let $t = 12 \cdots (n - 1)n$ and $u = n(n - 1) \cdots 21$, and let

$$T = P_{\text{hypo}}(t) = \begin{array}{cccccc} 1 & 2 & \cdots & n \\ \end{array}$$

and $U = P_{\text{hypo}}(u) = \begin{array}{cccccc} 2 \\ \vdots \\ n \\ \end{array}$

Then $T \equiv_{ev} U$ and so $T$ and $U$ are in the same connected component of $K(\text{hypo}_n)$. Reasoning similar to the proof of Proposition 4.3 shows that a path from $T$ to $U$ in $K(\text{hypo}_n)$ must have length at least $n - 1$. □

Having shown that there is a connected component of $K(\text{hypo}_n)$ with diameter at least $n - 1$, the next step is to prove that connected components of $K(\text{hypo}_n)$ have diameter at most $n - 1$. To do this, some more definitions are necessary:

- The **column reading** of a quasi-ribbon tableau $T$, denoted $C(T)$, is the word in $A^*$ obtained by reading each column from bottom to top, proceeding left to right through the columns. So the column reading of (5.1) is $1 \ 1 \ 2 \ 3 \ 4 \ 4 \ 5 \ 6 \ 6$ (where the spaces are simply for clarity, to show readings of individual columns):

- The **row reading** of a quasi-ribbon tableau $T$, denoted $R(T)$, is the word in $A^*$ obtained by reading the each row from left to right, proceeding through the rows from bottom to top. So the row reading of (5.1) is $66 \ 5 \ 344 \ 112$ (where the spaces are simply to show readings of individual rows):

Let $w \in A^*$ and let $a_1 < a_2 < \ldots < a_k$ be the symbols in $A_n$ that appear in $w$. The word $w$ contains an $(a_i, a_{i+1})$-inversion if it contains a symbol $a_{i+1}$ somewhere to the left of a symbol $a_i$. The following lemma is immediate from the statement of Algorithm 5.1.
Lemma 5.4. Let $w \in \mathcal{A}^*$ and let $a_1 < a_2 < \ldots < a_k$ be the symbols in $\mathcal{A}_n$ that appear in $w$. Then $w$ contains an $(a_i, a_{i+1})$-inversion if and only if $a_i$ and $a_{i+1}$ are on different rows of $P_{\text{hypo}}(w)$.

Proposition 5.5. Let $T$ be a quasi-ribbon tableau. Then $P_{\text{hypo}}(C(T)) = P_{\text{hypo}}(R(T)) = T$.

[The fact that $P_{\text{hypo}}(C(T)) = T$ follows from [Nov00, Note 4.5], but the following proof treats $P_{\text{hypo}}(C(T))$ in parallel.]

Proof. Let $a_1 < a_2 < \ldots < a_k$ be the symbols in $\mathcal{A}_n$ that appear in $T$. By definition, $C(T)$ and $R(T)$ will contain an $(a_i, a_{i+1})$-inversion if and only if $a_i$ and $a_{i+1}$ are on different rows of $T$. Hence, by [Lemma 5.4] symbols $a_i$ and $a_{i+1}$ are on different rows of $P_{\text{hypo}}(C(T))$ and $P_{\text{hypo}}(R(T))$ if and only if they are on different rows of $T$. Furthermore, $P_{\text{hypo}}(C(T))$ and $P_{\text{hypo}}(R(T))$ both have the same evaluation as $T$. Since quasi-ribbon tableau is determined by its evaluation and whether adjacent symbols are on different rows, it follows that $P_{\text{hypo}}(C(T)) = P_{\text{hypo}}(R(T)) = T$. \qed

Lemma 5.6. Every connected component of $K(\text{hypo}_n)$ has diameter at most $n - 1$.

(While reading this proof, the reader may wish to look ahead to [Example 5.8] which illustrates the strategy.)

Proof. Let $T$ and $U$ be elements of the same connected component of $K(\text{hypo}_n)$. Then $T \sim_{\text{ev}} U$. Let $a_1 < a_2 < \ldots < a_k$ be the symbols in $\mathcal{A}_n$ that appear in $T$ and $U$. Since the defining relations in $\mathcal{R}_{\text{hypo}}$ depend only on the relative order of symbols, it is clear that there is an isomorphism from $(a_1, \ldots, a_k)$ to $\text{hypo}_k$ extending $a_i \mapsto i$. Since $k \leq n$, it suffices to prove that the distance between $T$ and $U$ is at most $n - 1$ when $T$ and $U$ contain every symbol in $\mathcal{A}_n$.

The aim is to construct a path in $K(\text{hypo}_n)$ from $T$ to $U$ of length at most $n - 1$. For simplicity, the aim is to find a sequence $T_0, T_1, \ldots, T_{n-1}$ such that $T_0 = T$ and $T_{n-1} = U$, and $T_i \sim T_{i+1}$ for $i = 0, \ldots, n - 2$. The construction is inductive, starting from $T_0 = T$ and building each $T_i$ so that the part of $T_i$ that contains only symbols from $\{1, \ldots, i + 1\}$ is equal to the corresponding part of $U$.

Set $T_0 = T$. Notice that since $T \sim_{\text{ev}} U$, both $T$ and $U$ contain the same number of symbols 1, which must all lie at the left of the top rows of the two tableaux. Thus for $i = 0$, it holds that the part of $T_i$ that contains only symbols from $\{1, \ldots, i + 1\}$ is equal to the corresponding part of $U$.

Now suppose that for some $i$ with $1 \leq i < n$, it holds that the part of $T_{i-1}$ that contains only symbols $\{1, \ldots, i\}$ is equal to the corresponding part of $U$.

Consider the positions of symbols $i$ and $i + 1$ in a quasi-ribbon tableau. One of two cases holds:
(S) All symbols $i$ and $i + 1$ are on the same row, with the rightmost symbol $i$ immediately to the left of the leftmost symbol $i + 1$:

```
+-------------------+
| i | i+1 |         |
+-------------------+
```

(D) The symbols $i$ and the symbols $i + 1$ are on different rows, with the rightmost symbol $i$ immediately above the leftmost symbol $i + 1$:

```
+-------------------+
| i | i+1 |
+-------------------+
```

In each of the quasi-ribbon tableau $T_{i-1}$ and $U$, the symbols $i$ and $i + 1$ may be in the same row or in different rows. There are thus four possible combinations of cases:

1. Suppose case (S) holds in both $T_{i-1}$ and $U$. Set $T_i = T_{i-1}$; thus $T_{i-1} \sim T_i$ by the reflexivity of $\sim$. Since $T_i$ and $U$ contain the same number of symbols $i + 1$, all of which must lie in the same row, the part of $T_i$ that contains only symbols $\{1, \ldots, i + 1\}$ is equal to the corresponding part of $U$.

2. Suppose case (D) holds in both $T_{i-1}$ and $U$. Set $T_i = T_{i-1}$. By the same reasoning as above, $T_{i-1} \sim T_i$ and the part of $T_i$ that contains only symbols $\{1, \ldots, i + 1\}$ is equal to the corresponding part of $U$.

3. Suppose case (S) holds in $T_{i-1}$ but case (D) holds in $U$. Let $C(T_{i-1}) = st$, where $s$ is the column reading of $T_{i-1}$ up to and including the whole of the column containing the rightmost symbol $i$, and $t$ is the column reading of $T_{i-1}$ from (the whole of) the column containing the leftmost symbol $i + 1$. Let $T_i = P_{\text{hypo}}(ts)$; then $T_{i-1} \sim T_i$.

Notice that $s$ contains all the symbols $\{1, \ldots, i\}$ in the word $st$. Applying Lemma 5.4 twice, one therefore sees that for any $j < i$, the symbols $j$ and $j + 1$ are on different rows of $T_{i-1}$ if and only if $s$ contains a $(j + 1, j)$-inversion, which is true if and only if $j$ and $j + 1$ are on different rows of $T_i$. Thus the parts of $T_{i-1}$ and $T_i$ (and thus, by the induction hypothesis, $U$) that contain only symbols from $\{1, \ldots, i\}$ are equal. Furthermore, $ts$ also contains an $(i + 1, i)$-inversion, since $t$ contains at least one symbol $i + 1$ and $s$ contains at least one symbol $i$, and so by Lemma 5.4 the symbols $i$ and $i + 1$ are on different rows of $T_i$. Hence the parts of $T_i$ and $U$ that contain symbols from $\{1, \ldots, i + 1\}$ are equal.

4. Suppose case (D) holds in $T_{i-1}$ but case (S) holds in $U$. Let $R(T_{i-1}) = st$, where $s$ is the row reading of $T_{i-1}$ up to and including the whole of the row containing the symbols $i + 1$, and $t$ is the row reading of $T_{i-1}$ from (the whole of) the row containing the symbols $i$. Let $T_i = P_{\text{hypo}}(ts)$; then $T_{i-1} \sim T_i$.

Notice that $t$ contains all the symbols $\{1, \ldots, i\}$ in the word $st$. Applying Lemma 5.4 twice, one therefore sees that for any $j < i$, the symbols $j$ and $j + 1$ are on different rows of $T_{i-1}$ if and only if
$t$ contains a $(j + 1, j)$-inversion, which is true if and only if $j$ and $j + 1$ are on different rows of $T_i$. Thus the parts of $T_{i-1}$ and $T_i$ (and thus, by the induction hypothesis, $U$) that contain only symbols from \{1, \ldots, i\} are equal. Furthermore, $ts$ does not contains an $(i + 1, i)$ inversion, since $t$ contains all the symbols $i$ and $s$ contains all the symbols $i + 1$, and so by Lemma 5.4 the symbols $i$ and $i + 1$ are on the same row of $T_i$. Hence the parts of $T_i$ and $U$ that contain symbols from \{1, \ldots, i + 1\} are equal.

By induction, the parts of the quasi-ribbon tableaux $T_{n-1}$ and $U$ that contain symbols from \{1, \ldots, n\} are equal. That is, $T_{n-1} = U$. Therefore $T$ and $U$ are a distance at most $n - 1$ apart. \hfill \Box

Combining Lemmata 5.6 and 5.3 gives the following result:

**Theorem 5.7.**

1. Connected components of $K(\text{hypo})$ coincide with $\equiv_{ev}$-classes of hypo.
2. The maximum diameter of a connected component of $K(\text{hypo}_n)$ is $n - 1$.

The following example illustrates how the construction in the proof of Lemma 5.6

**Example 5.8.** Consider the following elements of hypo$_5$:

$$T = \begin{array}{cccc}
1 & 2 & 3 \\
4 & 4 & 5
\end{array} \quad \text{and} \quad U = \begin{array}{cccc}
1 & 2 \\
3 & 4 & 4 & 5
\end{array}$$

Then $T$ and $U$ have the same evaluation, and so lie in the same connected component of $K(\text{hypo})$ by Theorem 5.7(1) and the distance between them is at most 4 by Theorem 5.7(2). The connected component $K(\text{hypo}_5, T)$ is shown in Figure 2 and the construction in the proof of Lemma 5.6 yields the following path between $T$ and $U$:

$$T = T_0 = \begin{array}{cccc}
1 & 2 & 3 \\
4 & 4 & 5
\end{array} \equiv_{\text{hypo}} \begin{array}{cccc}
2 & 3 \\
4 & 4 & 5
\end{array} \circ \begin{array}{c}
1 \sim 1
\end{array} \equiv_{\text{hypo}} \begin{array}{cccc}
2 & 3 \\
4 & 4 & 5
\end{array} \circ \begin{array}{c}
1 \sim 1
\end{array}$$

\[\text{(case 4)}\]

$$\equiv_{\text{hypo}} T_1 = \begin{array}{cccc}
1 & 2 & 3 \\
4 & 4 & 5
\end{array} \equiv_{\text{hypo}} \begin{array}{cccc}
1 & 2 \\
3 & 4 & 4 & 5
\end{array} \sim \begin{array}{c}
3
\end{array} \equiv_{\text{hypo}} \begin{array}{cccc}
1 & 2 \\
3 & 4 & 4 & 5
\end{array} \circ \begin{array}{c}
1 \sim 1
\end{array}$$

\[\text{(case 3)}\]

$$\equiv_{\text{hypo}} T_2 = \begin{array}{cccc}
1 & 2 \\
3 & 4 & 4 & 5
\end{array} \equiv_{\text{hypo}} \begin{array}{cccc}
4 & 4 & 5 \\
1 & 2 & 3
\end{array} \sim \begin{array}{cccc}
1 & 2 \\
3 & 4 & 4 & 5
\end{array} \equiv_{\text{hypo}} \begin{array}{cccc}
4 & 4 & 5 \\
1 & 2 & 3
\end{array} \circ \begin{array}{c}
1 \sim 1
\end{array}$$

\[\text{(case 4)}\]
The connected component $K(\text{hypo}_5, P_{\text{hypo}}(123445))$. Note that its diameter is 4.

\[ \equiv_{\text{hypo}} T_3 = \begin{array}{cccc} 1 & 2 \\ 3 & 4 & 4 & 5 \end{array} \]

\[ \equiv_{\text{hypo}} T_4 = \begin{array}{cccc} 1 & 2 \\ 3 & 4 & 4 & 5 \end{array} \]

\( \sim \)

\[ \begin{array}{cccc} 1 & 2 \\ 3 & 4 & 4 \end{array} \]

\[ \begin{array}{cccc} 1 & 2 \\ 3 & 4 & 4 \end{array} \]

This gives a path of length 4 between $T$ and $U$ in $K(\text{hypo}_5)$. 
Notice, however, that $T$ and $U$ are actually a distance 1 apart in $K(\text{hypo}_5)$:

\[
T = \begin{array}{c}
1 \\
2 \\
3 \\
4 \\
5 \\
\end{array} \equiv_{\text{hypo}} \begin{array}{c}
2 \\
4 \\
4 \\
5 \\
\end{array} \circ \begin{array}{c}
1 \\
3 \\
5 \\
\end{array} \sim \begin{array}{c}
1 \\
2 \\
4 \\
4 \\
\end{array} \equiv_{\text{hypo}} \begin{array}{c}
1 \\
2 \\
3 \\
4 \\
5 \\
\end{array} = U.
\]

6. Sylvester monoid

6.1. Preliminaries. Only the necessary facts about the sylvester monoid are recalled here; see [HNT05] for further background.

A (right strict) binary search tree is a labelled rooted binary tree where the label of each node is greater than or equal to the label of every node in its left subtree, and strictly less than every node in its right subtree. An example of a binary search tree is:

(6.1)

The left-to-right postfix traversal, or simply the postfix traversal, of a rooted binary tree $T$ is the sequence that ‘visits’ every node in the tree as follows: it recursively perform the postfix traversal of the left subtree of the root of $T$, then recursively perform the postfix traversal of the right subtree of the root of $T$, then visits the root of $T$. Thus the postfix traversal of any binary tree with the same shape as the (6.1) visits nodes as follows:

(6.2)

The insertion algorithm for binary search trees adds the new symbol as a leaf node in the unique place that maintains the property of being a binary search tree:

**Algorithm 6.1** (Right strict leaf insertion).

Input: A binary search tree $T$ and a symbol $a \in A$.

Output: A binary search tree $a \rightarrow T$.

Method: If $T$ is empty, create a node and label it $a$. If $T$ is non-empty, examine the label $x$ of the root node; if $a \leq x$, recursively insert $a$ into the left subtree of the root node; otherwise recursively insert $a$ into the right subtree of the root note. Output the resulting tree.

Thus one can compute, for any word $u \in A^*$, a binary search tree $P_{\text{sylv}}(u)$ by starting with an empty binary search tree and successively inserting the symbols of $u$, proceeding right-to-left through the word. For example $P_{\text{sylv}}(5451761524)$ is (6.1).
A *reading* of a binary search tree $T$ is a word $u$ such that $\text{Psylv}(u) = T$. It is easy to see that a reading of $T$ is a word formed from the symbols that appear in the nodes of $T$, arranged so that every symbol from a parent node appears to the right of those from its children. For example, 1571456254 is a reading of (6.1).

Define the relation $\equiv_{\text{sylv}}$ by

$$u \equiv_{\text{sylv}} v \iff \text{Psylv}(u) = \text{Psylv}(v).$$

for all $u, v \in \mathcal{A}^*$. The relation $\equiv_{\text{sylv}}$ is a congruence, and the *sylvestre monoid*, denoted $\text{sylv}$, is the factor monoid $\mathcal{A}^*/\equiv_{\text{sylv}}$; the *sylvestre monoid of rank* $n$, denoted $\text{sylv}_n$, is the factor monoid $\mathcal{A}^*_n/\equiv_{\text{sylv}}$ (with the natural restriction of $\equiv_{\text{sylv}}$). Each element $[u]_{\equiv_{\text{sylv}}}$ (where $u \in \mathcal{A}^*$) can be identified with the binary search tree $\text{Psylv}(u)$. The words in $[u]_{\equiv_{\text{sylv}}}$ are precisely the readings of $\text{Psylv}(u)$.

The monoid $\text{sylv}$ is presented by $\langle \mathcal{A} \mid R_{\text{sylv}} \rangle$, where

$$R_{\text{sylv}} = \{ (cavb, acvb) : a \leq b < c, \ v \in \mathcal{A}^* \};$$

**Figure 3.** The connected component $K(\text{sylv}_4, \text{Psylv}(1234))$; note that its diameter is 3.
the monoid $\text{sylv}_n$ is presented by $\langle A_n | R_{\text{sylv}} \rangle$, where the set of defining relations $R_{\text{sylv}}$ is naturally restricted to $A_n^* \times A_n^*$. Notice that $\text{sylv}$ and $\text{sylv}_n$ are multihomogeneous.

The present authors proved that the relations $\equiv_{\text{ev}}$ and $\sim^*$ coincide in $\text{sylv}$ [CM15, Theorem 3.4]. In the terms of this paper, this proves that connected components of $K(\text{sylv})$ are $\equiv_{\text{ev}}$-classes. The aim in this section is to prove that connected components of $K(\text{sylv}_n)$ have diameter at most $n$.

### 6.2. Lower bound for diameters

As in the cases of the plactic and hypoplactic monoids, cocharge sequences are the key to proving that there is a connected component of $K(\text{sylv}_n)$ with diameter at least $n - 1$. Reasoning similar to the proofs of [Propositions 4.2 and 5.2](#) establishes the following result:

**Proposition 6.2.** Let $u, v \in A^*$ be standard words such that $u \equiv \text{sylv} v$. Then $\text{cochseq}(u) = \text{cochseq}(v)$.

For any standard binary tree $T$ in $\text{sylv}$, define $\text{cochseq}(T)$ to be $\text{cochseq}(u)$ for any standard word $u \in A^*$ such that $T = P_{\text{sylv}}(u)$. By Proposition 6.2, $\text{cochseq}(T)$ is well-defined.

**Lemma 6.3.** There is a connected component in $K(\text{sylv}_n)$ of diameter at least $n - 1$.

**Proof.** The strategy is the same as in the plactic and hypoplactic monoids: let $t = 12 \cdots (n - 1)n$ and $u = n(n-1) \cdots 21$, and let

$$T = P_{\text{sylv}}(t) = \begin{array}{c}
1 \\
2 \\
n-1 \\
n
\end{array} \quad \text{and} \quad U = P_{\text{sylv}}(u) = \begin{array}{c}
1 \\
2 \\
n-1 \\
n
\end{array}$$

The same reasoning as in the proof of Proposition 4.3 shows that $T$ and $U$ are not related by $\sim^{\leq n-2}$ in $\text{sylv}_n$.

### 6.3. Upper bound for diameters I: Overview

The proof that every connected component of $K(\text{sylv}_n)$ has diameter at most $n$ is long and complicated. To illustrate the strategy, Example 6.4 explicitly constructs a path of length 5 between two elements of $K(\text{sylv}_5)$ that have the same evaluation. Note, however, that these elements are standard, and much of the complexity of the general proof is due to having to consider multiple appearances of each symbol.

**Example 6.4.** Let $T$ and $U$ be the following elements of $\text{sylv}_5$:

$$T = \begin{array}{c}
1 \\
2 \\
3 \\
4 \\
5 \\
\end{array}, \quad U = \begin{array}{c}
1 \\
2 \\
3 \\
4 \\
5 \\
\end{array} \in \text{sylv}_5$$
Notice that $T \equiv_{ev} U$. The aim is to build a sequence $T = T_0 \sim T_1 \sim T_2 \sim T_3 \sim T_4 \sim T_5 = U$. The strategy is build the path based upon a left-to-right postfix traversal of $U$. At any point in such a traversal, the set of vertices already encountered is a union of subtrees of $U$. By applying an appropriate cyclic shift to obtain $T_{i+1}$ from $T_i$ (for each $i$), one gradually builds copies of these subtrees within the $T_i$, arranged down the path of left child nodes descending from the root, with the ‘just completed’ subtree at the root itself. In the example construction below, the left-hand column shows the $i$-th tree built so far, and the next column shows the $i$-th step of the left-to-right postfix traversal. The subtrees of $U$ containing the vertices encountered up to the $i$-th step are outlined, as are the corresponding vertices in the tree $T_i$. Note that cyclic shifts never break up the subwords (outlined) that represent the already-built subtrees.

$$T = T_0 = \text{psylv}(13254) \sim \text{psylv}(54132)$$

One cyclic shift moves the first node visited by the traversal to the root. This will be the base of the induction in the proof.

$$= T_1 = \begin{array}{c}
\text{2} \\
\text{1} \\
\text{3} \\
\text{4} \\
\text{5}
\end{array} \sim \begin{array}{c}
\text{1} \\
\text{4} \\
\text{5} \\
\text{3}
\end{array}$$

The postfix traversal moves from a left child directly to its parent (which has empty right subtree). This will be the induction step, case 3.

$$= \text{psylv}(54312) \sim \text{psylv}(12543)$$

$$= T_2 = \begin{array}{c}
\text{3} \\
\text{2} \\
\text{4} \\
\text{5} \\
\text{1}
\end{array}$$

The postfix traversal moves from a left child to a node in the right subtree of its parent. This will be the induction step, case 1.

$$= \text{psylv}(54123) \sim \text{psylv}(41235)$$

$$= T_3 = \begin{array}{c}
\text{5} \\
\text{3} \\
\text{4} \\
\text{1} \\
\text{2}
\end{array}$$

The postfix traversal moves from a right child to a parent whose left subtree is non-empty. This will be the induction step, case 2.

$$= \text{psylv}(41235) \sim \text{psylv}(12354)$$

$$= T_4 = \begin{array}{c}
\text{2} \\
\text{4} \\
\text{5} \\
\text{3} \\
\text{1}
\end{array}$$

The postfix traversal moves from a right child to a parent whose left subtree is empty. This will be the induction step, case 4.

$$= \text{psylv}(12354) \sim \text{psylv}(23541)$$

$$= T_5 = \begin{array}{c}
\text{1} \\
\text{4} \\
\text{3} \\
\text{2} \\
\text{5}
\end{array}$$

Before beginning the proof, it is necessary to set up some terminology and conventions for diagrams of binary search trees. For brevity, write ‘the
node $x$' instead of ‘the node labelled by $x$’ and ‘the (sub)tree $\alpha$’ instead of ‘the (sub)tree with reading $\alpha$’. However, equalities and inequalities always refer to comparisons of labels: for example, $x = y$ means that the nodes $x$ and $y$ have equal labels, not that they are the same node.

Let $x$ and $y$ be nodes of a binary tree. If $x$ is a descendent of $y$, then $x$ is below $y$ and $y$ is above $x$. (Note that the terms ‘above’ and ‘below’ do not refer to levels of the tree: the right child of the root is not above any node in the left subtree.) Let $v$ be the lowest common ancestor of $x$ and $y$. If $x$ is in the left subtree of $v$ or is $v$ itself, and $y$ is in the right subtree of $v$ or is $v$ itself, and $x$ and $y$ are not both $v$, then $x$ is to the left of $y$, and $y$ is to the right of $x$. Note that if $x$ is to the left of $y$, then $x$ is less than or equal to $y$.

Note that it important to distinguish directional terms like ‘above’ and ‘below’ from order terms like ‘less than’ and ‘greater than’. The former refer to the position of nodes within the tree, whereas the latter refer to the order of symbols in the alphabet $\mathcal{A}$.

As used in this section, a subtree of a binary search tree will always be a rooted subtree. The complete subtree at a node $x$ is the entire tree below and including $x$. Given a subtree $T'$ of a tree $T$, the left-minimal subtree of $T'$ in $T$ is the complete subtree at the left child of the left-most node in $T'$; the right-maximal subtree of $T'$ in $T$ is the complete subtree at the right child of the right-most node in $T'$. A node $x$ is topmost if it is above all other nodes labelled $x$. The path of left child nodes (respectively, path of right child nodes) from a node $x$ is the path obtained by starting at the $x$ and entering left (respectively, right) child nodes until a node with no left (respectively, right) child is encountered.

In diagrams, individual nodes are shown as round, while subtrees as shown as triangles. An edge emerging from the top of a triangle is the edge running from the root of that subtree to its parent. A vertical edge joining a node to its parent indicates that the node may be either a left or right child. An edge emerging from the bottom-left of a triangle is the edge to its left-minimal subtree; an edge emerging from the bottom-right of a triangle is the edge to its right-maximal subtree. For example, consider the following diagram:

![Diagram](image)

(6.3)

this shows a tree with root node $x$. Its left subtree consists of the subtree $\lambda$ and a single node $z$ (which may be a left or right child) whose parent is some node in the subtree $\lambda$. The right subtree of $x$ consists of subtrees with readings $\rho$, $\sigma$, and $\tau$, with $\sigma$ being the left-minimal subtree of $\rho$ and $\tau$ being the right-maximal subtree of $\rho$. Note that the tree $\rho$ may be deeper than $\sigma$ or $\tau$, in the sense that the paths leading to its lowest nodes may longer than the paths to the lowest nodes in $\sigma$ or $\tau$.

The strategy in the proof of Proposition 6.12 below is to pick $T, U \in \text{sylv}_n$ such that $T \cong_{ev} U$ and construct a path of length $n$ from $T$ to $U$ by using a left-to-right postfix traversal of $U$. Specifically, one considers only the $n$
steps in the left to right postfix traversal that visit the topmost node labelled by each symbol. (There is a unique topmost node labelled by each symbol by Lemma 6.6 below.) Just as in Example 6.4 if the node of \( U \) visited at the \( h \)-th step of the traversal has label \( x \), then the \( h \)-th cyclic shift in this path moves a node \( x \) in the \( h - 1 \)-th tree in the path to become the root of the tree \( h \)-th tree. However, the situation is more complicated because there are other nodes with the same label, and these may be distributed very differently in \( T \) and \( U \). For example, the following two binary search trees have the same evaluation, but nodes with the same labels are distributed differently:

6.4. Upper bound for diameters II: Properties of trees. This section gathers some properties of trees, and in particular properties of how nodes with the same label are arranged in binary search trees. These properties are mostly technical but simple to prove.

The left-to-right infix traversal (or simply the infix traversal) of a rooted binary tree \( T \) is the sequence that ‘visits’ every node in the tree as follows: it recursively performs the infix traversal of the left subtree of the root of \( T \), then visits the root of \( T \), then recursively performs the infix traversal of the right subtree of the root of \( T \). Thus the infix traversal of any binary tree with the same shape as the right-hand tree in (6.1) visits nodes as follows:

The following result is immediate from the definition of a binary search tree, but it is used frequently:

**Proposition 6.5.** For any binary search tree \( T \), if a node \( x \) is encountered before a node \( y \) in an infix traversal, then \( x \leq y \).

Let \( U \) be a binary search tree and let \( a \in \mathcal{A} \) be a symbol that appears in \( U \).

**Lemma 6.6.** Every node \( a \) appears on a single path descending from the root to a leaf; thus there is a unique topmost node \( a \).

**Proof.** Suppose the node \( a \) appeared on two different paths. Let \( v \) be the least common ancestor of two such appearances. Then \( a \) is in both the left and right subtrees of \( v \), and so \( a \leq v < a \) by the definition of a binary search tree, which is a contradiction. \( \square \)
Lemma 6.7. If a node $a$ has a non-empty right subtree, it is the topmost node $a$.

Proof. Suppose a particular node $a$ has a non-empty right subtree; let $b$ be a symbol in this subtree. Then $a < b$, since $b$ is in the right subtree of $a$. If this node $a$ is not the topmost node $a$, then $b$ is also in the left subtree of the topmost node $a$ (since the distinguished node $a$ must be in the left subtree of the topmost $a$); hence $b \leq a$, which is a contradiction. Thus this node $a$ must be topmost. □

Lemma 6.8. Let $x$ be a left child of a parent node $z$. Then the symbol $z$ is the least symbol in the tree $U$ greater than or equal to every node in the complete subtree at $x$. Furthermore, if $x$ is not topmost, then $x = z$.

Proof. In the infix traversal of $U$, the node $z$ is the first node visited after visiting all the nodes in the complete subtree at $x$. Since the infix traversal visit nodes in weakly increasing order, $z$ is certainly the least symbol greater than or equal to every node in the complete subtree at $x$. Suppose further $x$ is not topmost. Then its right subtree is empty and so $z$ is visited immediately after $x$. Since the topmost node $x$ is visited at some later point, and since nodes are visited in weakly increasing order, $x \leq z \leq x$ and so $x = z$. □

Lemma 6.9. Suppose $z$ is not a topmost node. Then it is a left child if and only if its parent is another node $z$.

Proof. If $z$ is a left child, then its parent is another node $z$ by Lemma 6.8. If the parent of $z$ is another node $z$, then the child node must be a left child by the definition of a binary search tree. □

Lemma 6.10. Suppose $x$ is a node and let $y$ be a symbol such that $y \leq x$ and $y$ labels some node in the complete subtree at $x$. Then the topmost node $y$ is also in the complete subtree at $x$.

Proof. The result holds trivially if $y = x$, so suppose $y < x$. Then the node $y$ is in the left subtree of $x$ and the infix traversal visits the node $y$ in the complete subtree at $x$ before it visits $x$ itself. Since the infix traversal visits nodes in weakly increasing order, it must visit the topmost node $y$ before visiting any node $x$. Hence the topmost node $y$ must also be in the left subtree of $x$. □

Lemma 6.11. Suppose $x$ is a topmost node and its right child $z$ is not a topmost node. Then $z$ is the least symbol that is greater than every topmost node in the complete subtree at $x$.

Proof. Since the node $z$ is not topmost, its right subtree is empty. Thus it is the maximum symbol in the complete subtree rooted at $x$. For any node $y$ in the left subtree of $x$, the topmost node $y$ is also in the left subtree of $x$ by Lemma 6.10. For any node $y'$ in the left subtree of $z$, the topmost node $y'$ is also in the left subtree of $z$ by Lemma 6.10. So $z$ is greater than every topmost node in the complete subtree at $x$. Since the symbols labelling these topmost nodes are the ones visited by the infix traversal immediately before it visits nodes labelled by $z$, it follows that $z$ is the least symbol that is greater than every topmost node in the complete subtree at $x$. □
These results give information about how repeated symbols can appear in a binary search tree. Consider a symbol $z$ that appears more than once in $U$. If one chooses a node $z$, then one of the following holds:

- the node $z$ is topmost;
- the node $z$ is not a topmost node, and is the left child of another node $z$ (by Lemma 6.9);
- the node $z$ is not a topmost node, and the right child of a topmost node $x$, and $z$ is the least symbol greater than every topmost node in the complete subtree at $x$ (by Lemma 6.11).

For example, consider the following binary search tree and the repeated symbol 5:

```
                     5
                    / \
                   2   5
                  / \  / \
                 4   5 5 5
                /   /   /   /
               5   5   5   5
```

The primary nodes $a$ are those nodes labelled by $a$ that are consecutive with the topmost node $a$, including the topmost node itself; in (6.5) there are two primary nodes 5. Any node $a$ that has no children, and any node $a$ consecutive with it, provided they are not primary, are the tertiary nodes $a$; in (6.5) there are three tertiary nodes 5. All other nodes $a$ are secondary. Note that in each group of consecutive secondary nodes $a$, the uppermost node is a right child of some non-$a$ node, and the lowermost node has as its left child another non-$a$ node. (Secondary and tertiary nodes always have empty right subtrees, since they are never topmost.) In (6.5), there is one secondary node 5.

In constructing a path of length $n$ from $T$ to $U$, the $h$-th cyclic shift, corresponding to visiting a topmost node $y$ of $U$, will move a node $y$ of $T_{h-1}$ to form the root of $T_h$, and must simultaneously deal with any secondary nodes $z$ that are attached at the right child of $y$ in $U$. Tertiary nodes $z$ either fall into place naturally or are dealt with during the cyclic shift that moves $z$ to the root. The difficulty is in proving that there always exists a cyclic shift that performs these tasks. This is the reason for the slightly complicated conditions that form the inductive statement in the proof of Proposition 6.12 below.

6.5. Upper bound for diameters III: Result. This subsection is dedicated entirely to Proposition 6.12 and its proof. Extensive use will be made of the concepts and results in Subsections 6.3 and 6.4.

**Proposition 6.12.** The diameter of any connected component of $K(\text{sylv}_n)$ is at most $n$.

**Proof.** Let $T$ and $U$ be in the same connected component of $K(\text{sylv}_n)$. Then $T \equiv_{ev} U$ and so $T$ and $U$ contain the same number of nodes labelled by
each symbol. Without loss of generality, assume that every symbol in $A_n$ appears in $T$ and $U$.

**Preliminaries.** Consider the left-to-right postfix traversal of $U$. Modify this traversal so that it only visits topmost nodes; for the purposes of this proof, call this the topmost traversal. Since $U$ contains every symbol in $A_n$, there are exactly $n$ steps in this traversal. Let $u_i$ be the $i$-th node visited in this modified traversal.

For $h = 1, \ldots, n$, define $U_h = \{u_1, \ldots, u_h\}$ and let $U_h^\uparrow$ be the set of nodes in $U_h$ that do not lie below any other node in $U_h$. Since a later step in a left-to-right postfix traversal is never below an earlier step, $u_h \in U_h^\uparrow$ for all $h$. (The set $U_h^\uparrow$ will turn out to be the roots of the complete subtrees that have been ‘built’ in $T_h$.)

Let $B_h$ be the complete subtree of $U$ at $u_h$; see Figure 4 for an example of this and later definitions.

Define $m_h$ to be the minimum symbol in $B_h$; thus $m_h$ is the minimum symbol below and including the node $u_h$ in $U$. Note that the topmost node $m_h$ is in the subtree $B_h$ by [Lemma 6.10] and must (by minimality) be on the path of left child nodes from $u_h$.

Define $q_h$ to be the minimum symbol that is greater than every topmost node in $B_h$, with $q_h$ undefined if there is no such symbol. Note that $q_h$ can be found by following the path from $u_h$ to the root: $q_h$ will be symbol labelling the first node entered from a left child, because this node is the node visited by the infix traversal of $U$ immediately after the nodes in the subtree $B_h$ have been visited. In particular, $q_h$ is defined precisely when $u_h$ does not lie on the path of right child nodes from the root of $U$.

Define $p_h$ to be the maximum symbol that is less than every symbol in $B_h$, with $p_h$ undefined if there is no such symbol. Note that $p_h$ can be found by following the path from $u_h$ to the root: $p_h$ will be the symbol labelling the first node entered from a right child, because this node is the node visited by the infix traversal of $U$ immediately before visiting nodes in the subtree $B_h$. (This process always locates the topmost node $p_h$, since it has a non-empty right subtree.) In particular, $p_h$ is defined precisely when $u_h$ does not lie on the path of left child nodes from the root of $U$.

Note that $p_h < x \leq q_h$ for all symbols $x$ in $B_h$, ignoring the inequalities involving $p_h$ or $q_h$ when these are undefined. Note that the symbol $q_h$ may appear in $B_h$, labelling a secondary or tertiary node. In particular, $p_h < m_h \leq u_h < q_h$, since $u_h$ is a topmost symbol.

Define $C_h$ to the the tree obtained from $B_h$ by deleting all nodes $m_h$ except the topmost. (Note that this leaves no ‘orphaned’ subtrees, since only the topmost $m_h$ can have a right subtree, and the bottommost $m_h$ has empty left subtree by the minimality of $m_h$.)

Define $D_h$ to be the tree obtained from $C_h$ by deleting any tertiary nodes $q_h$ from $C_h$.

If $D_h$ contains no node $q_h$, define $E_h = D_h$. If $D_h$ contains a node $q_h$, define $E_h$ to be the tree obtained from $D_h$ by inserting $s$ symbols $q_h$ into $D_h$ using [Algorithm 6.1] where $s$ is the difference between the number of nodes $q_h$ in $U$ and the the number of nodes $q_h$ in $D_h$. 
Figure 4. Example tree $U$ illustrating definitions of notation. Here, $u_h$ is the topmost node 5, and thus $p_h = 1$ and $q_h = 7$. The subtree $B_h$ consists of the complete subtree at $u_h$, and the minimum symbol in this subtree is $m_h = 2$. The subtree $C_h$ is obtained from $B_h$ by deleting all nodes 2 except the topmost, and $D_h$ is obtained from $C_h$ by deleting the tertiary nodes 8. Since there is a [secondary] node 8 in $D_h$, the tree $E_h$ is obtained from $D_h$ by inserting three symbols 8 using [Algorithm 6.1] since there are three nodes 8 in the tree $U$ outside $D_h$.

Notice that the set of symbols in $E_h$ is the same as the set of symbols in $D_h$ (in either case), and is contained in the set of symbols in $C_h$ (this containment will be strict if in $C_h$ there are tertiary nodes $q_h$ but no secondary nodes $q_h$), which in turn is equal to the set of symbols in $B_h$.

Suppose $B_h$ contains a node $x$, but that $B_h$ does not contain the topmost node $x$. Then by Lemma 6.6, $B_h$ is below the topmost node $x$ and must be in its left subtree since it contains a node $x$. In following the path from $u_h$ to the root, $q_h$ labels the first node entered from a left child. Hence $q_h \leq x$. However, $x$ appears in $B_h$, so $x \leq q_h$. Hence $x = q_h$. Thus $q_h$ is the only symbol that can label a node in $B_h$ but whose corresponding topmost node lies outside $B_h$. By their definitions, the same applies to $C_h$, $D_h$, and $E_h$.

**Statement of induction.** The aim is to construct inductively a sequence $T = T_0, T_1, \ldots, T_n = U$ with $T_i \sim T_{i+1}$ for $i \in \{1, \ldots, n-1\}$. Let $h = 1, \ldots, n$ and suppose $U_h = \{u_{i_1}, \ldots, u_{i_k}\}$ (where $i_1 < \ldots < i_k = h$). Then the tree $T_h$ will satisfy the following four conditions P1–P4:

P1 The subtree $E_{i_k}$ appears at the root of $T_h$.

P2 The subtrees $E_{i_k}, \ldots, E_{i_1}$ appear, in that order, on the path of left child nodes from the root of $T_h$. (These subtrees may be separated by other nodes on the path of left child nodes.)
P3 For \( j = 1, \ldots, k \), every node below \( E_{ij} \) is in its left-minimal or right-maximal subtrees in \( T_h \).

P4 For \( j = 1, \ldots, k \), no node \( m_{ij} \) is below a node \( p_{ij} \) in \( T_h \).

(Note that conditions P1–P4 do not apply to \( T_0 = T \), which is an arbitrary element of \( \text{sylv}_n \).)

**Base of induction.** The base of the induction is to apply a cyclic shift to \( T_0 \) and obtain a tree \( T_1 \) that satisfies conditions P1–P4.

Note first that \( U_1 = U_1 = \{ u_1 \} \). By the definition of the topmost traversal, there can be no topmost nodes below \( u_1 \) in \( U \). Since \( m_1 \leq u_1 \), the topmost node \( m_1 \) is in \( B_1 \), and thus \( m_1 = u_1 \). Thus \( B_1 \) consists only of symbols \( u_1 \) and possibly tertiary nodes \( q_1 \). Thus \( C_1 \) consists only of the topmost node \( m_1 = u_1 \) and possibly tertiary nodes \( q_1 \), and so \( D_1 \) consists only of the single node \( u_1 \). Thus \( E_1 = D_1 \) since \( D_1 \) does not contain a symbol \( q_1 \).

There are two cases to consider:

**Case 1.** Suppose that there is some node with label \( u_1 \) below some node with label \( p_1 \) in \( T_0 \). (Note that this case can only hold when \( p_1 \) is defined, or, equivalently, if \( u_1 \) is not on the path of left child nodes from the root of \( U \).)

In \( T_0 \), distinguish the uppermost node with label \( u_1 \) that lies below some node with label \( p_1 \). (Note that although \( u_1 \) and \( p_1 \) are defined in terms of the tree \( U \), here they are used to pick out nodes with the same labels in the tree \( T_0 \).) Since \( p_1 < u_1 \), this node \( u_1 \) must be in the right subtree of the node \( p_1 \). Thus this node \( p_1 \) must be a topmost node since it has non-empty right subtree. As shown in Figure 5, let \( \zeta \) be a reading of the part of \( T_0 \) outside the complete subtree at the topmost node \( p_1 \), let \( \alpha \) be a reading of the left subtree of the topmost node \( p_1 \), let \( \delta \) be a reading of the right subtree of the topmost node \( p_1 \) outside the complete subtree at the distinguished node \( u_1 \), and let \( \beta \) and \( \gamma \) be readings of the left and right subtrees of this node \( u_1 \). All nodes \( p_1 \) other than the distinguished topmost node \( p_1 \) must be in \( \alpha \). There are no nodes \( u_1 \) in \( \delta \), by the choice of the distinguished node \( u_1 \). It is possible that there may be nodes \( u_1 \) in \( \beta \) or in \( \gamma \). (If there is a node \( u_1 \) in \( \zeta \), then the distinguished node \( u_1 \) is not topmost and so \( \gamma \) is empty.)

Thus \( T_0 = P_{\text{sylv}}(\beta\gamma u_1 \delta \alpha p_1 \zeta) \). Let \( T_1 = P_{\text{sylv}}(\delta \alpha p_1 \zeta \beta \gamma u_1) \); note that \( T_0 \sim T_1 \).

In computing \( T_1 \), the symbol \( u_1 \) is inserted first and becomes the root node. Since other symbols \( u_1 \) can only appear in \( \beta \) and \( \zeta \), and other symbols \( p_1 \) can only appear in \( \alpha \), all symbols \( m_1 = u_1 \) are inserted before symbols \( p_1 \). Thus there is no node \( m_1 \) below a node \( p_1 \); thus \( T_1 \) satisfies P4. Since \( E_1 \) consists only of a node \( u_1 \), the tree \( E_1 \) appears at the root of \( T_1 \) and so \( T_1 \) satisfies P1 and P2. Furthermore, every node below \( E_1 \) is either in the left-minimal subtree of \( E_1 \) (that is, the left subtree of the root node \( u_1 \)) or the right-maximal subtree of \( E_1 \) (that is, right subtree of \( u_1 \)), and so \( T_1 \) satisfies P3.

**Case 2.** Suppose that no node labelled \( u_1 \) lies below a node with label \( p_1 \) in \( T_0 \). (This case always holds when \( p_1 \) is undefined.)
Distinguish the topmost node $u_1$ in $T_0$. As shown in Figure 6, let $\zeta$ be a reading of the part of $T_0$ outside the complete subtree at the topmost node $u_1$. Since no node $u_1$ lies below a node $p_1$, there exists a reading $\beta$ of the left subtree of the topmost node $u_1$ in which all symbols $p_1$ appear before all symbols $u_1$. Let $\gamma$ be a reading of the right subtree of the topmost node $u_1$. Thus $T_0 = P_{\text{syll}}(\beta \gamma u_1 \delta \alpha p_1 \zeta)$. Let $T_1 = P_{\text{syll}}(\delta \alpha p_1 \zeta \gamma u_1)$; note that $T_0 \sim T_1$.

In computing $T_1$, the symbol $u_1$ is inserted first and becomes the root node. Since other symbols $u_1$ must appear after symbols $p_1$ in $\beta$, all symbols $m_1 = u_1$ are inserted before symbols $p_1$. Thus there is no node $m_1$ below a node $p_1$; thus $T_1$ satisfies P4. Since $E_1$ consists only of a node $u_1$, the tree $T_1$ satisfies P1–P3 by the same reasoning as in Case 1.

This completes the base of the induction: the tree $T_1$ satisfies P1–P4 and $T_0 \sim T_1$.

**Induction step.** Let $h \in \{1, \ldots, n - 1\}$ and suppose that $U^h_1 = \{u_1, \ldots, u_h\}$ (where $i_1 < \ldots < i_k$). Recall that $h = i_k$; for brevity, let $q = i_{k-1}$. Suppose that the tree $T_h$ satisfies conditions P1–P4. The aim is to apply a cyclic shift to $T_h$ and obtain a tree $T_{h+1}$ that satisfies conditions P1–P4.

There are four cases, depending on the relatives positions of $u_h$ and $u_{h+1}$ in $U$:
(1) $u_h$ is in the left subtree of $v$ and $u_{h+1}$ is in the right subtree of $v$, where $v$ is the lowest common ancestor of $u_h$ and $u_{h+1}$ in $U$;
(2) $u_h$ is in the left subtree of $u_{h+1}$;
(3) $u_h$ is in the right subtree of $u_{h+1}$, and there is no node $u_i$ in the left subtree of $u_{h+1}$;
(4) $u_h$ is in the right subtree of $u_{h+1}$, and there is some node $u_i$ in the left subtree of $u_{h+1}$.

Case 1. Suppose that, in $U$, the node $u_h$ is in the left subtree of $v$ and $u_{h+1}$ is in the right subtree of $v$, where $v$ is the lowest common ancestor of $u_h$ and $u_{h+1}$ in $U$.

In this case, $U_{h+1} = U_h \cup \{u_{h+1}\}$. By the definition of the topmost traversal, there are no topmost nodes below $u_{h+1}$ in $U$. Since $m_{h+1} \leq u_{h+1}$, the topmost node $m_{h+1}$ is in $B_{h+1}$ by Lemma 6.10 and thus $m_{h+1} = u_{h+1}$. Thus $B_{h+1}$ consists only of symbols $u_{h+1}$ and possibly tertiary nodes $q_{h+1}$. Thus $C_{h+1}$ consists only of the topmost node $m_{h+1} = u_{h+1}$ and possibly tertiary nodes $q_{h+1}$, and so $D_{h+1}$ consists only of the single node $u_{h+1}$. Thus $E_{h+1} = D_{h+1}$ since $D_{h+1}$ does not contain a symbol $q_{h+1}$.

There are two sub-cases:

Sub-case 1(a). Suppose that there is some node labelled $u_{h+1}$ below some node with label $p_{h+1}$ in $T_h$ and that $q_h \neq p_{h+1}$.

Since $u_{h+1}$ is in the right subtree of $v$, the symbol $p_{h+1}$ is greater than or equal to $v$. The symbol $v$ is greater than or equal to every symbol in $B_h$. It is impossible that $p_{h+1}$ is equal to some symbol in $B_h$, since this would require $p_{h+1} = v = q_h$, which is excluded from this sub-case. Hence $p_{h+1}$ is strictly greater than every symbol in $B_h$ and thus in $E_h$.

The tree $E_h$ appears at the root of $T_h$ by P1. Since $p_{h+1}$ is strictly greater than every symbol in $E_h$, every symbol $p_{h+1}$ must be in the right-maximal subtree of $E_h$ in $T_h$ by P3. Distinguish the uppermost node $u_{h+1}$ that lies below some node $p_{h+1}$: since $p_{h+1} < u_{h+1}$, this node $u_{h+1}$ must be in the right subtree of the node $p_{h+1}$. Thus this node $p_{h+1}$ must be a topmost node since it has non-empty right subtree.

As shown in Figure 7, let $\gamma$ be a reading of the left-minimal subtree of $E_h$, note that $\gamma$ contains all the subtrees $E_i$ by P2. Let $\gamma$ be a reading of the right-maximal subtree of $E_h$ outside the complete subtree at the topmost node $p_{h+1}$, let $\alpha$ be a reading of the left subtree of the topmost node $p_{h+1}$, let $\delta$ be a reading of the right subtree of the topmost node $p_{h+1}$ outside the complete subtree at the distinguished node $u_{h+1}$, and let $\beta$ and $\gamma$ be readings of the left and right subtrees of this node $u_{h+1}$. All other nodes $p_{h+1}$ must be in $\alpha$. There are no nodes $u_{h+1}$ in $\delta$, by the choice of the distinguished node $u_{h+1}$. It is possible that there may be nodes $u_{h+1}$ in $\beta$ or in $\gamma$. (If there is a node $u_{h+1}$ in $\gamma$, then the distinguished node $u_{h+1}$ is not topmost and so $\gamma$ is empty.)

Thus

$$T_h = P_{sylv}(\beta \gamma u_{h+1} \delta \alpha p_{h+1} \zeta \lambda E_h).$$

Let

$$T_{h+1} = P_{sylv}(\delta \alpha p_{h+1} \zeta \lambda E_h \beta \gamma u_{h+1});$$

notice that $T_h \sim T_{h+1}$. 

No \( m_{i,j} \) below \( p_{i,j} \).

Possible \( u_{h+1} \).

All other \( p_{h+1} \).

Possible \( u_{h+1} \).

\( T_h = \text{P}_{\text{syv}}(\beta\gamma u_{h+1}\delta \alpha p_{h+1}\zeta \lambda E_h) \)

\( T_{h+1} = \text{P}_{\text{syv}}(\delta \alpha p_{h+1}\zeta \lambda E_h\beta \gamma u_{h+1}) \)

**Figure 7.** Induction step, sub-case 1(a): \( E_h = D_h \) and some node \( u_{h+1} \) lies below some node \( p_{h+1} \) in \( T_h \).

In computing \( T_{h+1} \), the symbol \( u_{h+1} \) is inserted first and becomes the root node. Since other symbols \( u_{h+1} \) can only appear in \( \beta \) and \( \zeta \), all symbols \( m_{h+1} = u_{h+1} \) are inserted before symbols \( p_{h+1} \). Thus there is no node \( m_{h+1} \) below a node \( p_{h+1} \). Since \( E_{h+1} \) consists only of a node \( u_{h+1} \), the tree \( T_{h+1} \) satisfies P1. Since every symbol in the trees \( \lambda \) and \( E_h \) are strictly less than every other symbol, these trees reinserted on the path of left child nodes in the same way; hence \( T_{h+1} \) satisfies P2 since \( T_h \) does, and satisfies P4 since \( T_h \) does and since there is no node \( m_{h+1} \) below a node \( p_{h+1} \). Finally, \( T_{h+1} \) satisfies P3 because all the \( E_{i,j} \) in \( \lambda \) satisfy the condition in P3 (since \( T_h \) satisfies P3), and trivially \( E_{h+1} \) satisfies the condition in P3.

**Sub-case 1(b).** Suppose that that no node \( u_{h+1} \) lies below a node \( p_{h+1} \) in \( T_h \), or that \( p_{h+1} = q_h \).

The tree \( E_h \) appears at the root of \( T_h \) by P1. The symbol \( u_{h+1} \) is strictly greater than every symbol in \( E_h \) and so every node \( u_{h+1} \) must be in the right-maximal subtree of \( E_h \) in \( T_h \) by P3. Distinguish the topmost node \( u_{h+1} \) in \( T_h \). As shown in **Figure 8**, let \( \lambda \) be a reading of the left-minimal subtree of \( E_h \); note that \( \lambda \) contains all the subtrees \( E_{i,j} \) by P2. Let \( \zeta \) be a reading of the right-maximal subtree of \( E_h \) outside the complete subtree at the topmost node \( u_{h+1} \). Note that no symbol \( u_{h+1} \) appears in \( \zeta \). If no node \( u_{h+1} \) lies below a node \( p_{h+1} \) in \( T_h \), choose a reading \( \beta \) of the left subtree of the topmost node \( u_{h+1} \) in which all symbols \( p_{h+1} \) appear before all symbols \( u_{h+1} \). On the other hand, if \( p_{h+1} = z_h \), so that every node with this label in \( T_h \) is in the subtree \( E_h \), then fix any reading \( \beta \) of the left subtree of the topmost node \( u_{h+1} \); then \( \beta \) vacuously has the same property (since it contains no symbols \( p_{h+1} \) at all). Let \( \gamma \) be a reading of the right subtree of the topmost node \( u_{h+1} \).

Thus

\( T_h = \text{P}_{\text{syv}}(\beta\gamma u_{h+1}\zeta \lambda E_h) \).

Let

\( T_{h+1} = \text{P}_{\text{syv}}(\zeta \lambda E_h\beta \gamma u_{h+1}) \);

note that \( T_h \sim T_{h+1} \).
In computing $T_{h+1}$, the symbol $u_{h+1}$ is inserted first and becomes the root node. Since other symbols $u_{h+1}$ can only appear in $\beta$, and any symbols $u_{h+1}$ in $\beta$ must appear after symbols $p_{h+1}$, all symbols $m_{h+1} = u_{h+1}$ are inserted before symbols $p_{h+1}$. Thus there is no node $m_{h+1}$ below a node $p_{h+1}$. Since $E_{h+1}$ consists only of a node $u_{h+1}$, the tree $T_{h+1}$ satisfies P1. Since every symbol in the trees $\lambda$ and $E_h$ are strictly less than every other symbol, these trees are re-inserted on the path of left child nodes in the same way; hence $T_{h+1}$ satisfies P2 since $T_h$ does, and satisfies P4 since $T_h$ does and since there is no node $m_{h+1}$ below a node $p_{h+1}$. Finally, $T_{h+1}$ satisfies P3 because all the $E_i$, in $\lambda$ satisfy the condition in P3 because $T_h$ satisfies P3, and trivially $E_{h+1}$ satisfies the condition in P3.

**Case 2.** Suppose that, in $U$, the node $u_h$ is in the left subtree of $u_{h+1}$. By the definition of the topmost traversal, the right subtree of $u_{h+1}$ contains no node $u_i$.

In this case, $U_{h+1}^\uparrow = (U_h^\uparrow \setminus \{u_h\}) \cup \{u_{h+1}\}$. It is immediate from the definitions that $p_{h+1} = p_h$ and $m_{h+1} = m_h$. Finally, $q_h$ is defined and $q_{h+1}$ is the next topmost node that the infix traversal of $U$ visits after visiting all nodes in $B_h$, and so $u_{h+1}$ must be the topmost node $q_h$ since the infix traversal visits nodes in weakly increasing order.

**Sub-case 2(a).** Suppose that $E_h \neq D_h$. Then $D_h$ contains nodes with label $q_h = u_{h+1}$. By the definition of $q_h$, the symbol $u_{h+1}$ is greater than or equal to every symbol in $D_h$. Thus $u_{h+1}$ is the rightmost symbol in $D_h$ and this is the node where the right-maximal subtree of $D_h$ (and $E_h$) is attached in $T_h$. The tree $E_h$ consists of $D_h$ with $s$ nodes $u_{h+1}$ inserted, where $s$ is the number of nodes $u_{h+1}$ that appear in $U$ outside of the complete subtree at $u_h$.

As shown in **Figure 9** let $\lambda$ be a reading of the left-minimal subtree of $D_h$; note that the subtree $\lambda$ contains all the $E_i$ except $E_h$ by P2. Let $\beta$ be a reading of the right-maximal subtree of $D_h$.

Thus

$$T_h = P_{\text{syv}}(\beta \gamma u_{h+1} \lambda E_h)$$

Let

$$T_{h+1} = P_{\text{syv}}(u_{h+1}^s \beta \lambda D_h u_{h+1}^s).$$
are the left-minimal and right-maximal subtrees of $\beta$

Notice that $T$ contains all the $s$ nodes

$s$

Finally, the remaining $s_1$ symbols $u_{h+1}$ are re-inserted into $D_h$.

All secondary nodes $u_{h+1}$ are inside $D_h$, so the $s$ nodes $u_{h+1}$ outside $D_h$ are either primary or tertiary. Since there are $s_2$ primary nodes $u_{h+1}$ in $U$, and since the evaluation of $U$ is the same as the evaluation of $T_h$, there are $s_1$ tertiary nodes $u_{h+1}$ in $U$. Hence $D_h$ and the other nodes $u_{h+1}$ in $T_{h+1}$ together make up $E_{h+1}$; thus $T_{h+1}$ satisfies P1. All the other $E_{i,j}$ are contained in $\lambda$, so $T_{h+1}$ satisfies P2. Since $T_h$ satisfies P3, and since $\lambda$ and $\beta$ are the left-minimal and right-maximal subtrees of $E_{h+1}$, it follows that $T_{h+1}$ satisfies P3. Finally, the relative positions of the $m_{i,j}$ and $p_{i,j}$ have not been altered, so $T_{h+1}$ satisfies P4.

**Sub-case 2(b).** Suppose that $E_h = D_h$. Thus $D_h$ does not contain nodes labelled $q_h = u_{h+1}$. Since $u_{h+1}$ is greater than every node in $D_h$, it follows that all nodes $u_{h+1}$ are in the right-maximal subtree of $D_h$ (and $E_h$) in $T_h$. Furthermore, since $u_{h+1}$ is the smallest symbol greater than every symbol in $D_h$, only another node $u_{h+1}$ can be the left child of a node $u_{h+1}$ in $T_h$.

As shown in Figure 10, let $\lambda$ be a reading of the left-minimal subtree of $D_h$; note that the subtree $\lambda$ contains all the $E_{i,j}$ except $E_h$ by P2. Let $\delta$ be a reading of the right-maximal subtree of $D_h$ outside of the complete subtree at the topmost node $u_{h+1}$. (Note that $\delta$ may be empty.) Let $\beta$ be a reading of the right subtree of the topmost node $u_{h+1}$; note that the left subtree of this node can only contain other nodes $u_{h+1}$. Suppose there are $s$ nodes $u_{h+1}$ in $U$ (and so in $T_h$).

$$T_h = P_{sylv}(u_{h+1}^{l_1} \beta \lambda D_h)$$

$$T_{h+1} = P_{sylv}(u_{h+1}^{s_1} \beta \lambda D_h u_{h+1}^{s_2})$$

**Figure 9.** Induction step, sub-case 2(a): $E_h \neq D_h$. 

where $s_2$ is the number of primary nodes $u_{h+1}$ in $U$, and where $s_1 = s - s_2$. Notice that $T_{h+1} \sim T_h$.
\[ T_h = \text{Psylv}(\beta u_h^1 \delta \lambda D_h) \]
\[ T_{h+1} = \text{Psylv}(u_{h+1}^{s_1} \delta \lambda D_h \beta u_{h+1}^{s_2}) \]

**Figure 10.** Induction step, sub-case 2(b): \( E_h = D_h \).

Thus \( T_h = \text{Psylv}(\beta u_h^1 \delta \lambda D_h) \). Let \( T_{h+1} = \text{Psylv}(u_{h+1}^{s_1} \delta \lambda D_h \beta u_{h+1}^{s_2}) \), where \( s_2 \) is the number of primary nodes \( u_{h+1} \) in \( U \), and where \( s_1 = s - s_2 \). In computing \( T_{h+1} \), the rightmost symbol \( u_{h+1} \) is inserted first and becomes the root node. Then the next \( s_2 - 1 \) nodes \( u_{h+1} \) are attached along the path of left child nodes. Since every symbol in \( \beta \) is strictly greater than \( u_{h+1} \), the subtree \( \beta \) is re-inserted as the right child of the root node \( u_{h+1} \). Since every symbol in \( D_h \) or \( \lambda \) is less than or equal to \( u_{h+1} \), the subtrees \( D_h \) and \( \lambda \) are re-inserted as the left child of the bottommost node \( u_{h+1} \). Since every symbol in \( \delta \) is strictly greater than \( u_{h+1} \), the symbols in \( \delta \) are also inserted into the right subtree of the root node \( u_{h+1} \). Finally, the remaining \( s_1 \) symbols \( u_{h+1} \) are re-inserted into \( D_h \).

By the definition of \( D_h \) and the fact that there are \( s_2 \) primary nodes \( u_{h+1} \) in \( U \), and the fact that the evaluation of \( U \) is the same as the evaluation of \( T_h \), there are \( s_1 \) tertiary nodes \( u_{h+1} \) in \( U \). Hence \( D_h \) and the other nodes \( u_{h+1} \) in \( T_{h+1} \) together make up \( E_{h+1} \); thus \( T_{h+1} \) satisfies P1. All the other \( E_{i_j} \) are contained in \( \lambda \), so \( E_{h+1} \) satisfies P2. Since \( T_h \) satisfies P3, and since \( \lambda \) and \( \delta \beta \) are the left-minimal and right-maximal subtrees of \( E_{h+1} \), it follows that \( T_{h+1} \) satisfies P3. Finally, the relative positions of \( m_{i_j} \) and \( p_{i_j} \) have not been altered, so \( T_{h+1} \) satisfies P4.

**Case 3.** Suppose that, in \( U \), the node \( u_h \) is in the right subtree of \( u_{h+1} \), and there is no node \( u_i \) in the left subtree of \( u_{h+1} \). Note that \( q_h \) is defined if and only if \( q_{h+1} \) is defined, in which case \( q_h = q_{h+1} \).

In this case, \( U_{h+1} = (U_h \setminus \{u_h\}) \cup \{u_{h+1}\} \), and \( p_h = u_{h+1} \).

By definition, \( B_{h+1} \) is the complete subtree of \( U \) at \( u_{h+1} \). So \( C_{h+1} \) is \( B_{h+1} \) with all but the topmost node \( m_{h+1} \) deleted. Since the left subtree of \( u_{h+1} \) in \( U \) contains no nodes \( u_i \), by Lemma 6.10 it only contains other nodes \( u_{h+1} \) and so \( m_{h+1} = u_{h+1} \). Thus \( C_{h+1} \) consists of \( u_{h+1} \) and its right subtree. By definition, \( q_{h+1} \) (if defined) is the least symbol greater than every topmost symbol in \( B_{h+1} \); since \( u_{h+1} \) is less than every symbol in \( B_h \), this implies that \( q_{h+1} = q_h \). By definition of the topmost traversal, there is no
Sub-case 3(a). Suppose that $E_h \neq D_h$. Then $q_h$ is defined and $D_h$ contains nodes $q_h$. Since $q_h$ is greater than or equal to every node in $D_h$, it follows that the uppermost node $u_{h+1}$ in $T_h$ must be on the path of right child nodes from the left child of the lowest node $m_h$, for otherwise it would be in a left subtree of some node $x$ below the lowest node $m_h$, which would imply $u_{h+1} = p_h < x < m_h$, which contradicts $p_h$ being the greatest symbol less than $m_h$.

**Figure 11.** Induction step, sub-case 3(a): $E_h \neq D_h$. 

Topmost node between $u_h$ and $u_{h+1}$, so only (non-topmost) nodes $q_{h+1}$ can lie between them. Thus $C_{h+1}$ consists of $u_{h+1}$, some number $s_2$ (possibly zero) of secondary nodes $q_{h+1}$, and the subtree $B_h$. Hence $D_{h+1}$ consists of $u_{h+1}$, these nodes $q_{h+1}$, and the subtree $B_h$ with its tertiary nodes $q_{h+1} = q_h$ deleted, since these tertiary nodes are the same in both $B_{h+1}$ and $B_h$.

Notice that, in $T_h$, all nodes $m_h$ that are not in $E_h$ itself are in the left-minimal subtree of $E_h$, but may not be consecutive. Since no $m_h$ is below $p_h = u_{h+1}$, which is the greatest symbol less than $m_h$, it follows that the uppermost node $u_{h+1}$ in $T_h$ is in the left subtree of the lowest node $m_h$.

Furthermore, as shown in Figures 11 and 12 below, this uppermost node $u_{h+1}$ in $T_h$ must be on the path of right child nodes from the left child of the lowest node $m_h$, for otherwise it would be in a left subtree of some node $x$ below the lowest node $m_h$, which would imply $u_{h+1} = p_h < x < m_h$, which contradicts $p_h$ being the greatest symbol less than $m_h$.

Sub-case 3(a). Suppose that $E_h \neq D_h$. Then $q_h$ is defined and $D_h$ contains nodes $q_h$. Since $q_h$ is greater than or equal to every node in $D_h$, it follows that the uppermost node $q_h$ is where the right-maximal subtree of $D_h$ (and $E_h$) is attached in $T_h$. The tree $E_h$ consists of $D_h$ with $s$ nodes $q_h$ inserted, where $s$ is the number of nodes $q_h$ that appear in $U$ outside of the subtree $D_h$. Suppose there are $r+1$ nodes $m_h$ in $U$, so there are $r$ nodes $m_h$ outside $D_h$ in $U$.}
As shown in Figure 11, let \( \lambda_r \) be a reading of the left-minimal subtree of \( D_h \) outside of the complete subtree at the uppermost \( m_h \) below \( D_h \). (Note that \( \lambda_r \) may be empty.) For \( i = r - 1, \ldots, 2 \), let \( \lambda_i \) be readings of the left subtree of the \( i \)-th node \( m_h \) (counting from the lowermost to the uppermostmost) outside of the complete subtree of the \( i \)-th node. (Note that \( \lambda_1 \) will be empty if the \( i \)-th node \( m_h \) is the left child of the \( i + 1 \)-th. Let \( \lambda_0 \) be a reading of the left subtree of the bottommost node \( m_h \) outside the complete subtree at the uppermost node \( u_{h+1} \). Let \( \tau \) be a reading of the left subtree of the uppermost node \( u_{h+1} \). Note that the uppermost non-empty subtree \( \lambda_i \) or \( \tau \) contains all the \( E_{ij} \) except \( E_h \) by P2. Let \( \beta \) be a reading of the right-maximal subtree of \( D_h \).

Thus

\[
T_h = P_{sylv}(\tau q_h^{s_2} u_{h+1} \lambda_0 m_h \lambda_1 m_h \cdots \lambda_{r-1} m_h \lambda_r q_h^{s_1} \beta D_h);
\]

where \( s_1 = s - s_2 \). (Recall that \( s_2 \) was defined above as the number of secondary nodes \( q_h \) between \( u_h \) and \( p_h = u_{h+1} \) in \( U \).)

Let

\[
T_{h+1} = P_{sylv}(\lambda_0 m_h \lambda_1 m_h \cdots \lambda_{r-1} m_h \lambda_r q_h^{s_1} \beta D_h \tau q_h^{s_2} u_{h+1}),
\]

Notice that \( T_h \sim T_{h+1} \).

In computing \( T_{h+1} \), the symbol \( u_{h+1} \) is inserted first and becomes the root node. Then the \( s_2 \) symbols \( q_h \) are inserted into the right subtree of the root nodes, since \( q_h > p_h = u_{h+1} \). Every symbol in \( \tau \) is less than or equal to \( u_{h+1} \) and so is inserted into the left subtree of the root note \( u_{h+1} \). Every symbol in \( D_h \) is greater than \( u_{h+1} \) and less than or equal to \( q_h \), so the tree \( D_h \) is re-inserted at the left child of the bottommost \( q_h \). Every symbol in \( \beta \) is greater than \( q_h \) (since in \( T_h \) the subtree \( \beta \) is the right child of a node \( q_h \), as discussed above), so \( \beta \) is inserted as the right subtree of the topmost \( q_h \). The remaining \( s_1 \) symbols \( q_h \) are re-inserted below \( D_h \), attached at the same position as in \( T_h \). The symbol \( m_h \) is the smallest symbol greater than \( u_{h+1} \) and all symbols \( m_h \) are inserted into the left-minimal subtree of \( D_h \) (which is attached at the single node \( m_h \) in \( D_h \)). Every symbol in every \( \lambda_i \) is less than every symbol in \( \tau \) and so are inserted into the left-minimal subtree of \( \tau \). Since every symbol in \( \lambda_i \) is greater than every symbol in \( \lambda_{i+1} \), the former is inserted into the right-maximal subtree of the latter.

As noted above, \( D_{h+1} \) consists of \( u_{h+1} \) with empty left subtree, \( s_2 \) nodes \( q_{h+1} = q_h \), and the subtree \( B_h \) with its tertiary nodes \( q_{h+1} = q_h \) deleted. Hence, since \( D_h \) contains secondary nodes \( q_h \), so does \( D_{h+1} \), and so \( E_{h+1} \) consists of \( D_{h+1} \) with \( s_1 \) nodes \( q_{h+1} = q_h \) inserted, as shown in Figure 11.

Therefore \( E_{h+1} \) appears at the root of \( U \) and so \( T_{h+1} \) satisfies P1. The other trees \( E_{ij} \) in \( T_h \) were in the uppermost non-empty \( \lambda_i \) or \( \tau \); this still holds and so \( T_{h+1} \) satisfies P2. Since \( T_h \) satisfies P3 and the insertions into the left-minimal and right-maximal subtrees of \( E_{h+1} \), the tree \( T_{h+1} \) satisfies P3. Finally, \( T_{h+1} \) satisfies P4 since \( T_h \) does. (Note that \( m_h \) is below \( p_h = u_{h+1} \), but this does not matter since \( u_{h+1} \) is not in \( U_{h+1} \).)

Sub-case 3(b). Suppose that \( E_h = D_h \). Then either \( q_h \) is undefined, or is defined but \( D_h \) does not contain nodes \( q_h \).

Suppose that \( q_h \) is defined. Let \( s \) be the number of nodes \( q_h \) that appear in \( U \) outside of the subtree \( D_h \).
Since $q_h$ is greater than every node in $D_h$, it follows that the $s$ nodes $q_h$ are all in the right-maximal subtree of $D_h$ (and $E_h$) in $T_h$. Since $q_h$ is the least symbol greater than every symbol in $D_h$, in $T_h$ the left child of a node $q_h$ can only be another node $q_h$.

Now return to the general situation, where $q_h$ may or may not be defined. As shown in Figure 12, let $\lambda$, $\tau$, and $\delta$ be as in sub-case 3(b). Let $\beta$ be a reading of the right subtree of the topmost node $q_h$. (If $q_h$ is undefined, $\beta$ is empty.)

Now,

$$T_h = P_{syv}(\tau \beta q_h^{s_2} u_{h+1} \lambda_0 m_h \lambda_1 m_h \cdots \lambda_{r-1} m_h \lambda_r q_h^{s_1} \delta D_h),$$

where $s_1 = s - s_2$. (Recall that $s_2$ was defined above as the number of secondary nodes $q_h$ between $u_h$ and $p_h = u_{h+1}$ in $U$.) Let

$$T_{h+1} = P_{syv}(\lambda_0 m_h \lambda_1 m_h \cdots \lambda_{r-1} m_h \lambda_r q_h^{s_1} \delta D_h \tau \beta q_h^{s_2} u_{h+1}).$$

Notice that $T_h \sim T_{h+1}$.

Assume for the moment that $q_h$ is defined and $s_2 > 0$. In computing $T_{h+1}$, the symbol $u_{h+1}$ is inserted first and becomes the root node. Then the $s_2$ symbols $q_h$ are inserted into the right subtree of the root nodes, since $q_h > u_{h+1}$. Every symbol in $\beta$ is greater than $q_h$, so $\beta$ is inserted as the right subtree of the topmost $q_h$. Every symbol in $\tau$ is less than or equal to

\[\begin{align*}
T_{h+1} &= P_{syv}(\lambda_0 m_h \lambda_1 m_h \cdots \lambda_{r-1} m_h \lambda_r q_h^{s_1} \delta D_h \tau \beta q_h^{s_2} u_{h+1}) \\
T_h &= P_{syv}(\tau \beta q_h^{s_2} u_{h+1} \lambda_0 m_h \lambda_1 m_h \cdots \lambda_{r-1} m_h \lambda_r q_h^{s_1} \delta D_h)
\end{align*}\]
Every symbol in $D_h$ is greater than $u_{h+1}$ and less than $q_h$, so the tree $D_h$ is re-inserted as the left child of the bottommost $q_h$. The remaining $s_1$ symbols $q_h$ are re-inserted below $D_h$, attached at the right-maximal subtree of $D_h$. The symbol $m_h$ is the smallest symbol greater than $p_h = u_{h+1}$ and so all symbols $m_h$ are inserted into the the left-minimal subtree of $D_h$ (which is attached at the single node $m_h$ in $T_h$). Every symbol in every $\lambda_i$ is less than every symbol in $\tau$ and so the $\lambda_i$ are inserted into the left-minimal subtree of $\tau$. Since every symbol in $\lambda_i$ is greater than every symbol in $\lambda_{i+1}$, the former is inserted into the right-maximal subtree of the latter.

As noted above, $D_{h+1}$ consists of $u_{h+1}$ with empty left subtree, $s_2$ nodes $q_{h+1} = q_h$, and the subtree $B_h$ with its tertiary nodes $q_{h+1} = q_h$ deleted. The tree $D_{h+1}$ contains $s_2$ nodes $q_{h+1} = q_h$, and so $E_{h+1}$ consists of $D_{h+1}$ with $s_1$ nodes $q_{h+1} = q_h$ inserted, as shown in Figure 12. Thus $E_{h+1}$ appears at the root of $T_{h+1}$ and every node below it is in its left-minimal or right-maximal subtrees.

If, on the other hand, $q_h$ is defined and $s_2 = 0$, then, by near-identical reasoning, $D_h$ is inserted at the right child of $u_{h+1}$ and $\delta \beta$ becomes the right-maximal subtree of $D_h$, and the $s = s_1$ nodes $q_h$ are inserted into the tree $\delta \beta$.

In this case, $D_{h+1}$ does not contain any nodes $q_{h+1} = q_h$ and so $E_{h+1} = D_{h+1}$ consists of $u_{h+1}$ and the subtree $B_h$ with its tertiary nodes $q_{h+1} = q_h$ deleted and so $E_{h+1}$ appears at the root of $T_{h+1}$ and every node below it is in its left-minimal or right-maximal subtrees.

Finally, if $q_h$ is undefined, then again $D_h$ is inserted at the right child of $u_{h+1}$ and $\delta \beta$ becomes the right-maximal subtree of $D_h$.

In this case, $q_{h+1}$ is also undefined and so there are no tertiary nodes in $B_h$. Hence $E_{h+1} = D_{h+1}$ consists precisely of $u_{h+1}$ with right subtree $B_h$. So $E_{h+1}$ appears at the root of $T_{h+1}$ and every node below it is in its left-minimal or right-maximal subtrees.

Therefore $T_{h+1}$ satisfies P1. The other trees $E_{i_j}$ in $T_h$ were in the uppermost non-empty $\lambda_i$ or $\tau$; this still holds and so $T_{h+1}$ satisfies P2. Since $T_h$ satisfies P3 and all nodes below $E_{i_j}$ are in its left-minimal and right-maximal subtrees, the tree $T_{h+1}$ satisfies P3. Finally, $T_{h+1}$ satisfies P4 since $T_h$ does. (Note that $m_h$ is below $p_h$, but this does not matter since $u_h$ is not in $U_{h+1}$.)

---

**Case 4.** Suppose that, in $U$, the node $u_i$ is in the right subtree of $u_{h+1}$, and there is some node $u_j$ in the left subtree of $u_{h+1}$.

Suppose there are topmost nodes $u_j$ and $u_{j'}$ in this left subtree. Then their lowest common ancestor $v$ is also in this left subtree; $v$ must have both subtrees non-empty and so be a topmost node and thus lie in $U_h$. Thus there is a unique node in $U_h$ in the left subtree of $v$; clearly this is $u_i$, which is the rightmost node in $U_h \setminus \{u_i\}$. (Recall that, for brevity, $h = i_k$ and $g = i_{k-1}$.) Furthermore, this node is on the path of left child nodes from $u_{h+1}$ (since only topmost nodes have right subtrees). Therefore, $U_{h+1} = (U_h \setminus \{u_i, u_j\}) \cup \{u_{h+1}\}$, where $u_i$ is the unique node from $U_h$ in the left subtree of $u_{h+1}$. As in case 3, $p_h = u_{h+1}$. The smallest symbol in
the tree $B_{h+1}$ is the smallest symbol in the left subtree of $u_{h+1}$ (which is certainly non-empty in this case) and so $m_{h+1} = m_g$. The least symbol less than or equal to every symbol in $B_{h+1}$ is the least symbol less than or equal to every symbol in the right subtree of $u_{h+1}$ (which is certainly non-empty in this case) and so $q_h = q_{h+1}$ (or $q_{h+1}$ is undefined if $q_h$ is undefined). The only nodes between $u_g$ and the topmost node $u_{h+1}$ are other nodes $u_{h+1}$, so $q_g = u_{h+1}$ (in particular, $q_g$ is defined). Finally, $u_{h+1}$ is the first node entered from a right child on ascending from $u_h$ to the root (by the definition of the topmost traversal) so and $u_{h+1} = p_h$.

Let $s_2$ be the number of secondary nodes $q_h$ between $u_h$ and $u_{h+1}$ in $U$, and let $t_2$ is the number of primary nodes $u_{h+1}$ and let $s_1 = s - s_2$.

Sub-case 4(a). Suppose that $E_h \neq D_h$ and $E_g \neq D_g$. Then $q_h$ is defined, $D_h$ contains nodes $q_h$, and $D_g$ contains nodes $q_h$. Since $q_h$ is greater than or equal to every node in $D_h$, it follows that the topmost node $q_h$ is where the right-maximal subtree of $D_h$ (and $E_h$) is attached in $T_h$. Similarly, since $q_g$ is greater than or equal to every node in $D_g$, it follows that the topmost node $q_g$ is where the right-maximal subtree of $D_g$ (and $E_g$) is attached in $T_h$. The tree $E_h$ consists of $D_h$ with $s$ nodes $q_h$ inserted, where $s$ is the number of nodes $q_h$ that appear in $U$ outside of the subtree $D_h$. The tree $E_g$ consists of $D_g$ with $t$ nodes $q_g$ inserted, where $t$ is the number of nodes $q_g = u_{h+1}$ that appear in $U$ outside of the subtree $D_g$. By P2, the subtree $E_g$ appears on the path of left child nodes and thus in the left-minimal subtree of $D_h$ (and $E_h$). The only symbols that are less than or equal to $m_h$ are inserted into the left subtree of the topmost node $q_h$ and greater than or equal to $q_g = p_h = u_{h+1}$ (the maximum symbol in $E_g$) are the symbols $m_h$ and $q_g = p_h = u_{h+1}$ themselves.

By P4, no node $m_h$ appears below a node $p_h = q_g$, so nodes $m_h$ cannot appear in the right-maximal subtree of $E_g$. Thus the nodes $m_h$ (except for the single node $m_h$ in $E_h$) are precisely the nodes on the path of left child nodes between $E_h$ and $E_g$.

As shown in Figure 13 let $\lambda$ be a reading of the left-minimal subtree of $D_g$ and let $\beta$ be a reading of the right-maximal subtree of $D_h$. Then

$$T_h = \mathsf{psylv}(q_h^{s_2}u_{h+1}^{t_2}\lambda D_g^r \beta m_h q_h^{s_1} D_h).$$

Let

$$T_{h+1} = \mathsf{psylv}(u_{h+1}^{t_1} \lambda D_g^r \beta m_h q_h^{s_1} D_h q_g^{s_2} u_{h+1}^{t_2}).$$

Note that $T_h \sim T_{h+1}$.

In computing $T_{h+1}$, the rightmost symbol $u_{h+1}$ is inserted first and becomes the root node, with the remaining $t_2 - 1$ symbols descending from it on the path of left child nodes. Since $q_h = q_{h+1} > u_{h+1}$, the $s_2$ symbols $q_h$ are inserted into the right subtree of the root node $u_{h+1}$. Every symbol in $D_h$ is greater than $u_{h+1}$ and less than or equal to $q_h$, so the subtree $D_h$ is re-inserted as the left child node of the bottommost node $q_h$. The remaining $s_1$ symbols $q_h$ are inserted below $D_h$ (attached at the same place as in $T_h$). The symbol $m_h$ is the smallest symbol greater than $u_{h+1}$ and so the $r$ symbols $m_h$ is re-inserted into the left-minimal subtree of $D_h$ (attached as the left child of the node $m_h$ in $D_h$). Every symbol in $\beta$ is greater than $q_h$, so $\beta$ is re-inserted as the right child of the topmost $q_h$. Every symbol in $D_g$ and
λ is less than or equal to $u_{h+1}$ and so $D_g$ and $\lambda$ are re-inserted at the left child of the bottommost node $u_{h+1}$. The remaining $t_1$ nodes $u_{h+1}$ are into the right-maximal subtree of $D_g$ (in the same place as they were attached in $T_h$).

The subtree $D_h$, the nodes $m_h$, and possibly some of the $q_h$ below $D_h$ make up $B_h$. This tree $B_h$, together with the nodes $q_h$ above $D_h$, the nodes $u_{h+1}$ and $D_g$ together make up $D_{h+1}$. Adding the remaining nodes $q_h = q_{h+1}$ below $D_h$ gives the tree $E_{h+1} = P_{sylv}(u_{h+1}^{t_1} \lambda D_g \beta m_h q_h^{s_1} D_h q_h^{s_2} u_{h+1})$.

**Figure 13.** Induction step, sub-case 4(a): $E_h \neq D_h$ and $E_g \neq D_g$.

By P2, in $T_h$ the subtree $E_h$ appears on the path of left child nodes and thus in the left-minimal subtree of $E_h$ (and thus of $D_h$), which appears at the root of $T_h$ by P1. The only symbols that are less than or equal to $m_h$ (the minimum symbol in $E_h$) and greater than or equal to every symbol in $E_g$ are $m_h$ and $p_h = u_{h+1} = q_g$. Thus nodes $m_h$ and $u_{h+1}$ must appear either
on the path of left child nodes between $E_h$ and $E_g$, or in the right-maximal subtree of $E_g$.

As shown in Figure 14 let $\lambda$ be a reading of the left-minimal subtree of $D_g$ and let $\beta$ be a reading of the right-maximal subtree of $D_h$. The nodes shown as empty consist of $r$ nodes $m_h$ and $t$ nodes $u_{h+1}$ (for some $r$ and $t$), with the $m_h$ above the $u_{h+1}$ by condition P4 since $u_{h+1} = p_h$. Note, however, that the boundary between the $m_h$ and the $u_{h+1}$ may be either above or below $D_g$.

Consider three sub-sub-cases:

(1) There are no nodes $u_{h+1}$ above $D_g$. Suppose there are $r_1$ nodes $m_h$ below $D_g$ and $r_2$ above. Then

$$T_h = P\left(q_h^{s_2}u_{h+1}^{t_2}m_h^{r_1}\lambda D_gm_h^{r_2}\beta q_h^{s_1}D_h\right).$$

Let

$$T_{h+1} = P\left(u_{h+1}^{t_1}m_h^{r_1}\lambda D_gm_h^{r_2}\beta q_h^{s_1}D_hq_h^{s_2}u_{h+1}^{t_2}\right).$$

Note that $T_h \sim T_{h+1}$.

In computing $T_{h+1}$, the rightmost symbol $u_{h+1}$ is inserted first and becomes the root node, with the remaining $t_2 - 1$ symbols descending from it on the path of left child nodes. Since $q_h = q_{h+1} > u_{h+1}$, the $s_2$ symbols $q_h$ are inserted into the right subtree of the root node $u_{h+1}$. Every symbol in $D_h$ is greater than $u_{h+1}$ and less than or equal to $q_h$, so if $s_2 > 0$, the subtree $D_h$ is re-inserted as the left child node of the bottommost node $q_h$, while if $s_2 = 0$, the subtree
$D_h$ is inserted as the right child of $u_{h+1}$. The remaining $s_1$ symbols $q_h$ are inserted below $D_h$ (attached at the same place as in $T_h$).

Every symbol in $\beta$ is greater than $q_h$, so if $s_2 > 0$, the subtree $\beta$ is re-inserted as the right child of the topmost $q_h$, while if $s_2 = 0$, the subtree $\beta$ is inserted as the right-maximal subtree of $D_h$. The symbol $m_h$ is the smallest symbol greater than $u_{h+1}$ and so the $r_2$ symbols $m_h$ are inserted into the left-minimal subtree of $D_h$ (attached as the left child of the node $m_h$ in $D_h$). Every symbol in $D_g$ and $\lambda$ is less than or equal to $u_{h+1}$ and so $D_g$ and $\lambda$ are re-inserted at the left child of the bottommost node $u_{h+1}$. The remaining $r_1$ nodes $m_h$ are inserted at the left child of the bottommost node $m_h$ (so that the nodes $m_h$ are now consecutive). The remaining $t_1$ nodes $u_{h+1}$ are into the right-maximal subtree of $D_g$.

(2) There are $o_1$ nodes $u_{h+1}$ below $D_g$ and $o_2$ above, where $o_2 \geq t_2$. Then

$$T_h = P_{\text{Sylv}}(q_h^{o_2} u_{h+1}^{o_1} \lambda D_g u_{h+1}^{o_2} m_h^r \beta q_h^{s_1} D_h).$$

Let

$$T_{h+1} = P_{\text{Sylv}}(u_{h+1}^{o_2-t_2} m_h^r \beta q_h^{s_1} D_h q_h^{s_2} u_{h+1}^{o_1} \lambda D_g u_{h+1}^{t_2}).$$

Note that $T_h \sim T_{h+1}$.

In computing $T_{h+1}$, the rootmost symbol $u_{h+1}$ is inserted first and becomes the root node, with the remaining $t_2 - 1$ symbols descending from it on the path of left child nodes. Every symbol in $D_g$ and $\lambda$ is less than or equal to $u_{h+1}$ and so $D_g$ and $\lambda$ are re-inserted at the left child of the bottommost node $u_{h+1}$. The next $o_1$ nodes $u_{h+1}$ are inserted into the right-maximal subtree $D_g$. Since $q_h = q_{h+1} > u_{h+1}$, the $s_2$ symbols $q_h$ are inserted into the right subtree of the root node $u_{h+1}$. Every symbol in $D_h$ is greater than $u_{h+1}$ and less than or equal to $q_h$, so if $s_2 > 0$, the subtree $D_h$ is re-inserted as the left child node of the bottommost node $q_h$, while if $s_2 = 0$, the subtree $D_h$ is inserted as the right child of $u_{h+1}$. The remaining $s_1$ symbols $q_h$ are inserted below $D_h$ (attached at the same place as in $T_h$).

Every symbol in $\beta$ is greater than $q_h$, so if $s_2 > 0$, the subtree $\beta$ is re-inserted as the right child of the topmost $q_h$, while if $s_2 = 0$, the subtree $\beta$ is attached at as the right-maximal subtree of $D_h$.

The symbol $m_h$ is the smallest symbol greater than $u_{h+1}$ and so the $r$ symbols $m_h$ are inserted into the left-minimal subtree of $D_h$ (attached as the left child of the node $m_h$ in $D_h$). The remaining $o_2 - t_2$ nodes $u_{h+1}$ are inserted at the left child of the bottommost node $u_{h+1}$ (so that the $o_1 + o_2 - t_2 = t_1$ nodes $u_{h+1}$ below $D_g$ are now consecutive).

(3) There are $o_1$ nodes $u_{h+1}$ below $D_g$ and $o_2$ above, where $o_2 < t_2$. Then

$$T_h = P_{\text{Sylv}}(q_h^{o_2} u_{h+1}^{o_1} \lambda D_g u_{h+1}^{o_2} m_h^r \beta q_h^{s_1} D_h).$$

Let

$$T_{h+1} = P_{\text{Sylv}}(u_{h+1}^{o_1-t_2-o_2} \lambda D_g u_{h+1}^{o_2} m_h^r \beta q_h^{s_1} D_h q_h^{s_2+t_2-o_2} u_{h+1}^{t_2}).$$

Note that $o_1 - t_2 + o_2 = t_1$ and that $T_h \sim T_{h+1}$. 

In computing $T_{h+1}$, the rightmost symbol $u_{h+1}$ is inserted first and becomes the root node, with the remaining $t_2 - o_2 - 1$ symbols descending from it on the path of left child nodes. Since $q_h = q_{h+1} > u_{h+1}$, the $s_2$ symbols $q_h$ are inserted into the right subtree of the root node $u_{h+1}$. Every symbol in $D_h$ is greater than $u_{h+1}$ and less than or equal to $q_h$, so if $s_2 > 0$, the subtree $D_h$ is re-inserted as the left child node of the bottommost node $q_h$, while if $s_2 = 0$, the subtree $D_h$ is inserted as the right child of $u_{h+1}$. The remaining $s_1$ symbols $q_h$ are inserted below $D_h$ (attached at the same place as in $T_h$). Every symbol in $\beta$ is greater than $q_h$, so if $s_2 > 0$, the subtree $\beta$ is re-inserted as the right child of the topmost $q_h$, while if $s_2 = 0$, the subtree $\beta$ is attached at as the right-maximal subtree of $D_h$. The symbol $m_h$ is the smallest symbol greater than $u_{h+1}$ and so the $r$ symbols $m_h$ are inserted into the left-minimal subtree of $D_h$ (attached as the left child of the node $m_h$ in $D_h$). The next $o_2$ symbols $u_{h+1}$ are inserted into the left subtree of the bottommost node $u_{h+1}$, so that there are $t_2 - o_2 - o_2 = t_2$ consecutive nodes $u_{h+1}$. Every symbol in $D_g$ and $\lambda$ is less than or equal to $u_{h+1}$ and so $D_g$ and $\lambda$ are re-inserted at the left child of the bottommost node $u_{h+1}$. The remaining $o_1 - t_2 + o_2 = t_1$ nodes $u_{h+1}$ are inserted into the right-maximal subtree of $D_g$.

The subtree $D_h$, the nodes $m_h$, and possibly some of the $q_h$ below $D_h$ make up $B_h$. This tree $B_h$, together with the nodes $q_h$ above $D_h$, the nodes $u_{h+1}$ and $D_g$ together make up $D_{h+1}$. Adding the remaining nodes $q_h = q_{h+1}$ below $D_h$ gives the tree $E_{h+1}$. So $T_{h+1}$ satisfies P1. The other trees $E_i$, in $T_2$ were in $\lambda$; this still holds and so $T_{h+1}$ satisfies P2. Every node not in $E_{h+1}$ is in its left-minimal or right-maximal subtree; together with the fact that $T_h$ satisfies P3, this shows that $T_{h+1}$ satisfies P3. Finally, $T_{h+1}$ satisfies P4 since $T_h$ does. (Note that $m_h$ is below $p_h = u_{h+1}$, but this does not matter since $u_h$ is not in $U_{h+1}$.)

Sub-case 4(c). Suppose that $E_h = D_h$ and $E_g \neq D_g$. Then $D_g$ contains nodes $q_g$. Since $q_g$ is greater than or equal to every node in $D_g$, it follows that the topmost node $q_g$ is where the right-maximal subtree of $D_g$ (and $E_g$) is attached in $T_h$. The tree $E_g$ consists of $D_g$ with $t$ nodes $q_g$ inserted, where $t$ is the number of nodes $q_g = u_{h+1}$ that appear in $U$ outside of the complete subtree at $u_g$.

The subtree $E_g$ appears on the path of left child nodes and thus in the left-minimal subtree of $E_h$ (and $E_h$). The only symbols that is less than or equal to $m_h$ and greater than or equal to every symbol in $q_g$ are $m_h$ and $p_h = u_{h+1} = q_g$. By P4, no node $m_h$ appears below a node $p_h$, so nodes $m_h$ cannot appear in the right-maximal subtree of $E_g$. Thus the nodes $m_h$ (except for the single node $m_h$ in $D_h$) are precisely the nodes on the path of left child nodes between $D_h$ and $D_g$.

As shown in Figure 15, let $\lambda$ be a reading of the left-minimal subtree of $D_g$. Let $\delta$ be a reading of the right-maximal subtree of $D_h$ outside the complete subtree at the topmost node $q_h$ (if $q_h$ is defined) and let $\beta$ be a reading of the right-maximal subtree of the topmost $q_h$. (Note that $\beta$ is empty if $q_h$ is not defined.)
(1) $T_h = P_{syh}(\beta q_h^{s_2} u_{h+1}^t \lambda D_g m_h^r q_h^{s_1} \delta D_h)$;

(2) $T_h = P_{syh}(u_{h+1}^t \lambda D_g m_h^r \beta q_h^{s_1} \delta D_h)$.

(1) $T_{h+1} = P_{syh}(u_{h+1}^t \lambda D_g m_h^r \beta q_h^{s_1} \delta D_h u_{h+1}^t)$;

(2) $T_{h+1} = P_{syh}(u_{h+1}^t \lambda D_g m_h^r \beta q_h^{s_1} \delta D_h u_{h+1}^t)$.

Figure 15. Induction step, sub-case 4(c): $E_h = D_h$ and $E_q \neq D_g$; sub-sub-cases (1) and (3) use different cyclic shifts.

Let $s_2$ be the number of secondary nodes $q_h$ between $u_h$ and $u_{h+1}$ in $U$, and let $t_2$ be the number of primary nodes $u_{h+1}$. Note that if $q_h$ is defined, then $s_2 < s$ since there must be at least one primary node $q_h$. Consider two sub-sub-cases:

1. Suppose $s_2 > 0$ and $q_h$ is defined. Then

   $T_h = P_{syh}(\beta q_h^{s_2} u_{h+1}^t \lambda D_g m_h^r \delta D_h)$.

   Let

   $T_{h+1} = P_{syh}(u_{h+1}^t \lambda D_g m_h^r q_h^{s_1} \delta D_h \beta q_h^{s_2} u_{h+1}^t)$.

   Note that $T_h \sim T_{h+1}$.

   In computing $T_{h+1}$, the rightmost symbol $u_{h+1}$ is inserted first and becomes the root node, with the remaining $t_2 - 1$ symbols descending from it on the path of left child nodes. Since $q_h = q_{h+1} > u_{h+1}$, the $s_2$ symbols $q_h$ are inserted into the right subtree of the root node $u_{h+1}$. Every symbol in $\beta$ is greater than $q_h$, so $\beta$ is re-inserted as the right child of the topmost node $q_h$. Every symbol in $D_h$ is greater than $u_{h+1}$ and less than or equal to $q_h$, so the subtree $D_h$ is re-inserted as the left child node of the bottommost node $q_h$. Every symbol in $\delta$ is greater than $q_h$, so $\delta$ is inserted into the subtree $\beta$. The remaining $s_1$ symbols $q_h$ are inserted into the right-maximal subtree of $D_h$. The symbol $m_h$ is the smallest symbol greater than $u_{h+1}$ and so the $r$ symbols $m_h$ are re-inserted into the left-minimal subtree of $D_h$ (attached as the left child of the node $m_h$ in $D_h$). Every symbol in $D_g$ and $\lambda$ is less than or equal to $u_{h+1}$ and so $D_g$ and $\lambda$ are re-inserted at the left child of the bottommost node $u_{h+1}$. The
remaining $t_1$ nodes $u_{h+1}$ are into $D_g$ (in the same place as they were attached in $T_h$).

(2) Suppose $s_2 = 0$ or $q_h$ is not defined. Then

$$T_h = P_{sylv}(u_{h+1}^t \lambda D_g m_h^r \beta q_h^s \delta D_h).$$

(If $q_h$ is undefined, formally treat $q_h$ and $\beta$ as empty and $s$ as 0.)

Let

$$T_{h+1} = P_{sylv}(u_{h+1}^{t_1} \lambda D_g m_h^r \beta q_h^s \delta D_h u_{h+1}^{t_2}).$$

Note that $T_h \sim T_{h+1}$.

In computing $T_{h+1}$, the rightmost symbol $u_{h+1}$ is inserted first and becomes the root node, with the remaining $t_2 - 1$ symbols descending from it on the path of left child nodes. Every symbol in $D_h$ and $\delta$ is greater than $u_{h+1}$, so the subtrees $D_h$ and $\delta$ are re-inserted as the right child node of the root node $u_{h+1}$. The $s$ symbols $q_h$ are inserted into the right-maximal subtree of $D_h$. Every symbol in $\beta$ is greater than every symbol in $D_h$, so $\beta$ is inserted into the subtree $\delta$. The symbol $m_h$ is the smallest symbol greater than $u_{h+1}$ and so the $r$ symbols $m_h$ are re-inserted into the left-minimal subtree of $D_h$ (attached as the left child of the node $m_h$ in $D_h$). Every symbol in $D_g$ and $\lambda$ is less than or equal to $u_{h+1}$ and so $D_g$ and $\lambda$ are re-inserted at the left child of the bottommost node $u_{h+1}$. The remaining $t_1$ nodes $u_{h+1}$ are into $D_g$ (in the same place as they were attached in $T_h$)

(The key difference between the sub-sub-case is the different placement of $\beta$ in the reading of $T_h$. In sub-sub-case (2), the subword $\beta q_h^s \delta D_h$ makes up the entire part of $T_h$ outside of the left-minimal subtree of $D_h$, and since this subword is intact in the reading of $T_{h+1}$, it will appear as the right subtree of the root, as shown by the reasoning below. This observation will be used to abbreviate some of the sub-sub-cases in sub-case 4(d) below.)

The subtree $D_h$, the nodes $m_h$, and possibly some of the $q_h$ below $D_h$ make up $B_h$. This tree $B_h$, together with any nodes $q_h$ above $D_h$, the nodes $u_{h+1}$ and $D_g$ together make up $D_{h+1}$. Adding the remaining nodes $q_h = q_{h+1}$ below $D_h$ gives the tree $E_{h+1}$. So $T_{h+1}$ satisfies P1. The other trees $E_j$ in $T_2$ were in $\lambda$; this still holds and so $T_{h+1}$ satisfies P2. Every node not in $E_{h+1}$ is in its left-minimal or right-maximal subtree; together with the fact that $T_h$ satisfies P3, this shows that $T_{h+1}$ satisfies P3. Finally, $T_{h+1}$ satisfies P4 since $T_h$ does. (Note that $m_h$ is below $p_h = u_{h+1}$, but this does not matter since $u_h$ is not in $U_{h+1}^t$.)

**Sub-case 4(d).** Suppose that $E_h = D_h$ and $E_g = D_g$. If $q_h$ is defined then it is the least symbol greater than any symbol in $D_h$ and so all nodes $q_h$ must appear in the right-maximal subtree of $E_h$ in $T_h$, and the left child of a node $q_h$ can only be another node $q_h$.

It is possible that $q_g$ is defined, in which case $q_g = u_{h+1}$, but $D_g$ does not contain nodes $q_g$. The subtree tree $D_g$ appears on the path of left child nodes and thus in the left-minimal subtree of $D_h$ (and $E_h$). The only symbols that is less than or equal to every symbol in $D_h$ and greater than or equal to every symbol in $D_g$ are $m_h$ and $p_h = u_{h+1}$ (which is equal to $q_g$, if $q_g$ is
(1) $T_h = P_{\mathbf{sysv}}(\beta q_h^{o_2} u_{h+1}^{r_1} \lambda D_g m_h^{r_2} q_h^{s_1} \delta D_h)$;

(2) $T_h = P_{\mathbf{sysv}}(\beta q_h^{o_2} u_{h+1}^{r_1} \lambda D_g m_h^{r_2} q_h^{s_1} \delta D_h)$;

(3) $T_h = P_{\mathbf{sysv}}(\beta q_h^{o_2} u_{h+1}^{r_1} \lambda D_g m_h^{r_2} q_h^{s_1} \delta D_h)$;

(4) $T_h = P_{\mathbf{sysv}}(\beta q_h^{o_2} u_{h+1}^{r_1} \lambda D_g m_h^{r_2} q_h^{s_1} \delta D_h)$;

(5) $T_h = P_{\mathbf{sysv}}(\beta q_h^{o_2} u_{h+1}^{r_1} \lambda D_g m_h^{r_2} q_h^{s_1} \delta D_h)$;

(6) $T_h = P_{\mathbf{sysv}}(\beta q_h^{o_2} u_{h+1}^{r_1} \lambda D_g m_h^{r_2} q_h^{s_1} \delta D_h)$.

Figure 16. Induction step, sub-case 4(d): $E_h = D_h$ and $E_g = D_g$; sub-sub-cases (1)–(6) use different cyclic shifts.

defined). Thus nodes $m_h$ and $u_{h+1}$ must appear either on the path of left child nodes between $D_h$ and $D_g$, or in the right-maximal subtree of $D_g$.

As shown in Figure 16 let $\lambda$ be a reading of the left-minimal subtree of $D_h$. Let $\delta$ be a reading of the right-maximal subtree of $D_h$ outside the complete subtree at the topmost node $q_h$ (if $q_h$ is defined) and let $\beta$ be a reading of the right-maximal subtree of the topmost $q_h$. (Note that $\beta$ is empty if $q_h$ is not defined.) The empty nodes are filled with $r$ nodes $m_h$ and $t$ nodes $m_{h+1}$, with the $m_h$ above the $u_{h+1}$. Note, however, that the boundary between the $m_h$ and the $u_{h+1}$ may be either above or below $D_g$. Let $s_2$ be the number of secondary nodes $q_h$ between $u_h$ and $u_{h+1}$ in $U$, and let $t_2$ is the number of primary nodes $u_{h+1}$. There are six sub-sub-cases: consider first the three sub-sub-cases where $s_2 > 0$:

(1) There are no $u_{h+1}$ above $D_g$. Suppose there are $r_1$ nodes $m_h$ below $D_g$ and $t_2$ above. Then

$$T_h = P_{\mathbf{sysv}}(\beta q_h^{o_2} u_{h+1}^{r_1} \lambda D_g m_h^{r_2} q_h^{s_1} \delta D_h).$$

Let

$$T_{h+1} = P_{\mathbf{sysv}}(u_{h+1}^{r_1} m_h^{r_2} \beta q_h^{s_1} \delta D_h \beta q_h^{o_2} u_{h+1}^{t_2}).$$
Note that $T_h \sim T_{h+1}$.

In computing $T_{h+1}$, the rightmost symbol $u_{h+1}$ is inserted first and becomes the root node, with the remaining $t_2 - 1$ symbols descending from it on the path of left child nodes. Since $q_h = q_{h+1} > u_{h+1}$, the $s_2$ symbols $q_h$ are inserted into the right subtree of the root node $u_{h+1}$. Every symbol in $\beta$ is greater than $q_h$, so the subtree $\beta$ is re-inserted as the right child of the topmost $q_h$. Every symbol in $D_h$ is greater than $u_{h+1}$ and less than or equal to $q_h$, so the subtree $D_h$ is re-inserted as the left child node of the bottommost node $q_h$. Every symbol in $\delta$ is greater than $q_h$, so $\delta$ is inserted into the subtree $\delta$. The remaining $s_1$ symbols $q_h$ are inserted into the right-maximal subtree of $D_h$. The symbol $m_h$ is the smallest symbol greater than $u_{h+1}$ and so the $r_2$ symbols $m_h$ are inserted into the left-minimal subtree of $D_h$ (attached as the left child of the node $m_h$ in $D_h$).

Every symbol in $D_g$ and $\lambda$ is less than or equal to $u_{h+1}$ and so $D_g$ and $\lambda$ are re-inserted at the left child of the bottommost node $u_{h+1}$. The remaining $r_1$ nodes $m_h$ are inserted at the left child of the bottommost node $m_h$ (so that the nodes $m_h$ are now consecutive). The remaining $t_1$ nodes $u_{h+1}$ are into the right-maximal subtree of $D_g$.

(2) There are $o_1$ nodes $u_{h+1}$ below $D_g$ and $o_2$ above, where $o_2 \geq t_2$. Then

$$T_h = P_{\text{sylv}}(\beta q_h^{s_2} u_{h+1}^{o_1} \lambda D_g u_{h+1}^{o_2} m_h^{r} q_h^{s_1} \delta D_h).$$

Let

$$T_{h+1} = P_{\text{sylv}}(u_{h+1}^{o_2-t_2} m_h^{r} q_h^{s_1} \delta D_h \beta q_h^{s_2} u_{h+1}^{o_1} \lambda D_g u_{h+1}^{t_2}).$$

Note that $T_h \sim T_{h+1}$.

In computing $T_{h+1}$, the rightmost symbol $u_{h+1}$ is inserted first and becomes the root node, with the remaining $t_2 - 1$ symbols descending from it on the path of left child nodes. Every symbol in $D_g$ and $\lambda$ is less than or equal to $u_{h+1}$ and so $D_g$ and $\lambda$ are re-inserted at the left child of the bottommost node $u_{h+1}$. The next $o_1$ nodes $u_{h+1}$ are re-inserted into the right-maximal subtree of $D_g$. Since $q_h = q_{h+1} > u_{h+1}$, the $s_2$ symbols $q_h$ are inserted into the right subtree of the root node $u_{h+1}$. Every symbol in $\beta$ is greater than $q_h$, so the subtree $\beta$ is re-inserted as the right child of the topmost $q_h$. Every symbol in $D_h$ is greater than $u_{h+1}$ and less than or equal to $q_h$, so the subtree $D_h$ is re-inserted as the left child node of the bottommost node $q_h$. Every symbol in $\delta$ is greater than $q_h$ and so $\delta$ is inserted into the subtree $\delta$. The remaining $s_1$ symbols $q_h$ are inserted into the right-maximal subtree of $D_h$. The symbol $m_h$ is the smallest symbol greater than $u_{h+1}$ and so the $r$ symbols $m_h$ are inserted into the left-minimal subtree of $D_h$ (attached as the left child of the node $m_h$ in $D_h$). The remaining $o_2 - t_2$ nodes $u_{h+1}$ are inserted at the left child of the bottommost node $u_{h+1}$ (so that the $o_1 + o_2 - t_2 = t_1$ nodes $u_{h+1}$ below $D_g$ are now consecutive).
(3) There are $o_1$ nodes $u_{h+1}$ below $D_g$ and $o_2$ above, where $o_2 < t_2$. Then

$$T_h = P_{\text{sylv}}(\beta q_h^{s_2} u_{h+1}^{o_1} \lambda D_g u_{h+1}^{o_2} m_h \delta D_h).$$

Let

$$T_{h+1} = P_{\text{sylv}}(u_{h+1}^{o_1-t_2+o_2} \lambda D_g u_{h+1}^{o_2} m_h q_h^{s_1} \delta D_h \beta q_h^{s_2} u_{h+1}^{t_2-o_2}).$$

Note that $o_1 - t_2 + o_2 = t_1$ and that $T_h \sim T_{h+1}$.

In computing $T_{h+1}$, the rightmost symbol $u_{h+1}$ is inserted first and becomes the root node, with the remaining $t_2 - o_2 - 1$ symbols descending from it on the path of left child nodes. Since $q_h = q_{h+1} > u_{h+1}$, the $s_2$ symbols $q_h$ are inserted into the right subtree of the root node $u_{h+1}$. Every symbol in $\beta$ is greater than $q_h$, so the subtree $\beta$ is re-inserted as the right child of the topmost $q_h$. Every symbol in $D_h$ is greater than $u_{h+1}$ and less than or equal to $q_h$, so the subtree $D_h$ is re-inserted as the left child node of the bottommost node $q_h$. Every symbol in $\delta$ is greater than $q_h$, so $\delta$ is inserted into the subtree $\beta$. The remaining $s_1$ symbols $q_h$ are inserted into the right-maximal subtree of $D_h$. The symbol $m_h$ is the smallest symbol greater than $u_{h+1}$ and so the $r$ symbols $m_h$ are inserted into the left-minimal subtree of $D_h$ (attached as the left child of the node $m_h$ in $D_h$).

The next $o_2$ symbols $u_{h+1}$ are inserted into the left subtree of the bottommost node $u_{h+1}$, so that there are $t_2 - o_2 + o_2 = t_2$ consecutive nodes $u_{h+1}$. Every symbol in $D_g$ and $\lambda$ is less than or equal to $u_{h+1}$ and so $D_g$ and $\lambda$ are re-inserted at the left child of the bottommost node $u_{h+1}$. The remaining $o_1 - t_2 + o_2 = t_1$ nodes $u_{h+1}$ are inserted into the right-maximal subtree of $D_g$.

The three sub-sub-cases where $s_2 = 0$ (see below) differ from the above three sub-sub-cases in the same way that the two sub-sub-cases in sub-case 4(c) differ: instead of taking a reading of $T_h$ with $\beta$ at the start, take one where $\beta$ appears just before the string $q_h^s$. Since the reasoning is so similar, these sub-sub-cases are thus treated in an abbreviated form:

(4) There are no $u_{h+1}$ above $D_g$. Suppose there are $r_1$ nodes $m_h$ below $D_g$ and $r_2$ above. Then

$$T_h = P_{\text{sylv}}(u_{h+1}^{r_1} m_h^{r_2} \lambda D_g m_h \beta q_h^{s_1} \delta D_h).$$

Let

$$T_{h+1} = P_{\text{sylv}}(u_{h+1}^{r_1} m_h^{r_2} \lambda D_g m_h \beta q_h^{s_1} \delta D_h u_{h+1}^{r_2}).$$

Note that $T_h \sim T_{h+1}$.

(5) There are $o_1$ nodes $u_{h+1}$ below $D_g$ and $o_2$ above, where $o_2 \geq t_2$. Then

$$T_h = P_{\text{sylv}}(u_{h+1}^{o_1} \lambda D_g u_{h+1}^{o_2} m_h \beta q_h^{s_1} \delta D_h).$$

Let

$$T_{h+1} = P_{\text{sylv}}(u_{h+1}^{o_1} \lambda D_g u_{h+1}^{o_2} m_h \beta q_h^{s_1} \delta D_h u_{h+1}^{o_2}).$$

(6) There are $o_1$ nodes $u_{h+1}$ below $D_g$ and $o_2$ above, where $o_2 < t_2$. Then

$$T_h = P_{\text{sylv}}(u_{h+1}^{o_1} \lambda D_g u_{h+1}^{o_2} m_h \beta q_h^{s_1} \delta D_h).$$
Let
\[ T_{h+1} = P_{\text{sylv}}(u_{h+1}^{o_1-l_2+o_2} D_\beta u_{h+1}^{o_2} m_h^\beta q_h^\delta D_h u_{h+1}^{l_2-o_2}). \]

Note that \( o_1 - l_2 + o_2 = t_1 \) and that \( T_h \sim T_{h+1} \).

The subtree \( D_h \), the nodes \( m_h \), and possibly some of the \( q_h \) below \( D_h \) make up \( B_h \). This tree \( B_h \), together with the nodes \( q_h \) above \( D_h \), the nodes \( u_{h+1} \) and \( D_q \) together make up \( D_{h+1} \). Adding the remaining nodes \( q_h = q_{h+1} \) below \( D_h \) gives the tree \( E_{h+1} \). So \( T_{h+1} \) satisfies P1. The other trees \( E_{i,j} \) in \( T_2 \) were in \( \lambda \); this still holds and so \( T_{h+1} \) satisfies P2. Every node not in \( E_{h+1} \) is in its left-minimal or right-maximal subtree; together with the fact that \( T_h \) satisfies P3, this shows that \( T_{h+1} \) satisfies P3. Finally, \( T_{h+1} \) satisfies P4 since \( T_h \) does. (Note that \( m_h \) is below \( p_h = u_{h+1} \), but this does not matter since \( u_h \) is not in \( U_{h+1} \).)

Conclusion. The tree \( T_n \) satisfies the conditions P1–P4. In particular, \( E_n \) appears at the root of \( T_n \). Since \( u_n \) is the root of \( U \) (since it is obviously the last node visited by the topmost traversal), \( B_n = U \). Thus \( C_n \) is \( U \) with all nodes \( m_n \) deleted except the topmost. Since \( q_n \) is undefined, \( E_n = D_n = C_n \). Hence \( C_n \) appears at the roots of \( T_n \) and \( U \). However, the number of nodes \( m_n \) in the trees \( T_n \) and \( U \) are equal, and since \( m_n \) is the smallest symbol appearing in \( T_n \) or \( U \), all the nodes \( m_n \) in \( T_n \) and \( U \) must appear in the paths of left child nodes in \( T_n \) and \( U \), in the left subtree of the single node \( m_n \) in \( E_n \). Hence \( T_n = U \).

Thus there is a sequence \( T = T_0, T_1, \ldots, T_n = U \) with \( T_i \sim T_{i+1} \) for \( i \in \{1, \ldots, n-1\} \). Since \( T \) and \( U \) were arbitrary elements of an arbitrary connected component of \( K(\text{sylv}_n) \), the diameter of any connected component of \( K(\text{sylv}_n) \) is at most \( n \). This completes the proof. □

7. Stalactic monoid

The stalactic monoid is primarily used in the definition of the more interesting taiga monoid (see Section 8), but its cyclic shift graph exhibits a particularly simple structure. As usual, this section recalls only the essentials background; for further reading, see [Pri13].

A stalactic tableau is a finite array of symbols from \( A \) in which columns are top-aligned, and two symbols appear in the same column if and only if they are equal. For example,

\[
\begin{array}{cccc}
3 & 1 & 2 & 6 \\
3 & 1 & 6 & 5 \\
1 & & & 5 \\
1 & & & \\
\end{array}
\]

(7.1)

is a stalactic tableau. The insertion algorithm is very straightforward:

Algorithm 7.1.

Input: A stalactic tableau \( T \) and a symbol \( a \in A \).
Output: A stalactic tableau \( T \leftarrow a \).
Method: If \( a \) does not appear in \( T \), add \( a \) to the left of the top row of \( T \). If \( a \) does appear in \( T \), add \( a \) to the bottom of the (by definition, unique) column in which \( a \) appears. Output the new tableau.
Thus one can compute, for any word $u \in A^*$, a stalactic tableau $P_{\text{stal}}(u)$ by starting with an empty stalactic tableau and successively inserting the symbols of $u$, proceeding right-to-left through the word. For example $P_{\text{stal}}(361135112565)$ is \((7.1)\). Notice that the order in which the symbols appear along the first row in $P_{\text{stal}}(u)$ is the same as the order of the rightmost instances of the symbols that appear in $u$. Define the relation $\equiv_{\text{stal}}$ by

$$u \equiv_{\text{stal}} v \iff P_{\text{stal}}(u) = P_{\text{stal}}(v)$$

for all $u, v \in A^*$. The relation $\equiv_{\text{stal}}$ is a congruence, and the stalactic monoid, denoted $\text{stal}$, is the factor monoid $A^*/\equiv_{\text{stal}}$. The stalactic monoid of rank $n$, denoted $\text{stal}_{n}$, is the factor monoid $A_n^*/\equiv_{\text{stal}}$ (with the natural restriction of $\equiv_{\text{stal}}$). Each element $[u]_{\equiv_{\text{stal}}}$ (where $u \in A^*$) can be identified with the stalactic tableau $P_{\text{stal}}(u)$. Note that if $T$ is a stalactic tableau consisting of a single row (that is, will all columns having height 1), then there is a unique word $u \in A^*$, formed by reading the entries of $T$ left-to-right, such that $P_{\text{stal}}(u) = T$. Thus, if $T = P_{\text{stal}}(a_1 \cdots a_k)$ and $U \in \text{stal}$ is such that $U \sim T$, then $U = P_{\text{stal}}(a_i \cdots a_k a_1 \cdots a_{i-1})$ for some $i$.

The monoid $\text{stal}$ is presented by $\langle A | R_{\text{stal}} \rangle$, where

$$R_{\text{stal}} = \{ (bavb, abvb) : a, b \in A, \ v \in A^* \}.$$ 

The monoid $\text{stal}_n$ is presented by $\langle A_n | R_{\text{stal}} \rangle$, where the set of defining relations $R_{\text{stal}}$ is naturally restricted to $A_n^* \times A_n^*$. Notice that $\text{stal}$ and $\text{stal}_n$ are multihomogeneous.

[The stalactic monoid was originally defined by Hivert et al. \cite{HNT07} § 3.7 using the defining relations $\{ (bavb, abvb) : b \in A, v \in A^* \}$; this would yield a monoid that is anti-isomorphic to $\text{stal}$. The definition of $\text{stal}$ here follows Priez \cite{Pri13} Example 3] so as to be compatible with the construction of the taiga monoid below.]

**Proposition 7.2.** Connected components of $K(\text{stal})$ are properly contained in $\equiv_{\text{ev}}$-classes.

**Proof.** By Lemma 2.1(1), $\sim \subseteq \equiv_{\text{ev}}$, so it remains to prove that equality does not hold. Since no defining relations in $R_{\text{stal}}$ can be applied to a word without repeated letters, a stalactic tableau consisting of a single row is represented by exactly one word over $A^*$. In particular, an element of the form $[\begin{array}{ccc} k & n & 1 \end{array}]$ is represented by the unique word $k \cdots n1 \cdots (k-1)$. Thus the elements of this form are all $\sim$-related and form a $\sim$-class and thus a connected component of $K(\text{stal})$. Thus, for $n \geq 3$, the elements $[\begin{array}{ccc} 1 & 2 & 3 \end{array}]$ and $[\begin{array}{ccc} 2 & 1 & 3 \end{array}]$ are $\equiv_{\text{ev}}$-related but in different connected components of $K(\text{stal})$. \hfill \Box

However, it is possible to characterize connected components of $K(\text{stal})$.

For any stalactic tableau $T$, let $\iota(T)$ be the word obtained by reading from left to right the symbols that appear in columns of height 1. Define $\kappa(T)$ to be the pair $((\iota(T))_\sim, \text{ev}(T))$. (Notice that $[\iota(T)]_\sim = [\iota]_\sim$.)

**Proposition 7.3.**

1. Two elements of $\text{stal}$ lie in the same connected component of $K(\text{stal})$ if and only if they have the same image under the map $\kappa$.

2. The maximum diameter of a connected component of $K(\text{stal})$ is 3.
(3) The maximum diameter of a connected component of $K(\text{stal}_n)$ is 3 if $n \geq 3$, and is respectively 1 and 0 for $n = 2$ and $n = 1$.

Proof. Suppose $T, U \in \text{stal}$ are such that $T \sim U$. Then there exist $x, y \in \mathcal{A}^*$ such that $xy$ represents $T$ and $yx$ represents $U$. Deleting from $x$ and $y$ every symbol $a$ such that $|x|_a + |y|_a > 1$ yields two words $x'$ and $y'$ with $\iota(T) = x'y'$ and $\iota(U) = y'x'$; thus $\iota(T) \sim \iota(U)$. Furthermore, since $T \sim U$ it follows that $ev(T) = ev(U)$. Thus $\kappa(T) = \kappa(U)$. Iterating this reasoning shows that if $T$ and $U$ lie in the same connected component of $K(\text{stal})$, then $\kappa(T) = \kappa(U)$.

Now suppose that $T, U \in \text{stal}$ are such that $\kappa(T) = \kappa(U)$. Let $B = \{b_1, \ldots, b_k\}$ consist of exactly the symbols in $\mathcal{A}$ that appear more than once in $U$ and thus in $T$. Choose any word $t$ such that $\text{P}_{\text{stal}}(t) = T$, and delete the leftmost appearance of each symbol in $B$ from $t$; call the resulting word $t'$. Let $t_0 = b_1 \cdots b_k t' \in \mathcal{A}^*$. Since the order of columns in a stalactic tableau corresponding to a word is determined by the rightmost appearance of each symbol in that word, and since $ev(t) = ev(t_0)$, it follows that $\text{P}_{\text{stal}}(t_0) = T$. Let $T_1 = \text{P}_{\text{stal}}(t' b_1 \cdots b_k)$, so that $T \sim T_1$. Then $T_1$ is of the form

Symbols that appear once

\[
\begin{array}{cccc}
\{a_1, a_m\} & b_1 & b_2 & b_k \\
& b_1 & & b_k \\
& b_1 & & \\
\end{array}
\]

(7.2)

Similarly, choose any word $u$ with $\text{P}_{\text{stal}}(u) = U$, delete the leftmost appearance of each symbol in $B$ to obtain a word $u'$, and let $u_0 = b_1 \cdots b_k u'$; then $\text{P}_{\text{stal}}(u_0) = U$. Let $U_1 = \text{P}_{\text{stal}}(b_1 \cdots b_k u')$. Then $\iota(U_1) \sim \iota(U) \sim \iota(T) \sim \iota(T_1)$, and so $\iota(U_1) \sim \iota(T_1)$. Thus $U_1$ of the form

Symbols that appear once

\[
\begin{array}{cccc}
\{a_{h+1}, a_m\} & a_h & b_1 & b_2 & b_k \\
& b_1 & & b_k \\
& b_1 & & \\
\end{array}
\]

(7.3)

Note that (7.2) and (7.3) differ only by a cyclic permutation of the columns of height 1.

Let $s \in \mathcal{A}^*$ be such that $\text{P}_{\text{stal}}(a_{h+1} \cdots a_m a_1 \cdots a_h s) = U_1$. Delete the leftmost appearance of each symbol in $B$ from the word $s$; call the resulting word $s'$. Again using the fact that the rightmost appearance of each symbol determines the order of columns, $\text{P}_{\text{stal}}(a_{h+1} \cdots a_m a_1 \cdots a_h s') = U_1$. Similarly, $\text{P}_{\text{stal}}(a_1 \cdots a_h s' a_{h+1} \cdots a_m b_1 \cdots b_k) = T_1$. Hence $U_1 \sim T_1$.

Thus $T \sim T_1 \sim U_1 \sim U$, and so there is a path of length at most 3 from $T$ to $U$. Hence $T$ and $U$ lie in the same connected component. This completes the proof of part 1).

Furthermore, this shows that connected components of $K(\text{stal})$ have diameter at most 3. Direct calculation shows that the connected component $K(\text{stal}, \text{P}_{\text{stal}}(1233))$ is as shown in Figure 17 and thus has diameter 3. This proves part 2). For part 3), note that connected components of $K(\text{stal}_1)$ are
singleton vertices, and the connected components of $K(\text{stal}_2)$ have at most two vertices corresponding to the two possible orders of columns filled by symbols 1 and 2.

\section{Taiga monoid}

The taiga monoid is a quotient of the sylvester monoid that is associated with a modified notion of binary search tree. As usual, this section only recalls the essential facts; see [Pri13, \S 5] for further background.

A \emph{binary search tree with multiplicities} is a labelled search tree in which each label appears at most once, where the label of each node is greater than the label of every node in its left subtree, and less than the label of every node in its right subtree, and where each node label is assigned a positive integer called its \emph{multiplicity}. An example of a binary search tree is:

\begin{equation}
\begin{array}{c}
1^2
\end{array}
\end{equation}

(The superscripts on the labels in each node denote the multiplicities.)

\begin{algorithm}[8.1.]
\textbf{Input:} A binary search tree with multiplicities $T$ and a symbol $a \in \mathcal{A}$.
\textbf{Output:} A binary search tree with multiplicities $T \leftarrow a$.
\textbf{Method:} If $T$ is empty, create a node, label it by $a$, and assign it multiplicity 1. If $T$ is non-empty, examine the label $x$ of the root node; if $a < x$, recursively insert $a$ into the left subtree of the root node; if $a > x$, recursively insert $a$ into the right subtree of the root node; if $a = x$, increment by 1 the multiplicity of the node label $x$.

Thus one can compute, for any word $u \in \mathcal{A}^*$, a binary search tree with multiplicities $P_{\text{taig}}(u)$ by starting with an empty binary search tree with multiplicities and successively inserting the symbols of $u$, proceeding right-to-left through the word. For example $P_{\text{taig}}(65117563254)$ is (8.1).

Define the relation $\equiv_{\text{taig}}$ by

\begin{equation}
u \equiv_{\text{taig}} v \iff P_{\text{taig}}(u) = P_{\text{taig}}(v),
\end{equation}

for all $u, v \in \mathcal{A}^*$. The relation $\equiv_{\text{taig}}$ is a congruence, and the \emph{taiga monoid}, denoted $\text{taig}$, is the factor monoid $\mathcal{A}^*/\equiv_{\text{taig}}$; the \emph{taiga monoid of rank} $n$, denoted $\text{taig}_n$, is the factor monoid $\mathcal{A}_n^*/\equiv_{\text{taig}}$ (with the natural restriction
of \(\equiv_{taig}\). Each element \([u]_{\equiv_{taig}}\) can be identified with the binary search tree with multiplicities \(P_{taig}(u)\).

As with ordinary binary search trees, a *reading* of a binary search tree with multiplicities \(T\) is a word \(u\) such that \(P_{taig}(u) = T\). It is easy to see that a reading of \(T\) is a word formed from the symbols that appear in the nodes of \(T\), with the number of times each symbol appears being its multiplicity, arranged so that the rightmost symbol from a parent node appears to the right of the rightmost symbol from its children. For example, \(135671456254\) is a reading of \((8.1)\).

The monoid \(taig\) is a quotient of the sylvester monoid under the homomorphism \(\tau : sylv \rightarrow taig\) sending \([u]_{sylv}\) to \([u]_{taig}\) (or equivalently, \(P_{sylv}(u)\) to \(P_{taig}(u)\)) for all \(u \in A^n\). This homomorphism naturally restricts to a surjective homomorphism \(\tau : sylv_n \rightarrow taig_n\). This connection between \(sylv\) and \(taig\) makes it possible to use the reasoning about the diameters of connected components in \(K(sylv_n)\) to prove the corresponding results for \(K(taig_n)\).

Since defining relations in \(R_{stal}\) involve repeated symbols, only relations in \(R_{sylv}\) apply to standard words. That is, standard words are related by \(\equiv_{taig}\) if and only if they are related by \(\equiv_{sylv}\). Thus the proof of Lemma 6.3 applies in \(taig_n\) to establish the following result:

**Lemma 8.2.** There is a connected component in \(K(taig_n)\) of diameter at least \(n - 1\).

**Lemma 8.3.** Every connected component of \(K(taig_n)\) has diameter at most \(n\).

**Proof.** Define a map \(\psi : taig_n \rightarrow sylv_n\) that maps a binary search tree with multiplicities \(T\) to the standard binary search tree obtained by deleting the multiplicities of \(T\). Note that, two elements \(T, U \in taig_n\) are equal if and only if \(\psi(T) = \psi(U)\) and \(ev(T) = ev(U)\).

Suppose \(P, Q \in taig_n\) are such that \(\psi(P) \sim \psi(Q)\) (in \(sylv_n\)) and \(ev(P) = ev(Q)\). Then there are readings \(xy\) of \(\psi(P)\) and \(yx\) of \(\psi(Q)\). Replacing each symbol \(a\) with \(a^{k_a}\) for each \(a \in A_n\), where \(k_a\) is the \(a\)-th component of \(ev(P) = ev(Q)\), gives readings \(\hat{x}\hat{y}\) of \(P\) and \(\hat{y}\hat{x}\) of \(Q\), so that \(P \sim Q\) (in \(taig_n\)).

Let \(T\) and \(U\) be elements of the same connected component of \(K(taig_n)\). Then \(T \equiv_{ev} U\). By the strategy for building a path in \(K(sylv_n)\) in the proof of Proposition 6.12 there is a path \(\psi(T) = T_0, \ldots, T_n = \psi(U)\) in \(K(sylv_n)\). By the reasoning in the previous paragraph, this path lifts to a path \(T = T_0, \ldots, T_n = U\) in \(K(taig_n)\). Thus the diameter of \(K(taig_n, T)\) is at most \(n\).

Combining Lemmata 8.2 and 8.3 gives the result:

**Theorem 8.4.**

1. Connected components of \(K(taig)\) coincide with \(\equiv_{ev}\)-classes in \(taig\).

2. The maximum diameter of a connected component of \(K(taig_n)\) is \(n - 1\) or \(n\).
9. Baxter monoid

The Baxter monoid is a monoid of pairs of twin binary search trees. As in previous sections, only the essential facts are given here; see [Gir12] for further background.

A left strict binary search tree is a labelled rooted binary tree where the label of each node is strictly greater than the label of every node in its left subtree, and less than or equal to every node in its right subtree; see the left tree shown in (9.1) below for an example.

The canopy of a binary tree $T$ is the word over $\{0, 1\}$ obtained by traversing the empty subtrees of the nodes of $T$ from left to right, except the first and the last, labelling an empty left subtree by 1 and an empty right subtree by 0. (See (9.1) below for examples of canopies.)

A pair of twin binary search trees consist of a left strict binary search tree $T_L$ and a right strict binary search tree $T_R$, such that $T_L$ and $T_R$ contain the same symbols, and the canopies of $T_L$ and $T_R$ are complementary, in the sense that the $i$-th symbol of the canopy of $T_L$ is 0 (respectively 1) if and only if the $i$-th symbol of the canopy of $T_L$ is 1 (respectively 0). The following is an example of a pair of twin binary search trees, with the complementary canopies 0110101 and 1001010 shown in grey:

(9.1)

The insertion algorithm for left strict binary search trees is symmetric to Algorithm 6.1:

Algorithm 9.1 (Left strict leaf insertion).

Input: A left strict binary search tree $T$ and a symbol $a \in A$.
Output: A left strict binary search tree $a \rightarrow T$.
Method: If $T$ is empty, create a node and label it $a$. If $T$ is non-empty, examine the label $x$ of the root node; if $a < x$, recursively insert $a$ into the left subtree of the root node; otherwise recursively insert $a$ into the right subtree of the root node. Output the resulting tree.

Thus one can compute, for any word $u \in A^*$, a pair of twin binary search trees $P_{\text{baxt}}(u) = (T_L, T_R)$, where $T_R$ is $P_{\text{sylv}}(u)$ and $T_L$ is obtained by starting with an empty left strict binary search tree and successively inserting the symbols of $u$, proceeding left-to-right through the word. For example, $P_{\text{baxt}}(42531643)$ is (9.1).

A reading of a pair of twin binary search trees $(T_L, T_R)$ is a word $u$ such that $P_{\text{baxt}}(u) = (T_L, T_R)$. It is easy to see that a reading of $(T_L, T_R)$ is a word formed from the symbols appearing in the two binary trees $T_L$ and $T_R$ (which, by definition, contain the same symbols), ordered so that every symbol from a parent node in $T_L$ appears to the left of those from its children in $T_L$, and every symbol from parent node in $T_R$ appears to the right of those from its children.
Define the relation $≡_{baxt}$ by

$$u ≡_{baxt} v \iff \mathcal{P}_{baxt}(u) = \mathcal{P}_{baxt}(v),$$

for all $u, v \in A^*$. The relation $≡_{baxt}$ is a congruence, and the Baxter monoid, denoted $baxt$, is the factor monoid $A^*/≡_{baxt}$: the Baxter monoid of rank $n$, denoted $baxtn$, is the factor monoid $A^*_n/≡_{baxt}$ (with the natural restriction of $≡_{baxt}$). Each element $[u]_{≡_{baxt}}$ (where $u \in A^*$) can be identified with the pair of twin binary search trees $\mathcal{P}_{baxt}(u)$. The words in $[u]_{≡_{baxt}}$ are precisely the readings of $\mathcal{P}_{baxt}(u)$.

The monoid $baxt$ is presented by $\langle A | R_{baxt} \rangle$, where

$$R_{baxt} = \{(cudavb, cuadvb) : a \leq b < c \leq d, u, v \in A^* \} \cup \{(budavc, buadvc) : a < b \leq c < d, u, v \in A^* \};$$

see [Gir12, Definition 3.1]. The monoid $baxtn$ is presented by $\langle A_n | R_{baxt} \rangle$, where the set of defining relations $R_{baxt}$ is naturally restricted to $A^*_n \times A^*_n$.

Note that $baxt$ and $baxtn$ are multihomogeneous.

There is a straightforward method for extracting every possible reading from a pair of binary search trees $(T_L, T_R)$:

**Method 9.2.** Input: A pair of twin binary search trees $(T_L, T_R)$.

Output: A reading of $(T_L, T_R)$.

1. Set $(U_L, U_R)$ to be $(T_L, T_R)$. (Throughout this computation, $U_L$ is a forest of left strict binary search trees and $U_R$ is a right strict binary search tree.)
2. If $U_L$ and $U_R$ are empty, halt.
3. Given some $(U_L, U_R)$, choose and output some symbol $a$ that labels a root of some tree in the forest $U_L$ and a leaf of the tree $U_R$.
4. Deleting the corresponding root vertex of $U_L$ and the corresponding leaf vertex of $U_L$.

This is essentially [Gir12 Algorithm on p.133], except that the method given here is non-deterministic in that there may be several choices for $a$ in step 3. As these choices vary, all possible readings of $(T_L, T_R)$ are obtained.

**Proposition 9.3.** Connected components of $K(baxt)$ are properly contained in $≡_{ev}$-classes.

**Proof.** Connected components of $K(baxt)$ are $\sim^*$-classes, and by [Lemma 2.1] $\sim^* \subseteq ≡_{ev}$. It thus remains to prove that equality does not hold. Since all the defining relations in $R_{baxt}$ have length at least 4, it follows that none of these relations can be applied to words of length 3. Thus all length-3 words represent distinct elements of $baxt$. Therefore the words in $\{123, 231, 312\}$ represent all the elements in one $\sim^*$-class in $baxt$ (and thus one connected component of $K(baxt)$). The word 132 is not in this set, but is in the same $≡_{ev}$-class. This completes the proof.

A natural question at this point is whether $\sim^*$ and $≡_{ev}$ do not coincide in $baxt$ only for the slightly trivial reason that relations in $R_{baxt}$ do not apply to words of length 3, and that perhaps $\sim^*$ and $≡_{ev}$ coincide for elements represented by words of length 4 or more. However, consider the elements...
of \( \text{baxt} \) represented by the words 1243, 2431, 4312, and 3124:

\[
\begin{align*}
P_{\text{baxt}}(1243) &= \left( \begin{array}{c}
1 \\
2 \\
3 \\
4 \\
\end{array} \right), \\
P_{\text{baxt}}(2431) &= \left( \begin{array}{c}
1 \\
2 \\
3 \\
4 \\
\end{array} \right), \\
P_{\text{baxt}}(4312) &= \left( \begin{array}{c}
1 \\
2 \\
3 \\
4 \\
\end{array} \right), \\
P_{\text{baxt}}(3124) &= \left( \begin{array}{c}
1 \\
2 \\
3 \\
4 \\
\end{array} \right).
\end{align*}
\]

It is straightforward to prove that there is exactly one reading of each of these pairs of twin binary search trees: for example, consider extracting a reading from \( P_{\text{baxt}}(2431) \). Following Method 9.2, \( (U_L, U_R) \) is initially \( P_{\text{baxt}}(2431) \). The first output symbol must be 2, since this is the unique root in \( U_L \). Deleting the corresponding vertices yields

\[
(U_L, U_R) = \left( \begin{array}{c}
1 \\
2 \\
3 \\
4 \\
\end{array} \right).
\]

From this point onwards, there will be exactly one leaf vertex in \( U_R \), and so only one choice for the symbol to output. Hence the method must output 4, 3, 1. Hence the unique reading of \( P_{\text{baxt}}(2431) \) is 2431.

Hence the element represented by the words in \( \{1243, 2431, 4312, 3124\} \) form a single \( \sim^* \)-class and so (for example) 1234 and 1243 are not related by \( \sim^* \).

Question 9.4. (1) Is there a characterization of \( \sim^* \)-classes in \( \text{baxt} \)?
(2) Is there a bound on the diameter of \( \sim^* \)-classes in \( \text{baxt}_n \)?

10. Questions

Question 10.1. For each monoid \( M \in \{\text{plac, hypo, sylv, stal, taig, baxt}\} \), is there an efficient algorithm that takes two elements \( T, U \in M \) such that \( T \equiv_{ev} U \) and computes the distance between them in \( K(M) \)?

With regard to the previous question, note that it is always possible to compute the distance via a brute-force computation: one could build the entire connected component \( K(M, T) \), then find the shortest path from \( T \) to \( U \). The question is whether this can be done efficiently. Note that the strategies for constructing paths in the various proofs in this paper do not in general find shortest paths between two elements; see Example 5.8.
11. APPENDIX: CONJUGACY

In a group, the relation ∼ is simply the usual notion of conjugacy. The concept of cyclic shifts can thus be viewed in an algebraic way as a generalization to monoids of the concept of conjugacy in groups. Another possible generalization, introduced by Otto [Ott84], is o-conjugacy, defined by

\[(11.1) \quad x \sim_o y \iff (\exists g, h \in M)(xg = gy \land hx = yh).\]

The relation ∼_o is an equivalence relation. The following result describes how ∼_o is related to ∼ and ≡_ev:

**Proposition 11.1.**

1. In any monoid, ∼^∗ ⊆ ∼_o.
2. In any multihomogeneous monoid ∼_o ⊆ ≡_ev.

**Proof.** For the first part, see [AKM14, § 1]. For the second part, see [CM15, Lemma 3.2]. □

Thus in a multihomogeneous monoid, ∼^∗ ⊆ ∼_o ⊆ ≡_ev. Since ∼^∗ = ≡_ev in the plactic, hypoplactic, sylvester, and taiga monoids, in these settings ∼_o coincides with ∼^∗ and ≡_ev and thus is not of independent interest. However, it turns out that ∼_o and ≡_ev coincide in the stalactic and Baxter monoids. (Recall that ∼^∗ is strictly contained in ≡_ev in both these monoids; see Propositions 7.2 and 9.3.)

**Proposition 11.2.** In stal, the relations ∼_o and ≡_ev coincide.

**Proof.** Let u, v ∈ A∗ be such that u ≡_ev v. In particular, P_{stal}(u) and P_{stal}(v) both have m columns, for some m ∈ N. For i ∈ {1, ..., m}, let a_i ∈ A be the symbol that appears in the i-th column of P_{stal}(u) and let b_i ∈ A be the symbol that appears in the i-th column of P_{stal}(v). Let g = a_1 \cdots a_m and h = b_1 \cdots b_m. Notice that every symbol that appears in u and v appears exactly once in g and h. Hence gu ≡_ev vg and uh ≡_ev hv. Furthermore, the order of rightmost appearances of symbols in gu and vg is identical; together with gu ≡_ev vg, this implies that P_{stal}(gu) = P_{stal}(vg). Thus gu ≡_stal vg. Similarly, uh ≡_stal hv. Hence u ∼_o v. This proves that ≡_ev ⊆ ∼_o. The opposite inclusion follows from Proposition 11.1(2). □

**Proposition 11.3.** In baxt, the relations ∼_o and ≡_ev coincide.

**Proof.** Let p, q ∈ A∗ be such that p ≡_ev q. By [CM, Proposition 3.8], ppq ≡_{baxt} pqq and qpp ≡_{baxt} gqp. Hence pg ≡_{baxt} gq with g = pq, and hp ≡_{baxt} qh with h = qp. Thus p ∼_o q. This proves that ≡_ev ⊆ ∼_o. The opposite inclusion follows from Proposition 11.1(2). □
