Deep Learning Enabled Preamble Collision Resolution in Distributed Massive MIMO

Jie Ding, Daiming Qu, Pei Liu, and Jinho Choi, Senior Member, IEEE

Abstract—Preamble collision is a bottleneck that impairs the performance of random access (RA) user equipment (UE) in grant-free RA (GFRA). In this paper, by leveraging distributed massive multiple input multiple output (mMIMO) together with deep learning, a novel access point (AP) clustering scheme is proposed to mitigate the preamble collision problem in GFRA. The key idea is to identify and employ the neighboring APs of a collided RA UE for its data decoding rather than all the APs, so that the mutual interference among collided RA UEs can be effectively mitigated. To this end, we first design a tailored deep neural network (DNN) to enable the preamble multiplicity estimation in GFRA. With the estimated preamble multiplicity, we then propose a $K$-means AP clustering algorithm to cluster the neighboring APs of collided RA UEs and organize each AP cluster to decode the received data individually. Simulation results show that a decent performance of preamble multiplicity estimation in terms of accuracy and reliability can be achieved by the proposed DNN, and confirm that the proposed DNN based AP clustering scheme is effective in preamble collision resolution in GFRA, which is able to achieve a near-optimal performance in terms of uplink achievable rate per collided RA UE, and offer significant performance improvement over traditional schemes.

Index Terms—Preamble collision resolution, grant-free random access, deep learning, distributed massive MIMO, clustering.

I. INTRODUCTION

The Fifth Generation (5G) and future wireless communication focus on three major communication categories: enhanced mobile broadband (eMBB), ultra-reliable low-latency communication (URLLC), and massive machine-type communication (MTC) (mMTC) [1]. Among them, mMTC has been regarded as an essential communication paradigm for a wide range of applications including healthcare, smart home, smart agriculture, and logistics and tracking [2]. Since mMTC usually features with massive uplink access and limited packet size in nature, it imposes new requirements and challenges in terms of random access (RA) design [3].

In Long Term Evolution (LTE) systems, a typical grant-based RA procedure is used to provide reliable access for human-type communication (HTC). Since the grant-based RA requires handshaking to issue exclusive channel reservation for each RA user equipment (UE), it is unable to support massive access due to limited channel resource utilization and also results in high signalling overhead to mMTC RA UEs. In the light of this, grant-free RA (GFRA) procedure has been recently actively studied in MTC for low signalling overhead and latency [4]–[6].

In GFRA, the request-grant handshaking steps in grant-based RA for channel reservations are skipped, which allows RA UEs to access the network without grant acquisition once they have data to send. As a result, the signalling overhead is reduced. Nevertheless, RA UEs have to contend for channel resources in an uncoordinated manner due to no channel reservation. Therefore, making efficient use of channel resources to simultaneously support a large number of RA UEs is essential.

Recently, massive multiple input multiple output (mMIMO) has been a key technology in 5G and future wireless communication to mitigate wireless resource scarcity and increase channel resource utilization [2]. As a large number of either co-located antennas (co-located mMIMO) or distributed antennas (distributed mMIMO) are employed at the base station (BS) in mMIMO, mutual channel orthogonality among RA UEs (also known as favorable propagation) can be asymptotically achieved as the number of antennas increases [8], [9]. By taking advantage of this property, RA UEs can share the same channel resource simultaneously without the need of channel reservation, while beamforming techniques can be used to spatially separate them in an effective manner. Thus, mMIMO has been considered a prominent enabler for GFRA.

A number of research works have been undertaken to study the performance of GFRA with co-located mMIMO. As pointed out by [10], preamble collision (i.e., multiple RA UEs choose the same preamble) is the main bottleneck in GFRA with co-located mMIMO that curbs the performance of RA UEs. In fact, since the traffic of mMTC RA UEs is usually random and sporadic, the BS has neither prior information of RA UEs’ activity nor their channel state information (CSI) in each GFRA slot. Thus, each RA UE needs to send a preamble prior to data for channel estimation. However, since the number of orthogonal preambles is limited and RA UEs choose preambles in a random and uncoordinated manner, there could be multiple RA UEs that select the same preamble. As a result, the estimated CSI for these collided RA UEs becomes inaccurate and data from them would be incorrectly decoded. Various approaches have been developed to address the preamble collision issue in GFRA with co-located mMIMO. For instance, non-orthogonal preambles are considered in [11] to expand preamble space without constraint on the preamble length and sporadic traffic pattern of RA UEs is exploited to...
detect and identify active RA UEs. In [12], a super-preamble consisting of multiple short preambles is adopted and features of favorable propagation and channel hardening in mMIMO are exploited to identify the super-preamble of each RA UE. In [13], an ensemble independent component analysis (EICA) based pilot random access is proposed to enable joint active UEs detection and uplink data decoding. These approaches are effective in reducing the preamble collision. However, how to resolve the preamble collision when it occurs is still an open issue in GFRA with co-located mMIMO. In particular, since all the signals of collided RA UEs are multiplexed and assembled at the centralized BS in co-located mMIMO, the BS can only deem that the received signals come from a single RA UE, making it practically difficult to find preamble multiplicity (i.e., the number of the RA UEs that select the same preamble) and resolve the preamble collision. Note that in [14], an effective preamble collision resolution scheme is proposed in co-located mMIMO. However, it only works in grant-based RA as a feedback after preamble detection from the BS to RA UEs is required.

Different from co-located mMIMO in terms of antenna topology, distributed mMIMO employs a large number of geographically distributed access points (APs) to serve UEs, and each AP is equipped with a single or a few antennas. Compared to co-located mMIMO, distributed mMIMO provides macro-diversity and has enhanced network coverage and capacity [15]–[20]. Nevertheless, the existing works on distributed mMIMO mainly focus on the performance analysis under the conditions that fully or partially CSI of UEs is known at the BS, which is not the case in the context of GFRA. Thus, GFRA with distributed mMIMO has not been well investigated yet. On the other hand, since APs are spatially distributed in distributed mMIMO and signals to different APs undergo different levels of large-scale fading, only neighboring APs within a communication range of an UE have non-negligible channel gains [18], [19], which implies signal spatial sparsity in distributed mMIMO [21]. This feature opens up a possibility for preamble collision resolution in GFRA. Specifically, due to the sporadic traffic pattern of RA UEs, collided RA UEs could be separate in space and surrounded by different groups of APs. If the BS is able to identify neighboring APs of a collided RA UE in GFRA and only employs the neighboring APs rather than all the APs to serve the collided RA UE, the interference from other collided RA UEs in the preamble domain could be largely mitigated.

Motivated by this, a novel deep learning based AP clustering scheme is proposed to resolve preamble collision in GFRA by leveraging distributed mMIMO. To facilitate preamble collision resolution, collided preamble multiplicity needs to be estimated by the BS. To this end, we first design a tailored deep neural network (DNN) to enable the preamble multiplicity estimation in GFRA. With the estimated preamble multiplicity, we propose a $K$-means AP clustering algorithm to cluster the neighboring APs of collided RA UEs, and then each AP cluster is employed to decode the received data individually. Under practical wireless environments and different deployments of distributed mMIMO, we investigate and analyze the performance of the proposed DNN and show that decent estimation accuracy and reliability can be achieved. Simulation results further confirm that the proposed DNN based AP clustering scheme is able to achieve a near-optimal performance in terms of preamble collision resolution, and provide significant performance enhancement over the traditional schemes.

The novelty and contribution of this paper are summarized as follows.

- We propose the idea of DNN based AP clustering scheme to mitigate the impact of preamble collision on the performance of collided RA UEs in GFRA with distributed mMIMO, which requires neither prior information of RA UEs’ activity nor their CSI. To the best of our knowledge, this is the first work that aims to resolve the preamble collision in GFRA by taking advantage of distributed mMIMO.

- To enable preamble collision resolution in GFRA, the preamble multiplicity is an indispensable parameter that needs to be estimated by the BS. To this end, we for the first time leverage deep learning based classification models to enable the preamble multiplicity estimation in distributed mMIMO, where connections between received preamble signal patterns and preamble multiplicities are exploited.

- With the estimated preamble multiplicity, we further propose a $K$-means AP clustering algorithm to enable the neighboring AP clustering of collided RA UEs and organize each AP cluster instead of all the APs to decode data of collided RA UEs individually. Thereby, the mutual interference among collided RA UEs in the preamble domain could be effectively mitigated, which results in appreciable performance improvement.

The remainder of this paper is organized as follows. In Section II, the system model of GFRA with distributed mMIMO is introduced and the motivation of this work is explained theoretically by a toy example. In Section III, the proposed DNN for preamble multiplicity estimation is detailed and its estimation performance is investigated. In Section IV, the proposed $K$-means AP clustering algorithm is presented and its performance in terms of uplink achievable rate per collided RA UE is evaluated. The work is concluded in Section V.

**Notation:** Boldface lower and upper case symbols represent vectors and matrices, respectively. $I_n$ is the $n \times n$ identity matrix. The conjugate, transpose, and complex conjugate transpose operators are denoted by $(\cdot)^*$, $(\cdot)^T$ and $(\cdot)^H$. $\| \cdot \|$ denotes the Euclidean norm. $x \sim \mathcal{CN}(0, \Sigma)$ indicates that $x$ is a circularly symmetric complex Gaussian (CSCG) random vector with zero-mean and covariance matrix $\Sigma$.

II. System Models and Motivation

A. System Model

We consider a distributed mMIMO system in a wide area to serve $N$ MTC UEs that are scattered in the area (each UE is equipped with a single antenna). As illustrated in Figure 1, there are $M$ APs uniformly and spatially distributed. We assume that these distributed APs are connected to a BS central
processing unit (CPU) via an error-free backhaul and each AP is equipped with \( S \) antennas.

In a GFRA channel slot, suppose that \( U \) UEs, indexed as \( 1, 2, \ldots, U \), are active to access the channel for uplink transmission in a grant-free manner, where \( U \) follows the binomial distribution \( \text{Bin}(N, \rho) \) and \( \rho (\rho \ll 1) \) is the sporadic activation probability of each UE.

To enable channel estimation at the BS, each RA UE directly transmits an RA preamble before data, which is randomly selected from an orthogonal preamble pool of size \( L \) (\( L \ll N \)), i.e., \( \mathbf{P} = \{ \mathbf{p}_1, \mathbf{p}_2, \ldots, \mathbf{p}_L \} \), where \( \mathbf{p}_l \) denotes the \( l \)th orthogonal preamble vector of length \( L \), \( ||\mathbf{p}_l||^2 = L \) and \( \mathbf{p}_l^H \mathbf{p}_l = 0 \), for \( l \neq l', l, l' \in \{1, 2, \ldots, L\} \).

Specifically, the received preamble signal, \( \mathbf{Y} \in \mathbb{C}^{MS \times L} \), can be given by

\[
\mathbf{Y} = \sum_{u=1}^{U} \sqrt{P_T} \mathbf{g}_u \psi_u^T + \mathbf{n},
\]

where \( P_T \) is the transmit power of each RA UE, \( \mathbf{g}_u = [\mathbf{g}_{u1}^T, \mathbf{g}_{u2}^T, \ldots, \mathbf{g}_{uM}^T]^T \in \mathbb{C}^{MS} \) is the channel response vector between RA UE \( u \) and the BS and \( \mathbf{h}_{um} = \sqrt{\bar{h}_{um}} \) \( \mathbf{h}_{um} \in \mathbb{C}^L \) is the channel response vector between RA UE \( u \) and AP \( m \), where \( \bar{h}_{um} \) denotes the large-scale fading coefficient and \( \mathbf{h}_{um} \sim \mathcal{CN}(0, \mathbf{I}_L) \), stands for the small-scale fading vector, \( \psi_u \in \mathbb{C}^{L} \) is the selected preamble by RA UE \( u \) from the preamble pool \( \mathbf{P} \), and \( \mathbf{n} \) is the noise matrix with i.i.d. elements distributed as \( \mathcal{CN}(0, \sigma^2) \).

Due to the randomness of preamble selection by each RA UE, a key issue to be addressed is the preamble collision, which constrains the throughput and transmission reliability of collided RA UEs. In the sequel, we detail the performance impairment caused by preamble collision in GFRA and present the intuition and motivation of preamble collision resolution in distributed mMIMO.

\( ^1 \)In practice, a GFRA slot consists of multiple channels over frequency and each channel can accommodate a number of RA UEs. Since each channel is independent in frequency, we only focus on a single channel scenario in this work.

B. Performance Impairment due to Preamble Collision

Without loss of generality, we consider the RA UE with index 1 as the RA UE of interest and explain the impact of preamble collision on its performance. In the case of preamble collision, without any prior CSI information, the least-squares (LS) based channel estimation for RA UE 1 can be used and the estimate is given by

\[
\hat{\mathbf{g}}_1 = \frac{\mathbf{Y} \psi_1^H}{P_T L} = \mathbf{g}_1 + \sum_{u' \in \Phi_{\psi_1}} \mathbf{g}_{u'} + \frac{1}{P_T L} \mathbf{n},
\]

where \( \Phi_{\psi_1} \) is the set of indices of RA UEs that select \( \psi_1 \) other than RA UE 1, \( \Phi_{\psi_1} = \{ 1 \} \), \( \rho_T = P_T / \sigma^2 \) is defined as the uplink transmit signal-to-noise ratio (SNR) corresponding to each RA UE, and \( \mathbf{n} \sim \mathcal{CN}(0, \mathbf{I}_{MS}) \). From (2), we see that the estimated channel under preamble collision is distorted by the channels of other RA UEs that select the same preamble.

Following preamble, each RA UE transmits its data. At the BS, the received data symbol vector \( \mathbf{r} \in \mathbb{C}^{MS} \) is given by

\[
\mathbf{r} = \sum_{u=1}^{U} \sqrt{P_T} \mathbf{g}_u \mathbf{s}_u + \mathbf{n},
\]

where \( \mathbf{n} \) the background noise vector distributed as \( \mathcal{CN}(0, \sigma^2 \mathbf{I}_{MS}) \) and \( \mathbf{s}_u \) is a data symbol transmitted by RA UE \( u \) and \( E[||\mathbf{s}_u||^2] = 1 \).

With (3) and (4), the estimated data symbol of RA UE 1 after conjugate beamforming is given by

\[
\hat{\mathbf{s}}_1 = \frac{\hat{\mathbf{g}}_1^H \mathbf{r}}{MS \sqrt{P_T}} = \frac{\hat{\mathbf{g}}_1^H \mathbf{g}_1 \mathbf{s}_1}{MS} + \frac{\sum_{u=2}^{U} \hat{\mathbf{g}}_1^H \mathbf{g}_u \mathbf{s}_u}{MS} + \frac{\hat{\mathbf{g}}_1^H \mathbf{n}}{MS \sqrt{P_T}}.
\]

As \( M \to \infty \) (here we fix \( S \)), it becomes

\[
\hat{\mathbf{s}}_{1\infty} = \lim_{M \to \infty} \left( \frac{\hat{\mathbf{g}}_1^H \mathbf{g}_1 \mathbf{s}_1}{MS} + \frac{\sum_{u=2}^{U} \hat{\mathbf{g}}_1^H \mathbf{g}_u \mathbf{s}_u}{MS} + \frac{\hat{\mathbf{g}}_1^H \mathbf{n}}{MS \sqrt{P_T}} \right)
\]

\[
= \frac{1}{M} \sum_{m=1}^{M} \hat{\beta}_m \mathbf{s}_1 + \frac{\sum_{u=\Phi_{\psi_1}} \mathbf{s}_u}{MS} \frac{1}{MS \sqrt{P_T}}
\]

\[
\approx \frac{1}{M} \sum_{m=1}^{M} \hat{\beta}_m \mathbf{s}_1 + \frac{\sum_{u \neq 1} \mathbf{s}_u}{MS} \frac{1}{MS \sqrt{P_T}}
\]

where \( \{ a \} \) is obtained based on Chebyshev’s Theorem, i.e.,

\[
\frac{\mathbf{g}_u^H \mathbf{n}}{MS} \xrightarrow{M \to \infty} \sum_{m=1}^{M} \frac{\hat{\beta}_m}{M} \mathbf{s}_u \xrightarrow{M \to \infty} 0 \text{ when } u \neq 1.
\]

As a result, the asymptotic signal-to-interference-and-noise ratio (SINR) of RA UE 1 is expressed by

\[
\text{SINR}_{1\infty} = \frac{\beta_1^2}{\sum_{u' \neq 1}^{U} \beta_{u'}^2}.
\]

As we can see, even the number of antennas increases without bound, it does not change the fact that the interference from the collided RA UEs that select the same preamble as RA UE 1 cannot be vanished and could have a significant impact on
the performance of RA UE 1.

In co-located mMIMO, since all M APs are geographically centralized, we have $\beta_{u1} = \beta_{u2} = \cdots = \beta_{uM} \triangleq \beta_u$ and thus the observation in (6) still holds. Unfortunately, in co-located mMIMO, since all the signals are multiplexed and assembled at the centralized BS, it is difficult to find preamble multiplicity under preamble collision and the performance impairment of collided RA UEs exists no matter where collided RA UEs are spatially located. However, distributed mMIMO opens up chances for mitigating the impairment thanks to the signal spatial sparsity in distributed mMIMO and random geographic distributions of RA UEs.

C. Preamble Collision Resolution in Distributed mMIMO based GFRA

In distributed mMIMO, considering the distance disparity between an RA UE and different APs, it is demonstrated that only neighboring APs within a communication range of an RA UE have non-negligible channel gains. Since all the collided RA UEs are uniformly and independently distributed in the area, they can be separate in space and surrounded by different groups of APs. If the BS can distinguish the neighboring APs of a collided RA UE in GFRA, it can organize the neighboring APs to serve the collided RA UE, which is expected to improve the performance of collided RA UEs significantly.

Herein, we use a toy example to explain the potential performance gain achieved by such a strategy. In particular, we assume that RA UE 1 is far away from the RA UEs in $\Phi_{\psi_1}$, so that the strength of received signals from the other collided RA UEs is negligible at the neighboring APs of RA UE 1 (for example in Figure 1, RA UE 1 and RA UE 2 are the collided RA UEs that select the same preamble but their locations are far away from each other). For simplicity, let $M_1 = \{1, 2, \ldots, M_1\}$ denote the set of indices of neighboring APs of RA UE 1 and $M_1 = |M_1| = \omega_1 M$, where $0 < \omega_1 \ll 1$ is a scaling factor that represents the ratio of the sizes of a communication range of RA UE 1 to the considered area.

By only employing the $M_1$ APs to decode data, similar to (2), the channel estimate of RA UE 1 over the $M_1$ APs, $\hat{g}_{1,M_1} \in C^{M_1 S}$, can be written by

$$\hat{g}_{1,M_1} = g_{1,M_1} + \sum_{u' \in \Phi_{\psi_1}} g_{u',M_1} + \frac{1}{\sqrt{\rho_1 L}} n_{M_1}, \quad (7)$$

where $g_{u,M_1} = [g_{u1}^T, g_{u2}^T, \ldots, g_{uM_1}^T]^T$ and $n_{M_1} \sim \mathcal{CN}(0, I_{M_1 S})$.

Similar to (3), the received data symbol vector over the $M_1$ APs, $r_{M_1} \in C^{M_1 S}$, is written by

$$r_{M_1} = \sum_{u=1}^{U} \sqrt{P_1} g_{u,M_1} s_u + \bar{n}_{M_1}, \quad (8)$$

where $\bar{n}_{M_1} \sim \mathcal{CN}(0, \sigma^2 I_{M_1 S})$.

In the considered example, due to significant large-scale fading between RA UE $u'$ in $\Phi_{\psi_1}$ and AP $m$ in $M_1$, $g_{u',M_1} \approx 0$, $u' \in \Phi_{\psi_1}$. Thus, we have following approximations:

$$\hat{g}_{1,M_1} \approx g_{1,M_1} + \frac{1}{\sqrt{\rho_1 L}} n_{M_1},$$

and

$$r_{M_1} \approx \sqrt{P_1} g_{1,M_1} s_1 + \sum_{u \neq \Phi_{\psi_1}} \sqrt{P_1} g_{u,M_1} s_u + \bar{n}_{M_1}.$$ 

Then, the estimated data symbol of RA UE 1 after conjugate beamforming as $M \to \infty$ (as $M_1 = \omega_1 M$, $M \to \infty$ leads to $M_1 \to \infty$) becomes

$$\hat{s}_{1,M_1} = \lim_{M_1 \to \infty} \frac{\hat{g}_{1,M_1}^H r_{M_1}}{M_1 S \sqrt{P_1}} \approx \frac{M_1}{M_1} \beta_{1,s_1} = \beta_{1,M_1} s_1. \quad (9)$$

Similarly, (b) is obtained based on Chebyshev’s Theorem as

$$\beta_{1,s_1} = \lim_{M_1 \to \infty} \sum_{m=1}^{M_1} \beta_{1m,s_1} M_1. \quad (10)$$

From (9), we can see that the received signal of RA UE 1 approximately becomes interference-free from preamble collision under the given scenario as $M \to \infty$, which indicates the possibility and practicality of preamble collision resolution (mitigating the interference due to preamble collision) in GFRA with distributed mMIMO.

Nevertheless, to achieve the potential preamble collision resolution and improve the performance of collided RA UEs in GFRA by distributed mMIMO, there are two issues remained to be addressed as follows:

- How to detect preamble collision and find preamble multiplicity?
- How to differentiate the neighboring APs of collided RA UEs for performance enhancement?

To address the above issues, it is expected to fully exploit the information obtained from the received preamble signals at APs. To this end, we propose a DNN based $K$-means clustering scheme in this paper.

Specifically, to mitigate the performance impairment of collided RA UEs in GFRA with distributed mMIMO, we first design a tailored DNN to enable the preamble multiplicity estimation. With the estimated preamble multiplicity, we then employ the $K$-means clustering algorithm to separate the neighboring APs of collided RA UEs and use each associated AP cluster to serve individual collided RA UE.

III. DNN BASED PREAMBLE MULTIPlicity ESTIMATION

For the estimation of preamble multiplicity of an arbitrary preamble, e.g., $p_l$, $l = 1, 2, \ldots, L$, we need to find out the mapping relationship between the preamble multiplicity and the received preamble signal associated with $p_l$ at APs, i.e.,

$$F: C^{M S} \to \mathbb{N}_0$$

$$g_{B_l} \mapsto B_l, \quad l = 1, 2, \ldots, L$$

where $F$ denotes the mapping function, $\mathbb{N}_0 = \mathbb{N} \cup \{0\}$, $B_l$ is the set of indices of RA UEs that select $p_l$ among $U$ RA UEs
and $B_l = |B_l| \in \mathbb{N}_0$ denotes the preamble multiplicity (e.g., $B_l = 0$ indicates that $p_l$ is not selected by any RA UE), and $g_{B_l} \in \mathbb{C}^{M \times S}$ represents the received preamble signal associated with $p_l$ at APs, which has a similar expression as in (2) and it is given by

$$g_{B_l} = \frac{Y_p}{\sqrt{P_l}} = \sum_{u \in B_l} g_u + \frac{1}{\sqrt{\rho L}} n,$$  \hspace{1cm} (11)

where $g_{B_l} = [g_{B_l1}, g_{B_l2}, \ldots, g_{B_lM}]^T$ and $g_{B_lm}$ is the received preamble signal vector associated with $p_l$ at AP $m$.

In the considered problem, obtaining $F$ by traditional programming algorithms is not a trivial task since deriving it is given by $J_+1$ features so that the desired function can be approximately modelled.

As illustrated in Figure 2, the proposed fully connected DNN consists of $J + 2$ layers, including one input layer (layer 0), $J$ hidden layers (layers 1 to $J$), and one output layer (layer $J + 1$). Let $N_j$ denote the number of neurons at layer $j$, $j = 0, 1, \ldots, J + 1$.

In the proposed DNN, layer 0 contains $N_0 = M$ neurons, which forwards the instantaneous information of $g_{B_l}$ to the following layers. Let $E_{B_l} = [E_{B_l1}, E_{B_l2}, \ldots, E_{B_lM}]^T \in \mathbb{R}^M$ denote the received preamble signal energy vector associated with $p_l$ at AP $m$.

$$E_{B_l} = \frac{\|g_{B_lm}\|^2}{S}, m = 1, 2, \ldots, M,$$ \hspace{1cm} (12)

where $\| \cdot \|$ is the Euclidean norm and $S$ is the number of APs.

To solve the problem in an effective manner, we design a feed-forward DNN (multi-layer perception) \cite{22} in this section thanks to its powerful approximation and prediction ability. As aforementioned in Section II-C, only neighboring APs within a communication range of an RA UE have non-negligible channel gains in distributed mMIMO. Thus, the neighboring APs of an RA UE usually capture more significant signal energy than the other APs. On the other hand, the separation of RA UEs in space makes the signals of different RA UEs concentrate in different geographic clusters. By capitalizing these properties, one could envision that there exists connections between the preamble multiplicities and the distribution patterns of received preamble signal energy over $M$ distributed APs. Therefore, the proposed DNN is used to explore the features so that the desired function $F$ can be approximately modelled.

### A. Proposed DNN Structure

![Figure 2: A simplified illustration of the proposed DNN diagram for preamble multiplicity estimation, where the circle nodes of different colors represent the neurons of different layers.](image)

To illustrate the pattern differences of normalized $I_0$ corresponding to different preamble multiplicities with $M = 100$.

![Figure 3: An example of pattern differences of normalized $I_0$ corresponding to different preamble multiplicities with $M = 100$.](image)

In Figure 3, we plot an example to illustrate the pattern features of normalized $I_0$ corresponding to different preamble multiplicities with $M = 100$, where we randomly generate three data sets for each individual preamble multiplicity based on the system setup in Section III-C. As shown in the example, different preamble multiplicities lead to different received energy patterns, which can be exploited by the proposed DNN to predict preamble multiplicity.

Building on $I_0$, the hidden layers of the feed-forward DNN are constructed through the following $J$ iterative processing steps:

$$I_j = f(W_{j-1}I_{j-1} + b_{j-1}), j = 1, 2, \ldots, J,$$ \hspace{1cm} (14)

where $I_j \in \mathbb{R}^{N_j}$ is the output of layer $j$, $f(\cdot)$ represents a non-linear activation function, and $W_{j-1} \in \mathbb{R}^{N_j \times N_{j-1}}$ and $b_{j-1} \in \mathbb{R}^{N_j}$ respectively stand for the weighting matrix and bias vector at layer $j - 1$, which are used to encode the output of layer $j - 1$. In this paper, a sigmoid function defined as $\sigma(x) = \frac{1}{1 + e^{-x}}$ is used as the activation function $f(\cdot)$.

As usually done in pattern recognition problems, the predicted output of the proposed DNN in layer $J + 1$ is expressed
that the cross-entropy loss function between the target outputs and the predicted outputs under practical wireless environments, where the performance of the proposed DNN for preamble multiplicity estimation depends on the system parameters, i.e., \( \theta \). The back-propagation (BP) algorithm can be used to iteratively update the parameters \( \theta \) by the scaled conjugate gradient method [23]. In this paper, we employ the conjugate gradient methods, including the gradient descent and the scaled conjugate gradient method [23] to iteratively update the parameter sets of all layers, i.e., \( \theta \).

In this subsection, we evaluate the performance of the proposed DNN in terms of classification accuracy and reliability in different deployments. Specifically, based on the system configurations in GFRA, we randomly generate \( Q \) training sample sets. For sample set \( q \) \((q = 1, 2, \ldots, Q)\), it consists of a pair of the received preamble signal energy \( E_{Bq} \) and the corresponding preamble multiplicity \( B \), which is associated with an arbitrary preamble (here we omit the subscript \( l \) for notation simplicity). With known training sample set \( q \), we can obtain a mapping pair of the proposed DNN, denoted by \( (I_0^q, I_{J+1}^q) \), where the input \( I_0^q \) is obtained from \( E_{Bq} \) by \( \theta \), and the target output \( I_{J+1}^q \) can be expressed by

\[
I_{J+1}^q = e_{B^q+1},
\]

where \( e_i \in \mathbb{R}^{T_{\max}+1} \) denotes the standard basis vector that has a single nonzero entry with value 1 at entry \( i \).

By using the \( Q \) mapping pairs, the proposed DNN is trained by back-propagation (BP) algorithm to adjust and optimize the parameter sets of all layers, i.e., \( \theta = [\theta_0, \theta_1, \ldots, \theta_J] \), so that the cross-entropy loss function between the target outputs \( \{I_{J+1}^q\}_{q=1}^Q \) and the predicted outputs \( \{\hat{I}_{J+1}^q\}_{q=1}^Q \), which is given in \( \theta \), could be minimized:

\[
\mathcal{L}(\theta) = -\sum_{q=1}^Q \sum_{i=1}^{T_{\max}+1} I_{J+1, i}^q \ln \left( \hat{I}_{J+1, i}^q | I_0^q, \theta \right).
\]

To achieve the minimization of \( \mathcal{L}(\theta) \), a number of out-of-the-box gradient methods including the gradient descent and the conjugate gradient can be used. In this paper, we employ the scaled conjugate gradient method [23] to iteratively update parameter sets \( \theta \).

**C. Performance Analysis of Proposed DNN**

1) Simulation Setup: In this subsection, we evaluate the performance of the proposed DNN for preamble multiplicity estimation under practical wireless environments, where the large-scale fading coefficient, depending on the RA UE’s location and the propagation environment, is modelled as \[ 25, \]

\[
\beta_{um} = \frac{X_{um}}{1 + PL(d_0) \left( \frac{d_{um}}{d_0} \right)^v},
\]

where \( X_{um} \) stands for the shadow fading that is a log-normal random variable with standard deviation \( \sigma_{SF} \) (dB), \( PL(d_0) \) is the path loss at a reference distance \( d_0 \) (m), \( d_{um} \) is the distance between UE \( u \) and AP \( m \), and \( v \) is the path loss exponent. The additive thermal noise is assumed to have a power spectral density of \(-174 \) dBm/Hz, while the front-end receiver at the AP is assumed to have a noise figure of \( 9 \) dB according to \[ 20 \]. Thus, the noise power \( \sigma^2 \) is \(-112 \) dBm with a narrow bandwidth of \( B_w = 200 \) KHz.

We consider a square area of \( 1 \) km\(^2\) and the distributed APs are deployed on a square grid. Three different deployments are considered: 1) \( M = 10 \times 10 \) APs with \( S = 2 \) antenna; 2) \( M = 10 \times 10 \) APs with \( S = 1 \) antenna; and 3) \( M = 7 \times 7 \) APs with \( S = 2 \) antennas. The rest of system parameters are summarized in Table I.

| Table I: System parameters |
|-----------------------------|
| Number of UEs \( N \)       | 2000 |
| Activation Probability \( \rho \) | 0.01 |
| Number of Preambles \( L \) | 20  |
| Transmit Power \( P_T \)    | 17 dBm |
| Shadow Fading \( \sigma_{SF} \) | 0 or 8 dB |
| Reference Distance \( d_0 \) | 1 m  |
| Path Loss \( PL(d_0) \)     | 30 dB |
| Path Loss Exponent \( v \)  | 3.8  |

For the proposed DNN, we simulate \( Q = 10^5 \) realizations to generate sample sets, which are randomly divided into the training sample sets (80\% of total instances) and the test sample sets (20\% of total instances). For each realization, the active RA UEs are randomly distributed in the considered area and their number \( U \) is generated following the binomial distribution \( \text{Bin}(N, \rho) \). Since each preamble is selected by RA UEs uniformly at random in GFRA, the preamble multiplicity \( B \) associated with an arbitrary preamble follows the binomial distribution \( \text{Bin}(N, \rho/L) \) as mentioned earlier. With the given system parameters, i.e., \( N = 2000 \), \( \rho = 0.01 \), and \( L = 20 \), over 99\% realizations are generated in the way that a preamble is selected by 4 RA UEs at most. As a result, we set \( T_{\max} = 4 \) as the maximum preamble multiplicity that we are interested in estimating. In the following, we discuss the performance of the proposed DNN in terms of classification accuracy and reliability in different deployments.

2) Performance Analysis for Different Deployments: We first consider the performance of deployment 1 with \( M = 10 \times 10 \) and \( S = 2 \). In this deployment, the proposed DNN consists of 4 hidden layers, whose numbers of neurons are 128, 128, 64, and 32, respectively.

To understand the classification accuracy of the proposed DNN for preamble multiplicity, confusion matrices for different \( \sigma_{SF} \) in Table II are included. In the scenario with no
shadow fading, i.e., $\sigma_{SF} = 0$, it is seen that the proposed DNN model is able to predict (estimate) the preamble multiplicity in GFRA with high accuracy over a wide range of multiplicities. In terms of the performance of preamble detection, i.e., determining whether a preamble is selected or not by any RA UE, the proposed DNN model provides almost error-free performance, with negligible false alarm and missed detection errors (0.2% missed detection probability occurs merely when preamble is selected by only one RA UE). When the preamble collision occurs, about 98% and 88% estimation accuracy can be achieved when the preamble multiplicity equals 2 and 4, respectively. The main reason that the estimation accuracy declines as the preamble multiplicity increases is due to the fact that, a larger preamble multiplicity means that more collided RA UEs select the same preamble. As a consequence, there are comparably more chances that some of the collided RA UEs are co-located in vicinity, which could make the proposed DNN mistakenly treat these close-located RA UEs as a single RA UE and results in an incorrect estimated preamble multiplicity that is smaller than the actual one. Therefore, the estimation performance is degraded. Nevertheless, it is noticed that, almost all the incorrect estimated multiplicities are only offset by 1 compared to the actual ones. For example, when the preamble multiplicity equals 2 and 3, the proposed DNN only gets the multiplicity wrong by $\pm 1$ (mostly by $-1$). When the preamble multiplicity equals 4, the proposed DNN guarantees an estimation result that is either correct or incorrect by $\pm 1$ with a high probability of 99.8% (only gets the multiplicity incorrect by $-2$ with a as little as 0.2% probability). These observations demonstrate the accuracy as well as the reliability achieved by the proposed DNN for preamble multiplicity estimation.

In addition, we also consider a practical channel scenario with shadow fading $\sigma_{SF} = 8$. Under such a condition, it is not surprising that, due to the impact of shadow fading variations on channel gains, the classification accuracy of the proposed DNN degrades compared to the case without shadow fading. As we can see, although shadow fading has little impact on the preamble detection performance of the proposed DNN, it incurs certain accuracy degradations for estimating collided preamble multiplicities. For instance, the estimation accuracy for a preamble multiplicity of 4 is decreased from 87.8% to 78.7% and more errors are introduced by incorrect estimation to multiplicity 3, which indicates that the channel randomness induced by shadow fading inherently increases confusion between adjacent multiplicity classes. Nevertheless, an estimation accuracy of 78.7% for preamble multiplicity 4 is still considered decent, under such an amount of collided RA UEs coexists at the same time. Besides, similar to what we observed in the case with no shadow fading, almost all the incorrect estimated multiplicities differ from the true ones by $\pm 1$ when $\sigma_{SF} = 8$, which reveals that although the accuracy performance of the proposed DNN is affected by the shadow fading, its estimation reliability remains uninfluenced.

Table II: Confusion matrix for the proposed DNN in the deployment of $M = 100$ and $S = 2$.

| Target $\hat{B}$ | 0 | 1 | 2 | 3 | 4 |
|------------------|---|---|---|---|---|
| $\sigma_{SF} = 0$ dB |
| 0                | 1 | 0 | 0 | 0 | 0 |
| 1                | 0.002 | 0.997 | 0.001 | 0 | 0 |
| 2                | 0 | 0.012 | 0.979 | 0.009 | 0 |
| 3                | 0 | 0 | 0.067 | 0.918 | 0.015 |
| 4                | 0 | 0 | 0.002 | 0.120 | 0.878 |
| $\sigma_{SF} = 8$ dB |
| 0                | 1 | 0 | 0 | 0 | 0 |
| 1                | 0.002 | 0.991 | 0.007 | 0 | 0 |
| 2                | 0 | 0.046 | 0.923 | 0.031 | 0 |
| 3                | 0 | 0 | 0.151 | 0.838 | 0.011 |
| 4                | 0 | 0 | 0.002 | 0.211 | 0.787 |

We also consider other two deployments, i.e., deployment 2 with $M = 10 \times 10$ and $S = 1$ and deployment 3 with $M = 7 \times 7$ and $S = 2$. Their confusion matrices are illustrated in Table III and Table IV respectively. In deployment 2, the proposed DNN consists of 4 hidden layers, whose numbers of neurons are the same as those in deployment 1. In deployment 3, the proposed DNN consists of 4 hidden layers, whose numbers of neurons are 64, 128, 64, and 32, respectively. As observed in Table III similar observations and conclusions can be drawn from Tables III and IV. In terms of estimation accuracy of the proposed DNN, we can see that it is slightly degraded in deployment 2 compared to that in deployment 1, which is mainly due to a loss of channel diversity in deployment 2 with $S = 1$. Nevertheless, a 72.7% estimation accuracy for preamble multiplicity 4 is still achievable with $\sigma_{SF} = 8$ in deployment 2. Moreover, with the roughly same amount of antennas in deployments 2 and 3, a reasonably close multiplicity estimation performance is observed without considering shadow fading. However, results show that the performance in deployment 3 seems more sensitive to the channel randomness resulted from shadow fading. In particular, under $\sigma_{SF} = 8$, its estimation accuracy for preamble multiplicities 3 and 4 is significantly degraded compared to that under $\sigma_{SF} = 0$. This could be explained by the fact that the antenna distribution in deployment 3 is more sparse, which makes that the shadow fading comparably has more influence.

Table III: Confusion matrix for the proposed DNN in the deployment of $M = 100$ and $S = 1$.

| Predicted $\hat{B}$ | 0 | 1 | 2 | 3 | 4 |
|---------------------|---|---|---|---|---|
| $\sigma_{SF} = 0$ dB |
| 0                  | 1 | 0 | 0 | 0 | 0 |
| 1                  | 0.004 | 0.992 | 0.004 | 0 | 0 |
| 2                  | 0 | 0.038 | 0.943 | 0.019 | 0 |
| 3                  | 0 | 0 | 0.116 | 0.864 | 0.020 |
| 4                  | 0 | 0 | 0.002 | 0.218 | 0.780 |
| $\sigma_{SF} = 8$ dB |
| 0                  | 1 | 0 | 0 | 0 | 0 |
| 1                  | 0.006 | 0.981 | 0.013 | 0 | 0 |
| 2                  | 0 | 0.051 | 0.919 | 0.030 | 0 |
| 3                  | 0 | 0 | 0.174 | 0.786 | 0.040 |
| 4                  | 0 | 0 | 0.004 | 0.269 | 0.727 |
significant impact on the channel fluctuations. As a result, the classification confusion between preamble multiplicities 3 and 4 gets more pronounced.

Table IV: Confusion matrix for the proposed DNN in the deployment of \( M = 49 \) and \( S = 2 \).

| \( \sigma_{SF} \) | \( \hat{B} \) | 0 | 1 | 2 | 3 | 4 |
|-----------------|---------|---|---|---|---|---|

|                 | 0 | 0 | 0 | 0.002 | 0.233 | 0.765 |

In the next section, the estimated preamble multiplicity information will be used to cluster neighboring APs of collided RA UEs for their performance enhancement.

IV. \( K \)-MEANS AP CLUSTERING

The estimated preamble multiplicity \( \hat{B} \) (associated with an arbitrary preamble) based on the proposed DNN indicates the status of associated preamble in GFRA, i.e., whether or not it is selected by any RA UE, and if selected then how many RA UEs select it. When \( \hat{B} \geq 2 \), the BS assumes that preamble collision occurs. Under such conditions, as revealed in Section II-C, it is expected that the BS only allocates the neighboring APs of a collided RA UE (rather than all the APs) to decode its data so that the mutual interference among collided RA UEs in the preamble domain can be mitigated.

In this paper, we denote \( M_c \) as the average number of neighboring APs to decode for each collided RA UE in the case of preamble collision. Ideally, the neighboring APs of a collided RA UE can be the \( M_c \) APs with its strongest channel gains [27]. In practice, this scenario is desirable, but unattainable in GFRA since the BS has no prior CSI of RA UEs. As a compromised solution, the \( K \)-means AP clustering algorithm is proposed to cluster neighboring APs for collided RA UEs.

On one hand, the neighboring APs in the vicinity of an RA UE usually capture more significant signal energy than other APs. As the collided RA UEs are randomly distributed in space, it can be reasonably envisaged that the APs with \( M_c \hat{B} \) strongest received preamble energy are most likely composed by the neighboring APs of \( \hat{B} \) collided RA UEs. On the other hand, the \( K \)-means clustering algorithm is one of the most popular clustering algorithms, which aims to partition observations into \( K \) clusters where each observation belongs to exactly one cluster with the nearest mean cluster centroid [28]. For these reasons, it motivates us to propose the \( K \)-means AP clustering algorithm that iteratively partitions the APs corresponding to largest \( M_c \hat{B} \) entries of \( \mathbf{E}_B \) into \( \hat{B} \) clusters based on their coordinates. Note that the deployment of distributed APs along with their coordinates are pre-determined and known at the BS.

Herein, we denote \( \mathcal{A}_B \) as the set of indices of APs corresponding to the largest \( M_c \hat{B} \) entries of \( \mathbf{E}_B \) and \( |\mathcal{A}_B| = M_c \hat{B} \). Then, we have \( \mathcal{C}_B = \{ c_m \mid m \in \mathcal{A}_B \} \) as the coordinate set of the APs in \( \mathcal{A}_B \), where \( c_m = [x_m, y_m]^T \) denotes the coordinate of AP \( m, m \in \mathcal{A}_B \), in a 2-dimensional Euclidean space.

With \( \mathcal{C}_B \), the proposed \( K \)-means AP clustering algorithm is described in Algorithm 1.

\[ \text{Algorithm 1: Proposed \( K \)-means AP clustering algorithm} \]

\begin{itemize}
  \item \textbf{Input:} \( M_c, \hat{B}, \) and \( \mathcal{C}_B \);
  \item \textbf{Output:} A set of \( \hat{B} \) clusters, i.e., \( \mathcal{Z}_k = \{ m \mid z_m = k, m \in \mathcal{A}_B \}, k = 1, 2, \ldots, \hat{B} \);
  \item \textbf{Initialization:} Randomly select \( \hat{B} \) coordinates from \( \mathcal{C}_B \) as the initial cluster centroids \( \mu_1, \mu_2, \ldots, \mu_{\hat{B}} \);
  \item \text{repeat}
  \item 2: AP assignment, i.e., assign each AP in \( \mathcal{C}_B \) to its closest cluster centroid with label: \( z_m = \arg \min_{k} \| c_m - \mu_k \| ^2 \);
  \item 3: Update the cluster centroids, i.e., compute the mean coordinates of APs assigned in each cluster to obtain new cluster centroid: \( \mu_k = \frac{1}{\sum_{m=1}^{M_c} \mathbf{1}(z_m = k)c_m} \sum_{m=1}^{M_c} \mathbf{1}(z_m = k)c_m \);
  \item \text{until} \{ \text{Cluster centroids are stabilized} \}
\end{itemize}

With the AP clusters \( \{ \mathcal{Z}_k \}_{k=1}^{\hat{B}} \), the BS deems that there exists one collided RA UE in the vicinity of each AP cluster, and organizes each cluster to decode the received data individually.

A. Exemplary Outputs of Algorithm 1

With a predetermined \( M_c \), the outcome of the proposed AP clustering algorithm relies on the estimated preamble multiplicity of proposed DNN. As observed and discussed in Section II-C, the proposed DNN is able to provide a decent estimation accuracy for each preamble multiplicity. In most error multiplicity estimation, the proposed DNN only gets the multiplicity wrong by \(-1\). For instance, for preamble multiplicity 3 in deployment 2 with \( \sigma_{SF} = 8 \) dB, an estimation accuracy of 78.6% is achieved and an estimation error of 17.4% is caused by mistakenly classifying it as multiplicity 2. Based on these facts, we present two kinds of representative outcomes of the proposed AP clustering algorithm with \( M_c = 4 \) in Figure 4(a) and Figure 4(b) respectively. Specifically, under deployment 2 with \( \sigma_{SF} = 8 \) dB, the outcome in Figure 4(a) represents a typical clustering output for correctly estimated preamble multiplicity 3, while the outcome in Figure 4(b) represents a typical clustering output for incorrectly estimated preamble multiplicity 3. In both subfigures, red empty circles represent the locations of \( M = 100 \) deployed APs in a 2-dimensional Euclidean space, blue diamonds represent the locations of collided RA UEs (associated with a certain preamble) that are randomly
In this paper, we consider the uplink achievable rate of an arbitrary RA UE under preamble collision as a performance metric. Like in Section II-C, we consider RA UE 1 as the collided RA UE of interest under preamble collision (|Φψ1| ≥ 1) and M1 as the set of indices of APs employed for decoding data of RA UE 1. Based on (7) and (8), the estimated data symbol of RA UE 1 is given by

\[ \hat{s}_1 = \frac{\hat{g}^H_{1,M_1} r_{M_1}}{M_1 S \sqrt{\rho_T}} + \sum_{u \neq \Phi_1} \frac{\hat{g}^H_{1,M_1} g_{u,M_1} s_u}{M_1 S} + \frac{\hat{g}^H_{1,M_1} n_{M_1}}{M_1 S \sqrt{\rho_T}}. \]  

From (20), the uplink achievable rate of RA UE 1 under preamble collision is given by

\[ R_1 = B_w \log (1 + \text{SINR}_1), \]  

where SINR1 is the uplink SINR of RA UE 1, which is given by

\[ \text{SINR}_1 = \frac{\sum_{u \in \Phi_1} \rho_T |\hat{g}^H_{1,M_1} g_{u,M_1}|^2 + \sum_{u \neq \Phi_1} \rho_T |\hat{g}^H_{1,M_1} g_{u,M_1}|^2 + |\hat{g}^H_{1,M_1} n_{M_1}|^2}{\sum_{u \neq \Phi_1} \rho_T |\hat{g}^H_{1,M_1} g_{u,M_1}|^2}. \]  

To show the performance superiority of the proposed DNN based AP clustering scheme in terms of R1 in GFRA, simulation results are presented in the sequel. Throughout the simulations, the three deployments in Section III-C1 are considered only with σSF = 8, and the following four schemes are compared:
achieving about $16$ M throughout the three deployments, the proposed scheme with comparing the $95$ M.

In addition, different M achievable rate for collided RA UEs with a wide range of

the proposed scheme is able to significantly improve the

functions (CCDF) per collided RA UE with different

uplink achievable rate complementary cumulative distribution

considered three deployments with

Figure 6: Comparisons of uplink achievable rate CCDF per collided RA UE among different schemes, with $M_c = 4$.

- Proposed DNN based AP clustering scheme: in the proposed scheme, the AP cluster closest to RA UE 1 is employed as set $M_1$.
- All-AP scheme: in this scheme, without preamble multiplicity estimation, all M APs are employed as set $M_1$.
- $M_c$-strongest-AP scheme: in this scheme, without preamble multiplicity estimation, the $M_c$ APs with the strongest received preamble signal energy are simply employed as set $M_1$.
- Genie-aided scheme: in this genie-aided scheme, we assume that the set of APs that have the $M_c$ largest channel gains of RA UE 1 is perfectly known at the BS and these APs are employed as set $M_1$. The performance of this scheme can be seen as an upper bound of the proposed scheme, which is desirable but unattainable in practical GFRA.

We first investigate the performance of the proposed DNN based AP clustering scheme with different $M_c$ in the considered three deployments with $\sigma_{SF} = 8$. In Figure 5, uplink achievable rate complementary cumulative distribution functions (CCDF) per collided RA UE with different $M_c$ are presented. As observed, compared to the all-AP scheme, the proposed scheme is able to significantly improve the achievable rate for collided RA UEs with a wide range of $M_c$. In addition, different $M_c$ leads to different performance. By comparing the $95\%$-likely performance, it is clear to see that, throughout the three deployments, the proposed scheme with $M_c = 4$ provides the highest achievable rate, for example, achieving about $16$ dB performance gain over the case of $M_c = 1$ and $4$dB over the case of $M_c = 16$ in deployment 1. This is mainly explained by the facts that: 1) compared to large $M_c$, the proposed scheme with $M_c = 1$ is more vulnerable to the clustering errors as only a single AP is used to decode the data. As a result, it is more likely to provide low rate for collided RA UEs when clustering errors occur; 2) Since the signal of an RA UE is usually concentrated at its few neighboring APs, a large $M_c$ brings little benefit to the amount of desired signals, but introduces more interference from all of the other RA UEs in GFRA. Thus, setting a too small or too large $M_c$ is not desirable in the proposed scheme. In the following, we further study the performance of the proposed scheme with only $M_c = 4$ in different deployments.

In Figure 6, the uplink achievable rate CCDF per collided RA UE in different deployments are shown. Under different deployments, both the all-AP and $M_c$-strongest-AP schemes provide poor performance for collided RA UEs due to the preamble collision in GFRA. Interestingly, we see that the all-AP scheme is more preferable to the $M_c$-strongest-AP scheme in terms of the $95\%$-likely performance. This results from that, without preamble multiplicity information and sensible AP clustering, the $M_c$-strongest-AP scheme leads to severe clustering errors, which make the selected APs contain little desirable signals of the targeted RA UE, but strong interference from other collided RA UEs at most time. This implies the necessity of preamble multiplicity estimation to enable correct AP clustering. Contrastively, based on the DNN based preamble multiplicity estimation, the proposed AP clustering scheme is significantly superior to the all-AP
and $M_c$-strongest-AP schemes. For instance in deployment 1, compared to the two schemes, the 95%-likely achievable rate of a collided RA UE can be largely enhanced by 26 dB and 34 dB, respectively. This performance superiority is also validated in Figure 7 where the uplink ergodic achievable rate per collided RA UE in deployment 1 is shown.

![Figure 7: Comparisons of uplink ergodic achievable rate per collided RA UE under different schemes, with $\sigma_{SF} = 8$ dB and $M_c = 4$.](image)

In summary, the proposed scheme can achieve a near-optimal performance under preamble collision resolution in GFRA. Particularly, as examples shown in the simulation, the proposed scheme is able to achieve a close performance to the genie-aided scheme in terms of uplink achievable rate per RA UE under preamble collision. In the considered deployments of distributed mMIMO, the proposed scheme provided its best performance when $M_c = 4$, which exhibits a significant performance gain of up to 26 dB over the all-AP scheme.
