Since January 2020 Elsevier has created a COVID-19 resource centre with free information in English and Mandarin on the novel coronavirus COVID-19. The COVID-19 resource centre is hosted on Elsevier Connect, the company's public news and information website.

Elsevier hereby grants permission to make all its COVID-19-related research that is available on the COVID-19 resource centre - including this research content - immediately available in PubMed Central and other publicly funded repositories, such as the WHO COVID database with rights for unrestricted research re-use and analyses in any form or by any means with acknowledgement of the original source. These permissions are granted for free by Elsevier for as long as the COVID-19 resource centre remains active.
COVID-19 and climatic factors: A global analysis

ABSTRACT

Background: It is unknown if COVID-19 will exhibit seasonal pattern as other diseases e.g., seasonal influenza. Similarly, some environmental factors (e.g., temperature, humidity) have been shown to be associated with transmission of SARS-CoV and MERS-CoV, but global data on their association with COVID-19 are scarce.

Objective: To examine the association between climatic factors and COVID-19. Methods: We used multilevel mixed-effects (two-level random-intercepts) negative binomial regression models to examine the association between 7- and 14-day-lagged temperature, humidity (relative and absolute), wind speed and UV index and COVID-19 cases, adjusting for Gross Domestic Products, Global Health Security Index, cloud cover (%), pre-p precipitation (mm), sea-level air-pressure (mb), and daytime length. The effects estimates are reported as adjusted rate ratio (aRR) and their corresponding 95% confidence interval (CI). Results: Data from 206 countries/regions (until April 20, 2020) with ≥100 reported cases showed no association between COVID-19 cases and 7-day-lagged temperature, relative humidity, UV index, and wind speed, after adjusting for potential confounders, but a positive association with 14-day-lagged temperature and a negative association with 14-day-lagged wind speed. Compared to an absolute humidity of <5 g/m³, an absolute humidity of 5–10 g/m³ was associated with a 23% (95% CI: 6–42%) higher rate of COVID-19 cases, while absolute humidity >10 g/m³ did not have a significant effect. These findings were robust in the 14-day-lagged analysis. Conclusion: Our results of higher COVID-19 cases (through April 20) at absolute humidity of 5–10 g/m³ may be suggestive of a ‘sweet point’ for viral transmission, however only controlled laboratory experiments can decisively prove it.

1. Introduction

Since its outbreak in late 2019 across China (Guan et al., 2020; Chen et al., 2020), the novel coronavirus SARS-CoV-2 spread rapidly across the continents owing to its high transmissibility (Bogoch et al., 2020) and increased global mobility with a potentially delayed travel ban in Wuhan, China (Linka et al., 2020). With subsequent global spread, it was declared a pandemic by the World Health Organization on March 11, 2020. SARS-CoV-2 belongs to the Coronaviridae family (Nowak et al., 2020), as are other “β” viruses such as severe acute respiratory syndrome (SARS-CoV), and Middle East respiratory syndrome (MERS-CoV). Previous studies reported the association between SARS-CoV and MERS-CoV with climatic factors including temperature and humidity (Price et al., 2019; Cai et al., 2007; Sun et al., 2020; Altamimi and Ahmed, 2020). Since SARS-CoV-2 belongs to the same virus family,
there has been widespread speculation and interest whether SARS-CoV-2 too will exhibit a similar pattern (Cohen, 2020). Some studies, mostly from China (Liu et al., 2020; Xie and Zhu, 2020; Ma et al., 2020), also reported the association between COVID-19 and climatic factors, albeit with conflicting results. Most of these studies were from a specific country with limited range of climatic variabilities, and reported results without robustly adjusting for potential confounding factors. In this study, we aimed to undertake a global study to examine the association between COVID-19 cases and temperature, humidity, UV index, and wind speed adjusting for a range of climatic variables and country-level systemic factors.

2. Methods

2.1. Data sources

2.1.1. Weather data

We obtained weather data from ‘World Weather Online’ using a Python based API from January 8, 2020 to April 20, 2020. Weather data included temperature, relative humidity, UV index, wind speed, cloud cover, precipitation, sea-level air-pressure, and day-time length. We obtained these data 7- and 14-day prior to the reported COVID-19 cases (more below). (Ren et al., 2017).

We calculated absolute humidity (AH) using Clausius Clapeyron equation (Iriarte et al., 1981) as follows:

\[ AH = \frac{6.112 \cdot e^{\left(\frac{17.27 \cdot T}{T + 237.5}\right)} \cdot \text{RH}^2 \cdot 1.674}{273.15 + T} \tag{1} \]

where AH is the absolute humidity, T is the temperature in °C and RH is the relative humidity.

For Australia, China, Canada and US, we obtained weather data at provincial/state level and for the remaining countries, we obtained weather data at country level.

2.1.2. COVID-19 cases

COVID-19 cases (up to April 20, 2020), estimating approximately 2.5 million cases worldwide, were obtained from the database developed by Johns Hopkins University (data available at https://github.com/CSSEGISandData/COVID-19).

2.1.3. Other variables

GDP per capita (2018 estimates) were obtained from the International Monetary Fund (International Monetary Fu, 2020). The 2019 Global Health Security Index - a measure of country’s emergency pandemic preparedness developed by the Johns Hopkins University - was obtained from the official report (Johns Hopkins Center for, 2019). These two variables were adjusted in all the analyses to address the issue of potential country-level factors (such as variability in testing rates, health systems financing, healthcare resource mobilization during emergency situations such as pandemics) that may confound the reported effects estimates.

2.2. Statistical analysis

Our analysis included the regions/countries that reported ≥100 COVID-19 cases by April 20, 2020.

Since the COVID-19 cases were nested within time (starting at the day the first case was reported by the respective country/region), which in turn is nested within the countries/regions, we used multilevel mixed-effects negative binomial regression model (Hilbe, 2011) to examine the association between daily weather variables and the daily number of new COVID-19 cases using a two-level random intercepts nested within the regions (countries, or states/provinces for larger countries). The

number of newly reported COVID-19 cases each day were regressed on the historical weather (preceding 1- and 2-week to coincide with the SARS-CoV-2 incubation period) (Lauer et al., 2020). Population of the respective region/country was added as an offset term in the model.

Our primary weather variables of interest were daily maximum temperature (Celsius), humidity (g/m²), UV index, and wind speed (kmph) since these have been reported to be associated with other coronaviruses in previous studies. (Price et al., 2019; Cai et al., 2007; Sun et al., 2020; Altamimi and Ahmed, 2020). All the models were adjusted for GDP per capita, Global Health Security Index, and other (standardized) climatic factors including cloud cover (%), precipitation (mm), sea-level air-pressure (mb), and length of downtime with the following exception: since temperature and UV index were highly correlated (Pearson’s correlation coefficient: 0.95), we did not use them together in the same model. Instead, two separate models were fit for the temperature and the UV index keeping all the other variables identical. For example, the model for temperature would have the number of cases regressed on temperature, humidity, wind speed, cloud cover, precipitation, sea-level air pressure and the length of downtime. The model for UV index will have all the variables stated above except temperature, which would be replaced by UV index.

From exploratory analysis, we observed an excess number of new daily cases in the range of absolute humidity between 5 and 10 g/m². Therefore, we also tested the hypothesis whether this observed association holds when we adjust for the potential confounders stated above. Specifically, we reported the association between absolute daily humidity (<5 g/m², 5–10 g/m², and >10 g/m²) and daily number of new COVID-19 cases adjusting for the variables listed above. The theoretical relationship between the temperature, relative humidity, and absolute humidity is shown in Fig. 1.

The effects estimates are reported as adjusted rate ratio (aRR) and their corresponding 95% confidence interval (CI). Data analysis was conducted in Stata/SE v.14.2 (StataCorp, 2015). P-values are two-sided and are considered statistically significant at the 0.05 level of significance.

3. Results

Two-hundred-six (206) regions/countries were included in the analysis that reported ≥100 cases each by April 20, 2020. Data from France were dropped from the analysis due to changes in their reporting that resulted in an anomalous increase on April 4, 2020.

We divided the data in five time periods (period 1 - Jan 22, 2020 to Feb 15, 2020, period 2 - Feb 16, 2020 to Feb 29, 2020, period 3 - March 2-6, 2020, period 4 - March 7-11, 2020, period 5 - March 12-16, 2020) and are considered statistically significant at the 0.05 level of significance.

Fig. 1. Variation of absolute humidity (AH) as a function of temperature and relative humidity. More than 75% of the COVID-19 cases (so far) have occurred in the area shown in light brown (5 g/m² ≤ AH ≤ 10 g/m²). Less than 25% of the cases have been reported in areas where absolute humidity is > 10 g/m² or <5 g/m². (For interpretation of the references to color in this figure legend, the reader is referred to the Web version of this article.)
1, 2020 to March 15, 2020, period 4 - March 16, 2020 to March 31, 2020 and period 5 - April 1, 2020 to April 20, 2020) and plotted the number of COVID-19 cases against daily maximum temperature (Celsius), humidity (g/m$^3$), UV index for each of those time periods (Fig. 2). Majority of the cases between January 22, 2020 and 20, April 2020 occurred at temperatures ranging between 0 and 17.5 °C, absolute humidity between 5 and 10 g/m$^3$ and UV index between 0 and 5. In March, the number of COVID-19 cases was similar for temperatures between 2.5 and 17.5 °C; with low cases in the temperature range between 17.5 and 20 °C. However, for April, the cases per million people between 17.5 and 20 °C increased likely due to natural warming up of the northern hemisphere as summer approaches. Unlike, temperature, where the observed trend of COVID-19 cases was observed across a wide range of temperature, approximately 75% of the cases through April 20, 2020 occurred between an absolute humidity between 5 and 10 g/m$^3$ suggesting a much stronger influence of AH on COVID-19 incidence (Fig. 2).

After adjusting for cloud cover, precipitation, sea-level air-pressure, length of daytime, GDP and Global Health Security Index, no climatic factor was associated with COVID-19 cases in the 7-day-lagged analysis. There was an indication of a negative association between wind speed and COVID-19 cases, but the effect estimates included the null value (Table 1).

In the 14-day-lagged analysis, daily maximum temperature was positively associated with COVID-19 cases showing a 7% increase (95% CI: 2–12%) for every 5 °C increase in temperature, after adjusting for the same variables mentioned above. In the same analysis, a 5 kmph increase in wind speed was associated with a 6% (95% CI: 2–9%) decrease in COVID-19 cases; the association between COVID-19 and 14-day-lagged relative humidity and UV index was inconclusive (Table 1).

Table 2 shows the association between absolute humidity and number of new COVID-19 cases. In the adjusted model, an absolute humidity between 5 and 10 g/m$^3$, inclusive, was associated with a 23% (95% CI: 6–42%) higher number of new COVID-19 cases, compared to an absolute humidity <5 g/m$^3$, while the effect of an absolute humidity above 10 g/m$^3$ was not different compared with absolute humidity <5 g/m$^3$ (aRR: 1.03, 95% CI: 0.88–1.39). These results were robust and consistent in the analyses using 14-day-lagged data (Table 2).

4. Discussion

To our knowledge, this is one of the largest studies to date that examines the association between the incidence of COVID-19 and a range of climatic factors spanning across 206 regions of the world with approximately 2.5 million cases reported through April 20, 2020.

---

Table 1: Association between climatic factors and COVID-19.

| Weather factors       | 7-day lagged |        | 14-day lagged |        |
|-----------------------|-------------|--------|--------------|--------|
|                       | aRR (95% CI)| P-value| aRR (95% CI) | P-value|
| Model 1               |             |        |              |        |
| Daily maximum         | 1.00        | 0.904  | 1.07         | 0.003  |
| temperature (°C)      | (0.95–1.04) |        | (1.02–1.12)  |        |
| Relative humidity (%) | 0.99        | 0.215  | 1.02         | 0.076  |
| Wind speed (kmph)     | 0.97        | 0.071  | 0.94         | 0.001  |
| Model 2               |             |        |              |        |
| UV index              | 1.00        | 0.874  | 1.03         | 0.180  |
| Relative humidity (%) | 0.99        | 0.213  | 1.01         | 0.201  |
| Wind speed (kmph)     | 0.97        | 0.069  | 0.94         | <0.001 |

The models were additionally adjusted for cloud cover (%), precipitation (mm), sea-level air-pressure (mb), length of daytime, GDP per capita, and Global Health Security Index; aRR: Adjusted rate ratio; CI: confidence interval.

* Estimated effects with every 5 unit increase in the respective variables (e.g., 5 °C increase in temperature).

* Estimated effects per one unit increase in UV index.

---

Fig. 2. COVID-19 cases across the world versus temperature, absolute humidity, and UV. (For interpretation of the references to color in this figure legend, the reader is referred to the Web version of this article.)
used robust statistical methods adjusted for a range of potential systems-related and climatic confounding factors to assess the relationship of COVID-19 cases and climatic factors. Our results show that the hypothesized associations between many of the climatic variables and COVID-19 do not hold when adjusted for a range of potential confounding factors. In fact, a positive association between 14-day-lagged COVID-19 and relative humidity, cloud cover (%), precipitation (mm), sea-level air-pressure (mb), length of daytime, GDP per capita, and Global Health Security Index; aRR: Adjusted rate ratio; CI: confidence interval.

| Absolute humidity | 7-day lagged aRR (95% CI) P-value | 14-day lagged aRR (95% CI) P-value |
|-------------------|-----------------------------------|-----------------------------------|
| >5 g/m³           | Ref                               | Ref                               |
| 5-10 g/m³         | 1.23 (1.06-1.42) 0.005             | 1.25 (1.08-1.44) 0.003             |
| >10 g/m³          | 1.03 (0.81-1.33) 0.815             | 1.13 (0.89-1.42) 0.325             |

The models were additionally adjusted for daily maximum temperature, relative humidity, cloud cover (%), precipitation (mm), sea-level air-pressure (mb), length of daytime, GDP per capita, and Global Health Security Index; aRR: Adjusted rate ratio; CI: confidence interval.

Conclusions

In conclusion, our study finds conflicting results on the association between temperature and COVID-19 cases. The association between COVID-19 and humidity, and UV index were inconclusive. We found a negative association between wind speed and COVID-19 cases. A higher rate of COVID-19 was found between an absolute humidity between 5 and 10 g/m³. However, our results do not infer causality, and these reported findings may provide baseline data for experimental studies to provide a confirmatory result. Any pandemic, and therefore COVID-19, requires a multifaceted expertise and approaches to handle it properly. We need more data to understand the clinical and epidemiological nature of SARS-CoV-2 while we continue to improve our understanding of other closely related areas such as public health interventions.
