We study quark confinement physics using lattice QCD. In the maximally abelian (MA) gauge, the off-diagonal gluon amplitude is strongly suppressed, and then the off-diagonal gluon phase shows strong randomness, which leads to a large effective off-diagonal gluon mass, $M_{\text{off}} \approx 1.2 \text{GeV}$. Due to the large off-diagonal gluon mass in the MA gauge, low-energy QCD is abelianized like nonabelian Higgs theories. In the MA gauge, there appears a macroscopic network of the monopole world-line covering the whole system. We extract and analyze the dual gluon field $B_{\mu}$ from the monopole-current system in the MA gauge, and evaluate the dual gluon mass as $m_{B} = 0.4 \sim 0.5 \text{GeV}$ in the infrared region, which is a lattice-QCD evidence of the dual Higgs mechanism by monopole condensation. Even without explicit use of gauge fixing, we can define the maximal abelian projection by introducing a “gluonic Higgs field” $\phi(x)$, whose hedgehog singularities lead to monopoles. From infrared abelian dominance and infrared monopole condensation, infrared QCD is describable with the dual Ginzburg-Landau theory. In relation to the color-flux-tube picture for baryons, we study the three-quark (3Q) ground-state potential $V_{3Q}$ in SU(3)$_{c}$ lattice QCD at the quenched level, with the smearing technique for enhancement of the ground-state component. With accuracy better than a few %, $V_{3Q}$ is well described by a sum of the two-body Coulomb part and the three-body linear confinement part $\sigma_{3Q}L_{\text{min}}$, where $L_{\text{min}}$ denotes the minimal value of the total length of the color flux tube linking the three quarks. Comparing with the Q-\bar{Q} potential, we find a universal feature of the string tension as $\sigma_{3Q} \approx \sigma_{Q\bar{Q}}$ and the OGE result for the Coulomb coefficient as $A_{3Q} \approx \frac{1}{2}A_{Q\bar{Q}}$.

1. Nonabelian Feature in QCD

Nowadays, quantum chromodynamics (QCD) is established as the fundamental theory of the strong interaction. In spite of the simple form of QCD lagrangian

$$\mathcal{L}_{\text{QCD}} = -\frac{1}{2} \text{tr} G_{\mu\nu} G^{\mu\nu} + \bar{q} (i \slashed{D} - m_{q}) q,$$

it is still hard to understand nonperturbative QCD (NP-QCD) phenomena, such as color confinement and dynamical chiral-symmetry breaking, in the infrared strong-coupling region. In fact, QCD tells us the “rule” of the elementary interaction between quarks and gluons, but to solve QCD is another difficult problem.
In this point, QCD may resemble the Rubik Cube, where the rule is quite simple, but to solve this puzzle is rather difficult. Like QCD, the difficulty of the Rubik cube comes from the non-commutable procedures of the “nonabelian” rotational process as shown in Fig.1. Here, a kind of “local procedure” on $3 \times 3 \times 3$ subcubes leads to extremely large number of configurations, which makes this puzzle difficult and interesting. Then, the Rubik cube may be regarded as a miniature of QCD. The main difficulties of QCD originate from the nonabelian and the strong-coupling features in the infrared region below $1 \text{ GeV}$. In the ultraviolet region, the QCD coupling is weak and then we can use the perturbative QCD, where the three and the four gluon vertices stemming from the nonabelian nature of QCD are treated as perturbative interactions. In the infrared region, however, the nonabelian and the strong-coupling features are significant.

In the electro-magnetism, the superposition of solutions is possible, because of the linearity of the field equation $\partial_\mu F^{\mu\nu} = j^\nu$, so that we can consider the partial electro-magnetic field formed by each charge and the total electro-magnetic field can be obtained by summing up the individual field solution. On the other hand, the QCD field equation becomes
nonlinear as
\[ \partial_\mu G^{\mu\nu} + ig[A_\mu, G^{\mu\nu}] = j^\nu, \] (2)
due to the nonabelian feature, and then it is difficult to solve it even at the classical level, because the superposition of solutions is impossible. So, we cannot divide the color-electromagnetic field into each part formed by each quark. Instead, the QCD system is to be analyzed as a whole system. In this way, for the analysis of QCD, the nonabelian feature provides one of serious difficulties.

2. Abelianization of QCD in MA Gauge

The nonabelian nature of QCD in the infrared region is, however, removed in the MA gauge. In fact, QCD is reduced into an abelian gauge theory with color-magnetic monopoles, keeping essence of infrared nonperturbative features.

2.1. Dual Superconductor Theory and QCD

In QCD, to understand the confinement mechanism is one of the most difficult problems remaining in the particle physics. As is indicated by hadron Regge trajectories and lattice QCD calculations, the confinement phenomenon is characterized by one-dimensional squeezing of the color-electric flux and the string tension \( \sigma \approx 1 \text{GeV}/\text{fm} \), which is the key quantity of confinement.

On the confinement mechanism, Nambu first proposed the dual superconductor theory for quark confinement,\(^2\) based on the electro-magnetic duality in 1974. In this theory, there occurs the one-dimensional squeezing of the color-electric flux between quark and anti-quark by the dual Meissner effect due to condensation of bosonic color-magnetic monopoles. However, there are two large gaps between QCD and the dual superconductor theory.\(^3\)\(^5\)

- The dual superconductor theory is based on the abelian gauge theory subject to the Maxwell-type equations, where electro-magnetic duality is manifest, while QCD is a nonabelian gauge theory.
- The dual superconductor theory requires condensation of color-magnetic monopoles as the key concept, while QCD does not have color-magnetic monopoles as the elementary degrees of freedom.

These gaps may be simultaneously fulfilled by taking MA gauge fixing, which reduces QCD to an abelian gauge theory including color-magnetic monopoles.
2.2. MA Gauge Fixing and Relevant Mode for Confinement

In Euclidean QCD, the maximally abelian (MA) gauge is defined so as to minimize the total amount of the off-diagonal gluons,

\[ R_{\text{off}}[A_\mu(x)] = \int d^4x \text{ tr} \left\{ [\hat{D}_\mu, \hat{H}] [\hat{D}_\mu, \hat{H}]^\dagger \right\} = \frac{e^2}{2} \int d^4x \sum_\alpha |A_\mu^\alpha(x)|^2, \quad (3) \]

by the SU($N_c$) gauge transformation. Here, we have used the Cartan decomposition,

\[ A_\mu(x) = \vec{A}_\mu(x) \cdot \vec{H} + \sum_\alpha A_\mu^\alpha(x) E^\alpha. \]

Since the SU($N_c$) covariant derivative operator \( \hat{D}_\mu \equiv \partial_\mu + ieA_\mu \) obeys the adjoint gauge transformation, the local form of the MA gauge condition is easily derived as

\[ [\hat{H}, [\hat{D}_\mu, [\hat{D}_\mu, \hat{H}]]] = 0. \quad (3-5) \]

In the MA gauge, the gauge symmetry \( G \equiv \text{SU}(N_c)_{\text{local}} \) is reduced into

\[ H \equiv U(1)^{N_c-1}_{\text{local}} \times \text{Weyl}^{\text{global}}, \]

where the global Weyl symmetry is a subgroup of SU($N_c$) relating the permutation of \( N_c \) bases in the fundamental representation. In the MA gauge, off-diagonal gluons behave as charged matter fields like \( W_\pm^\mu \) in the Standard Model, and provide the color-electric current in terms of the residual abelian gauge symmetry. In addition, according to the reduction of the gauge symmetry, color-magnetic monopoles appear as topological objects reflecting the nontrivial homotopy group

\[ \Pi_2(\text{SU}(N_c)/U(1)^{N_c-1}) = \Pi_1(U(1)^{N_c-1}) = \mathbb{Z}_{\infty}^{N_c-1}, \quad (4) \]

in a similar manner to similarly in the GUT monopole. Here, the global Weyl symmetry and color-magnetic monopoles are relics of nonabelian nature of QCD.

Thus, in the MA gauge, QCD is reduced into an abelian gauge theory including color-magnetic monopoles, which is expected to provide a theoretical basis of the dual superconductor theory for quark confinement. Furthermore, recent lattice QCD studies show remarkable features of abelian dominance and monopole dominance for NP-QCD in the MA gauge.

1. Without gauge fixing, all the gluon components equally contribute to NP-QCD, and it is difficult to extract relevant degrees of freedom for NP-QCD.

2. In the MA gauge, QCD is reduced into an abelian gauge theory including the electric current \( j_\mu \) and the magnetic current \( k_\mu \), which forms the global network of the monopole world-line covering the whole system. In the MA gauge, lattice QCD shows abelian dominance for NP-QCD (confinement, chiral symmetry breaking \(^9\), gluon propagators \(^10\)): only the diagonal gluon, which remains an abelian
gauge field, is relevant for NP-QCD, while off-diagonal gluons do not contribute to NP-QCD.

(3) By the Hodge decomposition, the diagonal gluon is decomposed into the “photon part” and the “monopole part”, corresponding to the separation of $j_{\mu}$ and $k_{\mu}$. In the MA gauge, lattice QCD shows monopole dominance\textsuperscript{9,11–12} for NP-QCD: the monopole part ($k_{\mu} \neq 0, j_{\mu} = 0$) leads to NP-QCD, while the photon part ($j_{\mu} \neq 0, k_{\mu} = 0$) seems trivial like QED and does not contribute to NP-QCD. For example, on the $Q - \bar{Q}$ potential, the purely linear confinement potential appears in the monopole part, while the Coulomb potential appears in the photon part like QED.\textsuperscript{13}

In fact, by taking the MA gauge, the relevant collective mode for NP-QCD can be extracted as the color-magnetic monopole.\textsuperscript{4,5}

3. Strong Random Phase of Off-diagonal Gluon in MAQCD

To find out essence of the MA gauge, we study the feature of the off-diagonal gluon field $A_{\mu}^{\pm} \equiv \frac{1}{\sqrt{2}}(A_{\mu}^{1} \pm iA_{\mu}^{2})$ in the MA gauge in SU(2) lattice QCD.

In SU(2) lattice QCD, the SU(2) link variable is factorized as $U_{\mu}(s) = M_{\mu}(s)u_{\mu}(s)$, according to the Cartan decomposition SU(2) $\times$ U(1). Here, $u_{\mu}(s) \equiv \exp\{i\tau^{3} \theta^{3}_{\mu}(s)\} \in$ U(1) is the abelian link variable, and the abelian projection is defined by the replacement as $U_{\mu}(s) \rightarrow u_{\mu}(s)$. The off-diagonal matrix $M_{\mu}(s) \in$ SU(2)/U(1) is parameterized as

$$M_{\mu}(s) \equiv e^{i\sqrt{2} \theta^{3}_{\mu}(s)} = \begin{pmatrix} \cos \theta_{\mu}(s) & ie^{-i\chi_{\mu}(s)}\sin \theta_{\mu}(s) \\ ie^{i\chi_{\mu}(s)}\sin \theta_{\mu}(s) & \cos \theta_{\mu}(s) \end{pmatrix}. \quad (5)$$

In the continuum limit, $\chi_{\mu}(s)$ coincides with the off-diagonal gluon phase as $A_{\mu}^{\pm}(x) = e^{\pm i\chi_{\mu}(x)}|A_{\mu}^{\pm}(x)|$, and $\theta_{\mu}(s)$ is proportional to the off-diagonal gluon amplitude as $\theta_{\mu}(s) = \frac{1}{\sqrt{2}}a|eA_{\mu}^{\pm}(s)|$ with the lattice spacing $a$. In the MA gauge, the diagonal element $\cos \theta_{\mu}(s)$ in $M_{\mu}(s)$ is maximized by the SU(2) gauge transformation, e.g. $\langle \cos \theta_{\mu}(s) \rangle_{MA} \simeq 0.93$ at $\beta = 2.4$. Accordingly, the off-diagonal gluon $A_{\mu}^{\pm}(x) = e^{\pm i\chi_{\mu}(x)}|A_{\mu}^{\pm}(x)|$ has two relevant features in the MA gauge.\textsuperscript{3–5}

(1) The off-diagonal gluon amplitude $|A_{\mu}^{\pm}(x)|$ (or $|\sin \theta_{\mu}(s)|$ on lattices) is strongly suppressed by SU($N_{c}$) gauge transformation in the MA gauge.

(2) The off-diagonal gluon phase $\chi_{\mu}(x)$ tends to be random, because $\chi_{\mu}(x)$ is not constrained by MA gauge fixing at all, and only the constraint from the QCD action is weak due to a small accompanying factor $|A_{\mu}^{\pm}|$ or $|\sin \theta_{\mu}|$. 
Now, we consider the behavior of $\Delta \chi \equiv |\chi_\mu(s) - \chi_\mu(s + \hat{v})|(\text{mod } \pi)$ in the MA gauge. If the off-diagonal gluon phase $\chi_\mu(x)$ is a continuum variable, as lattice spacing $a$ goes to 0, $\Delta \chi \approx a |\partial_\nu \chi_\mu|$ must go to zero, and hence $P(\Delta \chi)$ approaches to the $\delta$-function with the peak at $\Delta \chi = 0$. However, as shown in Fig.2(a), $P(\Delta \chi)$ is almost $a$-independent and almost flat. These features indicate the strong randomness of the off-diagonal gluon phase $\chi_\mu(x)$ in the MA gauge. Then, $\chi_\mu(x)$ is approximately a random angle variable in the MA gauge.\(^3\)

3.1. Randomness of Off-diagonal Gluon Phase and Abelian Dominance

Within the random-variable approximation\(^3-5\) for the off-diagonal gluon phase $\chi_\mu(s)$ in the MA gauge, we analytically prove abelian dominance of the string tension. Here, we use

$$\langle e^{i\chi_\mu(s)} \rangle_{\text{MA}} \simeq \frac{1}{2\pi} \int_0^{2\pi} d\chi_\mu(s) \exp\{i\chi_\mu(s)\} = 0. \quad (6)$$

In the Wilson loop $\langle W_C[U] \rangle = \langle \text{tr}\Pi_C U_\mu(s) \rangle = \langle \text{tr}\Pi_C \{M_\mu(s)u_\mu(s)\} \rangle$, the off-diagonal matrix $M_\mu(s)$ is reduced to a $c$-number factor,

$$M_\mu(s) \rightarrow \cos \theta_\mu(s) \mathbf{1}, \quad (7)$$

\(^3\)However, as shown in Sect. 6, near the monopole, there remains a large amplitude of $|\sin \theta_\mu(s)|$ even in the MA gauge, and $\chi_\mu(s)$ is strongly constrained so as to make the QCD action small. Hence, $\chi_\mu(s)$ cannot be regarded as a random variable near monopoles.
and then the SU(2) link variable $U_{\mu}(s)$ is reduced to a diagonal matrix as
\[ U_{\mu}(s) \equiv M_{\mu}(s)u_{\mu}(s) \to \cos \theta_{\mu}(s)u_{\mu}(s), \]  
(8)
after the integration over $\chi_{\mu}(s)$. For the $R \times T$ rectangular $C$, the Wilson loop $W_{C}[U]$ in the MA gauge is approximated as
\[ \langle W_{C}[U] \rangle = \langle \text{tr} \prod_{i=1}^{L} \{ M_{\mu_{i}}(s_{i})u_{\mu_{i}}(s_{i}) \} \rangle_{\text{MA}} \approx \langle \exp \{ \Sigma_{i=1}^{L} \ln(\cos \theta_{\mu_{i}}(s_{i})) \} \} \rangle_{\text{MA}} \langle W_{C}[u] \rangle_{\text{MA}} \]  
(9)
with perimeter $L \equiv 2(R + T)$ and the abelian Wilson loop $W_{C}[u] \equiv \text{tr} \prod_{i=1}^{L} u_{\mu_{i}}(s_{i})$. Replacing $\sum_{i=1}^{L} \ln(\cos \theta_{\mu_{i}}(s_{i}))$ by its average $L \langle \ln(\cos \theta_{\mu}) \rangle_{\text{MA}}$ in a statistical sense, we derive the perimeter law of the off-diagonal gluon contribution to the Wilson loop as
\[ W_{C}^{\text{off}} \equiv \langle W_{C}[U] \rangle / \langle W_{C}[u] \rangle_{\text{MA}} \approx \exp \{ L \langle \ln(\cos \theta_{\mu}) \rangle_{\text{MA}} \}, \]  
(10)
which is confirmed in lattice QCD, as shown in Fig.2(b). Near the continuum limit, we find also the relation between the macroscopic quantity $W_{C}^{\text{off}}$ and the microscopic quantity of the off-diagonal gluon amplitude $\langle |A_{\mu}^{\pm}|^{2} \rangle_{\text{MA}}$ as
\[ W_{C}^{\text{off}} \equiv \langle W_{C}[U] \rangle / \langle W_{C}[u] \rangle_{\text{MA}} \approx \exp \{ -\frac{L a^{2}}{4} \langle |A_{\mu}^{\pm}|^{2} \rangle_{\text{MA}} \}. \]  
(11)
In this way, perfect abelian dominance for the string tension, $\sigma_{\text{SU}(2)} = \sigma_{\text{Abel}}$, is analytically derived within the random-variable approximation for the off-diagonal gluon phase in the MA gauge.

### 3.2. Strongly Random Phase and Large Mass of Off-diagonal Gluons

As another remarkable fact, strong randomness of off-diagonal gluon phases leads to rapid reduction of off-diagonal gluon correlations. In fact, if $\chi_{\mu}(x)$ is a complete random phase, Euclidean off-diagonal gluon propagators exhibit $\delta$-functional reduction,
\[ \langle A_{\mu}^{+}(x) A_{\nu}^{-}(y) \rangle_{\text{MA}} = \langle |A_{\mu}^{+} (x)||A_{\nu}^{-} (y)|e^{i(\chi_{\nu}(x) - \chi_{\nu}(y))} \rangle_{\text{MA}} = \langle |A_{\mu}^{\pm} (x)|^{2}\rangle_{\text{MA}} \delta_{\mu \nu} \delta^{4}(x - y), \]  
(12)
which means the infinitely large mass of off-diagonal gluons. Of course, the real off-diagonal gluon phases are not complete but approximate random phases. Then, off-diagonal gluon mass would be large but finite. In this way, strong randomness of off-diagonal gluon phases is expected to provide a large effective mass of off-diagonal gluons.
4. Large Mass Generation of Off-diagonal Gluons in MA Gauge: Essence of Infrared Abelian Dominance

Using SU(2) lattice QCD, we actually investigate the Euclidean gluon propagator \( G_{ab}^{\mu \nu}(x-y) \equiv \langle A^a_\mu(x) A^b_\nu(y) \rangle \) \((a, b = 1, 2, 3)\) and the off-diagonal gluon mass \( M_{\text{off}} \) in the MA gauge. As for the residual U(1)$_3$ gauge symmetry, we take U(1)$_3$ Landau gauge, to extract most continuous gluon configuration under the MA gauge constraint and to compare with the continuum theory. The continuum gluon field \( A^a_\mu(x) \) is derived from the link variable as

\[
U_\mu(s) = \exp\{iaeA^a_\mu(s)\tau^a/2\}.
\]

We show in Fig.3(a) the scalar-type gluon propagators \( G^3_{\mu \nu}(r) \) and \( G^{+ -}_{\mu \nu}(r) \equiv \langle A^+_\mu(x) A^-_\nu(y) \rangle = \frac{1}{2}(G^+_{\mu \nu}(r) + G^-_{\mu \nu}(r)) \), which depend only on the four-dimensional Euclidean distance \( r \equiv \sqrt{(x_\mu - y_\mu)^2} \), in SU(2) lattice QCD with \( 2.2 \leq \beta \leq 2.4 \) with various sizes \((12^3 \times 24, 16^4, 20^4)\). We find infrared abelian dominance for the gluon propagator in the MA gauge: only the abelian gluon \( A_3^\mu(x) \) propagates over the long distance and can influence the long-distance physics.\(^4,5,10\)

Since the four-dimensional Euclidean propagator of the massive vector boson with the mass \( M \) takes a Yukawa-type asymptotic form as

\[
G_{\mu \nu}(r) = \frac{3M}{4\pi^2r}K_1(Mr) + \frac{1}{M^2} \delta^4(x-y) \simeq \frac{3M^{1/2}}{2(2\pi)^{3/2}} e^{-M r} \frac{e^{-Mr}}{r^{3/2}},
\]

we investigate the effective mass \( M_{\text{eff}} \) of off-diagonal gluons \( A^\pm_\mu(x) \) from the slope of the logarithmic plot of \( r^{3/2}G^{+ -}_{\mu \nu}(r) \sim \exp\{-M_{\text{eff}}r\} \) in Fig.3(b).

1. The off-diagonal gluon \( A^+_\mu(x) \) behaves as a massive field with a large mass about 1 GeV for \( r \geq 0.2\)fm in the MA gauge.
2. From the fitting analysis of the lattice QCD data with \( r \geq 0.2\)fm, the off-diagonal gluon mass is evaluated as \( M_{\text{eff}} \simeq 1.2 \) GeV in the MA gauge.

We perform also the mass measurement of off-diagonal gluons from the temporal correlation of the zero-momentum projected operator \( O^{\pm}_\mu(\tau) \),

\[
\Gamma^{+ -}_{\mu \nu}(\tau) = \langle O^+_{\mu}(\tau)O^-_{\nu}(0) \rangle, \quad O^\pm_{\mu}(\tau) \equiv \int dx \ A^\pm_{\mu}(x, \tau),
\]

in lattice QCD in the MA gauge plus U(1)$_3$ Landau gauge. We find the off-diagonal gluon mass \( M_{\text{off}} \simeq 1.2\)GeV again from the slope of the logarithmic plot of \( \Gamma^{+ -}_{\mu \nu}(\tau) \) in SU(2) lattice QCD with \( 2.3 \leq \beta \leq 2.35 \) with \( 16^3 \times 32 \) and \( 12^3 \times 24 \).
Thus, off-diagonal gluons $A_{\mu}^{\pm}$ acquire a large effective mass $M_{\text{eff}} \simeq 1.2\text{GeV}$ in the MA gauge, which is essence of infrared abelian dominance.\cite{4,5,10} In the MA gauge, due to the large effective mass $M_{\text{eff}} \simeq 1.2\text{GeV}$, off-diagonal gluons $A_{\mu}^{\pm}$ can propagate only within a short range as $r \lesssim M_{\text{eff}}^{-1} \simeq 0.2\text{fm}$, and becomes infrared inactive like weak bosons in the Standard Model. Then, in the MA gauge, off-diagonal gluons $A_{\mu}^{\pm}$ cannot contribute to the infrared NP-QCD, which leads to infrared abelian dominance.\cite{4,5,7,10,14}

Figure 3. (a) The scalar-type gluon propagator $G_{\mu\mu}(r)$ as the function of the four-dimensional distance $r$ in the MA gauge in SU(2) lattice QCD with $2.2 \leq \beta \leq 2.4$ with various sizes ($12^3 \times 24$, $16^3$, $20^3$). (b) The logarithmic plot of $r^{3/2}G_{\mu\mu}(r)$ v.s. $r$. The off-diagonal gluon propagator behaves as the Yukawa-type function, $G_{\mu\mu} \sim \exp(-M_{\text{eff}}^{3/2}r)$. (c) The logarithmic plot of the temporal correlation $\Gamma_{\mu\mu}^{\pm}(\tau) \equiv \langle O_{\mu}^{\pm}(\tau)O_{\mu}^{\pm}(0) \rangle$ as the function of the temporal distance $\tau$ in SU(2) lattice QCD with $2.3 \leq \beta \leq 2.35$ with $16^3 \times 32$ and $12^3 \times 24$. From the slope of the dotted lines in (b) and (c), the effective mass of the off-diagonal gluon $A_{\mu}^{\pm}$ is estimated as $M_{\text{eff}} \simeq 1.2\text{GeV}$.

5. Lattice-QCD Evidence of Monopole Condensation

In the MA gauge, there appears the global network of the monopole worldline covering the whole system as shown in Fig.4(a), and this monopole-current system (the monopole part) holds essence of NP-QCD. Using SU(2) lattice QCD, we examine the dual Higgs mechanism by monopole condensation in the NP-QCD vacuum in the MA gauge.\cite{4,5}

Since QCD is described by the “electric variable” as quarks and gluons, the “electric sector” of QCD has been well studied with the Wilson loop or the inter-quark potential, however, the “magnetic sector” of QCD is hidden and still unclear. To investigate the magnetic sector directly, it is useful to introduce the “dual (magnetic) variable” as the dual gluon field $B_{\mu}$, which is the dual partner of the diagonal gluon and directly couples with the magnetic current $k_{\mu}$. 
Owing to the absence of the electric current $j_\mu$ in the monopole part, the dual gluon $B_\mu$ can be introduced as the regular field satisfying $(\partial \wedge B)_{\mu\nu} = *F_{\mu\nu}$ and the dual Bianchi identity, $\partial^\nu (\partial \wedge B)_{\mu\nu} = j_\nu = 0$. By taking the dual Landau gauge $\partial_\mu B^\mu = 0$, the field equation is simplified as

$$\partial_\mu \ast (\partial \wedge B)_{\mu\nu} = j_\nu = 0.$$  

(15)

$$B_\mu(x) = (\partial^{-2} k_\mu)(x) = -\frac{1}{4\pi^2} \int d^4y \frac{k_\mu(y)}{(x-y)^2}.$$  

Since the dual gluon $B_\mu$ is massive under monopole condensation, we investigate the dual gluon mass $m_B$ as the evidence of the dual Higgs mechanism.

First, we put test magnetic charges in the monopole-current system in the MA gauge in SU(2) lattice QCD, and measure the inter-monopole potential $V_M(r)$ to get information about monopole condensation. Since the dual Higgs mechanism provides the screening effect on the magnetic flux, $V_M(r)$ is expected to be short-range Yukawa-type, if monopole condensation occurs. The potential between the monopole and the anti-monopole can be derived as

$$V_M(R) = -\lim_{T \to \infty} \frac{1}{T} \ln\langle W_D(R, T) \rangle, \quad (16)$$

Figure 4. The SU(2) lattice-QCD results in the MA gauge. (a) The monopole world-line projected into $\mathbf{R}^3$ on the $16^3 \times 4$ lattice with $\beta = 2.2$ (the confinement phase). There appears a global network of monopole currents covering the whole system. (b) The inter-monopole potential $V_M(r)$ v.s. the 3-dimensional distance $r$ in the monopole-current system on the $20^4$ lattice. The solid curve denotes the Yukawa potential with $m_B = 0.5\text{GeV}$. The dotted curve denotes the Yukawa-type potential including the monopole-size effect. (c) The scalar-type dual-gluon correlation $\ln\langle r^{-3/2}_E (B_\mu(x)B_\mu(y))_{\text{MA}} \rangle$ as the function of the 4-dimensional Euclidean distance $r_E$ on the $24^4$ lattice. The slope corresponds to the dual gluon mass $m_B$. 
using the dual Wilson loop $W_D$ as the loop-integral of the dual gluon,$^{4,5}$
\[ W_D(C) \equiv \exp\left\{ i e \frac{1}{2} \oint_C dx_\mu B^\mu \right\} = \exp\left\{ i e \frac{1}{2} \int d\sigma_{\mu\nu} *F^{\mu\nu} \right\}, \quad (17) \]
which is the dual version of the abelian Wilson loop
\[ W_{\text{Abel}}(C) \equiv \exp\left\{ i e \frac{1}{2} \oint_C dx_\mu A^\mu_3 \right\} = \exp\left\{ i e \frac{1}{2} \int d\sigma_{\mu\nu} F^{\mu\nu} \right\}, \quad (18) \]
and the test monopole charge is set to be $e/2$.

In Fig.4(b), we show $V_M(r)$ in the monopole part in the MA gauge.$^{4,5}$ Except for the short distance, the inter-monopole potential is well fitted by the Yukawa potential
\[ V_M(r) = -\frac{(e/2)^2}{4\pi} e^{-m_B r/r}, \quad (19) \]
and thus the magnetic screening is observed. In the MA gauge, the dual gluon mass is estimated as $m_B \simeq 0.5\text{GeV}$ from the infrared behavior of $V_M(r)$.

Second, we investigate also the Euclidean scalar-type dual gluon propagator $\langle B_\mu(x)B_\mu(y)\rangle_{\text{MA}}$ as shown in Fig.4(c), and estimate the dual gluon mass as $m_B = 0.4 \sim 0.5 \text{GeV}$ from its long-distance behavior.$^5$

From these two tests, the dual gluon mass is evaluated as $m_B = 0.4 \sim 0.5 \text{GeV}$, and this can be regarded as the lattice-QCD evidence for the dual Higgs mechanism by monopole condensation at the infrared scale.$^{4,5}$

To conclude, lattice QCD in the MA gauge exhibits infrared abelian dominance and infrared monopole condensation, and therefore the dual Ginzburg-Landau (DGL) theory$^{8,17-23}$ can be constructed as the infrared effective theory directly based on QCD in the MA gauge. (See Fig.5).

### 6. Monopole Structure in terms of the Off-diagonal Gluon

Let us compare the QCD-monopole with the point-like Dirac monopole. There is no point-like monopole in QED, because the QED action diverges around the point-like monopole. The QCD-monopole also accompanies a large abelian action density, however, owing to cancellation with the off-diagonal gluon contribution, the total QCD action is kept finite even around the QCD-monopole.$^{3-5}$

To see this, we examine the QCD-monopole structure in the MA gauge in terms of the action density using SU(2) lattice QCD.$^{3-5}$ From the SU(2) plaquette $P_{\mu\nu}^{SU(2)}(s)$ and the abelian plaquette $P_{\mu\nu}^{\text{Abel}}(s) \in U(1)_3 \subset SU(2)$, we define the “SU(2) action density” $S_{\mu\nu}^{SU(2)}(s) \equiv 1 - \frac{1}{2} \text{tr} P_{\mu\nu}^{SU(2)}(s)$, the
"abelian action density" $S^{\text{Abel}}_{\mu \nu}(s) \equiv 1 - \frac{1}{2} \text{tr} P_{\mu \nu}^{\text{Abel}}(s)$ and the "off-diagonal gluon contribution" $S^{\text{off}}_{\mu \nu}(s) \equiv S^{\text{SU}(3)}_{\mu \nu}(s) - S^{\text{Abel}}_{\mu \nu}(s)$. In the lattice formalism, the monopole current $k_{\mu}(s)$ is defined on the dual link, and there are 6 plaquettes around the monopole. Then, we consider the local average over

From Lattice QCD to Dual Ginzburg-Landau Theory

--- Infrared Effective Theory directly based on QCD ---

| QCD : SU(3)$_C$ Nonabelian Gauge Theory |

Dual Gauge Symmetry is spontaneously broken instead of Gauge Symmetry

Figure 5. Construction of the dual Ginzburg-Landau (DGL) theory from lattice QCD in the maximally abelian gauge.
the 6 plaquettes around the dual link,

\[ S(s, \mu) \equiv \frac{1}{12} \sum_{\alpha \beta \gamma} \sum_{m=0}^{1} |\varepsilon_{\mu\alpha\beta\gamma}| S_{\alpha\beta}(s + m\hat{\gamma}). \] (20)

We show in Fig.6(b) the probability distribution of the action densities \( S_{SU(2)} \), \( S_{\text{Abel}} \) and \( S_{\text{off}} \) around the QCD-monopole in the MA gauge.

Figure 6. (a) The total probability distribution \( P(S) \) on the whole lattice and (b) the probability distribution \( P_k(S) \) around the monopole for SU(2) action density \( S_{SU(2)} \) (dashed curve), abelian action density \( S_{\text{Abel}} \) (solid curve) and off-diagonal gluon contribution \( S_{\text{off}} \) (dotted curve) in the MA gauge at \( \beta = 2.4 \) on 16\(^4\) lattice. Around the QCD-monopole, large cancellation between \( S_{\text{Abel}} \) and \( S_{\text{off}} \) keeps the total QCD-action small. (c) The schematic figure for the QCD-monopole structure in the MA gauge. The QCD-monopole includes a large amount of off-diagonal gluons around its center as well as the diagonal gluon.

We summarize the results on the QCD-monopole structure as follows.

1. Around the QCD-monopole, both the abelian action density \( S_{\text{Abel}} \) and the off-diagonal gluon contribution \( S_{\text{off}} \) are largely fluctuated, and their cancellation keeps the total QCD-action density \( S_{SU(2)} \) small.

2. The QCD-monopole has an intrinsic structure relating to a large amount of off-diagonal gluons around its center like the ’t Hooft-Polyakov monopole. At a large scale, off-diagonal gluons inside the QCD-monopole become invisible, and QCD-monopoles can be regarded as point-like Dirac monopoles.

3. From the concentration of off-diagonal gluons around QCD-monopoles in the MA gauge, we can naturally understand the local correlation between monopoles and instantons.\(^3\)−\(^5\),\(^11\),\(^12\),\(^15\),\(^16\) In fact, instantons tend to appear around the monopole world-line in the MA gauge, because instantons need full SU(2) gluon components for existence.
7. Gluonic Higgs and Gauge Invariant Description of MA Projection

In the MA gauge, the gauge group $G \equiv SU(N_c)$ is partially fixed into its subgroup $H \equiv U_{\text{local}}^{N_c-1} \times \text{Weyl}_N$, and then the gauge invariance becomes unclear.\(^b\)

In this section, we propose a gauge invariant description of the MA projection in QCD. Even without explicit use of gauge fixing, we can naturally define the MA projection by introducing a “gluonic Higgs scalar field” $\phi(x)$. For a given gluon field configuration $\{A_\mu(x)\}$, we define a gluonic Higgs scalar $\tilde{\phi}(x) = \Omega(x)\tilde{H}\Omega^\dagger(x)$ with $\Omega(x) \in SU(N_c)$ so as to minimize

$$R[\tilde{\phi}(\cdot)] = \int d^4x \text{tr} \left\{ [\tilde{D}_\mu, \tilde{\phi}(x)][\tilde{D}_\mu, \tilde{\phi}(x)]^\dagger \right\}.$$  \hspace{1cm} (21)

We summarize the features of this description as follows.\(^3\)

1. The gluonic Higgs scalar $\tilde{\phi}(x)$ does not have amplitude degrees of freedom but has only color-direction degrees of freedom, and $\tilde{\phi}(x)$ corresponds to a “color-direction” of the nonabelian gauge connection $\tilde{D}_\mu$ averaged over $\mu$ at each space-time $x$.

2. Through the projection along $\tilde{\phi}(x)$, we can extract the abelian $U(1)^{N_c-1}$ sub-gauge-manifold which is most close to the original $SU(N_c)$ gauge manifold. This projection is manifestly gauge invariant, and is mathematically equivalent to the ordinary MA projection.\(^3\)

3. Similar to $\tilde{D}_\mu$, the gluonic Higgs scalar $\tilde{\phi}(x)$ obeys the adjoint gauge transformation, and is diagonalized in the MA gauge. Then, monopoles appear at the hedgehog singularities of $\tilde{\phi}(x)$ as shown in Fig.7.\(^3,8\)

4. In this description, infrared abelian dominance is interpreted as infrared relevance of the gluon mode along the color-direction $\tilde{\phi}(x)$, and QCD seems similar to a nonabelian Higgs theory.

8. The 3Q Ground-State Potential in SU(3) Lattice QCD

In relation to the color-flux-tube picture for baryons,\(^24,25\) we study the three-quark (3Q) ground-state potential in SU(3)\(_c\) lattice QCD at the

\(^b\)In Refs.[3,12], we show a useful gauge-invariance criterion on the operator $O_{\text{MA}}$ defined in the MA gauge: If $O_{\text{MA}}$ defined in the MA gauge is $H$-invariant, $O_{\text{MA}}$ is also invariant under the whole gauge transformation of $G$.\(^3\)
Figure 7. The correlation between the gluonic Higgs scalar field $\phi(x) = \phi^a(x)\tau^a$ and monopoles denoted by dots in SU(2) lattice QCD with $\beta = 2.4$ and $16^4$. The arrow denotes the color direction of $(\phi^1(x), \phi^2(x), \phi^3(x))$ in the SU(2) internal space. The monopole in the MA gauge appears at the hedgehog singularity of the gluonic Higgs scalar $\phi(x)$ in the Landau gauge.

...quenched level. In contrast with a number of studies on the Q-$\bar{Q}$ potential using lattice QCD, there were only a few preliminary lattice-QCD works for the 3Q potential.

To begin with, let us consider the potential form in the Q-$\bar{Q}$ and 3Q systems with respect to QCD. In the short-distance limit, perturbative QCD is applicable and the Coulomb-type potential appears as the one-gluon-exchange (OGE) result. In the long-distance limit at the quenched level, the flux-tube picture would be applicable from the argument of the strong-coupling limit of QCD, and hence a linear confinement potential proportional to the total flux-tube length is expected to appear. Indeed, lattice QCD results for the Q-$\bar{Q}$ ground-state potential are well described by

$$V_{Q\bar{Q}}(r) = -A_{Q\bar{Q}} \frac{r}{r} + \sigma_{Q\bar{Q}} r + C_{Q\bar{Q}}$$

(22)

at the quenched level. In fact, $V_{Q\bar{Q}}$ is described by a sum of the short-distance OGE result and the long-distance flux-tube result.

Also for the 3Q ground-state potential $V_{3Q}$, we try to apply this simple picture of the short-distance OGE result plus the long-distance flux-tube result. Then, the 3Q potential $V_{3Q}$ is expected to take a form of

$$V_{3Q} = -A_{3Q} \sum_{i<j} \frac{1}{|r_i - r_j|} + \sigma_{3Q} L_{\min} + C_{3Q},$$

(23)

with $L_{\min}$ the minimal value of total length of flux tubes linking the three quarks.

Similar to the derivation of the Q-$\bar{Q}$ potential from the Wilson loop, the 3Q static potential $V_{3Q}$ can be derived from the 3Q Wilson loop $W_{3Q}$...
as \(^{25-31}\)

\[ V_{3Q} = -\lim_{T \to \infty} \frac{1}{T} \ln(W_{3Q}), \quad W_{3Q} \equiv \frac{1}{3!} \varepsilon_{abc} \varepsilon_{a'b'c'} U_1^{a'a'} U_2^{b'b'} U_3^{c'c'} \]  

with \( U_k \equiv \exp\{ig \int_{V_k} dx^\mu A_\mu(x)\} \) \((k = 1, 2, 3)\) (see Fig.8). Here, the 3Q Wilson loop \( W_{3Q} \) is defined in a gauge-invariant manner. The 3Q gauge-invariant state is generated at \( t = 0 \) and is annihilated at \( t = T \). For \( 0 < t < T \), the three quarks are spatially fixed in \( \mathbb{R}^3 \).

![Figure 8. The 3Q Wilson loop \( W_{3Q} \). The 3Q state is generated at \( t = 0 \) and is annihilated at \( t = T \). The three quarks are spatially fixed in \( \mathbb{R}^3 \) for \( 0 < t < T \).](image)

Physically, the true ground state of the 3Q system would be expressed by the flux tubes instead of the strings, and the 3Q state which is expressed by the three strings generally includes many excited-state components such as flux-tube vibrational modes. Since the practical measurement of \( \langle W_{3Q} \rangle \) is quite severe for large \( T \) in lattice QCD calculations, the smearing technique for ground-state enhancement\(^{27,28}\) is practically indispensable for the accurate measurement of the 3Q ground-state potential \( V_{3Q} \).

The standard smearing for link-variables\(^ {33}\) is expressed as the iteration of the replacement of the spatial link-variable \( U_i(s) \) \((i = 1, 2, 3)\) by the obscured link-variable \( \bar{U}_i(s) \in \text{SU}(3) \) which maximizes

\[ \text{Re} \, \text{tr} \left( \bar{U}_i(s) \left\{ \alpha U_i(s) + \sum_{\pm, j \neq i} U_{\pm j}(s) U_i(s \pm \hat{j}) U_{\mp j}(s + \hat{i}) \right\} \right), \]  

with a real smearing parameter \( \alpha \) and \( U_{-\mu}(s) \equiv U_{\mu}^\dagger(s - \hat{\mu}) \). The \( n \)-th smeared link-variables \( U^{(n)}_\mu(s) \) \((n = 1, 2, \ldots, N_{\text{smear}})\) are iteratively defined starting from \( U^{(0)}_\mu(s) \equiv U_{\mu}(s) \) as

\[ U^{(n)}_i(s) \equiv \bar{U}_i^{(n-1)}(s) \quad (i = 1, 2, 3), \quad U^{(n)}_4(s) \equiv U_4(s). \]  

This smearing procedure keeps the gauge covariance of the “fat” link-variable \( U^{(n)}_{\mu}(s) \) properly. In fact, the gauge invariance of \( F(U^{(n)}_{\mu}(s)) \)
is ensured if $F(U_\mu(s))$ is a gauge-invariant function. Since the fat link-variable $U_\mu^{(n)}(s)$ includes a spatial extension, the “spatial line” expressed with $U_\mu^{(n)}(s)$ physically corresponds to a “flux tube” with a spatial extension. Therefore, if a suitable smearing is done, the “spatial line” of the fat link-variable is expected to be close to the ground-state flux tube. We search reasonable values of the smearing parameter $\alpha$ and the iteration number $N_{\text{smear}}$ in the lattice QCD calculation.

Table 1. The best fit coefficients in Eq.(23) for the 3Q potential and those in Eq.(22) for the Q-\overline{Q} potential in the lattice unit.

|   | $\sigma$  | $A$    | $C$    |
|---|-----------|--------|--------|
| 3Q| 0.1524(28)| 0.1331(66) | 0.9182(213) |
| Q\overline{Q} | 0.1629(47) | 0.2793(116) | 0.6203(161) |

Table 2. Lattice QCD results for the 3Q potential $V_{\text{lat}}^{3Q}$ for 16 patterns of the 3Q system, where the three quarks are put on $((i, 0, 0), (0, j, 0) \text{ and } (0, 0, k))$ in $\mathbb{R}^3$ in the lattice unit. For each 3Q configuration, $V_{\text{lat}}^{3Q}$ is measured from the single-exponential fit $\langle W_{3Q} \rangle = \overline{C} e^{-V_{3Q}^T}$ in the range of $T$ listed at the fourth column. The statistical errors listed are estimated with the jackknife method, and $\chi^2/N_{\text{DF}}$ is listed at the fifth column. The fitting function $V_{\text{fit}}^{3Q}$ in Eq.(23) with the best fitting parameters in Table 1 is also added.

| $(i, j, k)$ | $V_{\text{lat}}^{3Q}$ | $\overline{C}$ | fit range | $\chi^2/N_{\text{DF}}$ | $V_{\text{fit}}^{3Q}$ | $V_{\text{fit}}^{3Q} - V_{\text{lat}}^{3Q}$  |

We show lattice QCD results for the 3Q ground-state potential. We generate 210 gauge configurations using SU(3)$_c$ lattice QCD Monte-Carlo simulation with the standard action with $\beta = 5.7$ and $12^3 \times 24$ at the quenched level. The lattice spacing $a \simeq 0.19$ fm is determined so as to
reproduce the string tension as $\sigma = 0.89$ GeV/fm in the $Q\bar{Q}$ potential $V_{QQ\bar{Q}}$. Here, the pseudo-heat-bath algorithm is used for updating, and the gauge configurations are taken every 500 sweeps after a thermalization of 5000 sweeps.

We measure the 3Q ground-state potential $V_{3Q}$ using the smearing technique, and compare the lattice data with the theoretical form of Eq.(23). Owing to the smearing with $\alpha = 2.3$ and $N_{\text{smear}} = 12$, the ground-state component is largely enhanced, and therefore the 3Q Wilson loop $\langle W_{3Q} \rangle$ composed with the smeared link-variable exhibits a single-exponential behavior as $\langle W_{3Q} \rangle \approx e^{-V_{3Q}T}$ even for a small value of $T$. For each 3Q configuration, we extract $V_{3Q}^{\text{lat}}$ from the least squares fit with the single-exponential form

$$\langle W_{3Q} \rangle = \bar{C}e^{-V_{3Q}T}$$

(27)

in the range of $T_{\text{min}} \leq T \leq T_{\text{max}}$ listed in Table 2. Here, the fit range of $T$ is chosen such that the stability of the "effective mass"

$$V(T) \equiv \ln \{ \langle W_{3Q}(T)/W_{3Q}(T+1) \rangle \}$$

(28)

is observed in the range of $T_{\text{min}} \leq T \leq T_{\text{max}} - 1$.

For each 3Q configuration, we summarize the lattice QCD data $V_{3Q}^{\text{lat}}$ as well as the prefactor $\bar{C}$ in Eq.(27), fit range of $T$ and $\chi^2/N_{\text{DF}}$ in Table 2. The statistical error of $V_{3Q}^{\text{lat}}$ is estimated with the jackknife method. We find a large ground-state overlap as $\bar{C} > 0.8$ for all 3Q configurations.

Now, we consider the potential form of $V_{3Q}$. We show in Table 1 the best fit parameters in Eq.(23) for $V_{3Q}$. We compare in Table 2 the lattice QCD data $V_{3Q}^{\text{lat}}$ with the fitting function $V_{3Q}^{\text{fit}}$ in Eq.(23) with the best fit parameters. The three-quark ground-state potential $V_{3Q}$ is well described by Eq.(27) with accuracy better than a few $\%$, although $\chi^2/N_{\text{DF}} = 3.76$ seems relatively large, which may reflect a systematic error on the finite lattice spacing. (The fitting with $\Delta$-type flux-tube ansatz suggested in Refs.[29,31,34] is rather worse and shows unacceptably large $\chi^2/N_{\text{DF}} = 10.1$ even for the best fit.)

By comparing the coefficients $(\sigma_{3Q}, A_{3Q})$ with $(\sigma_{QQ}, A_{QQ})$ in Table 1, we find a universal feature of the string tension, $\sigma_{3Q} \simeq \sigma_{QQ}$, and the OGE result for the Coulomb coefficient, $A_{3Q} \simeq \frac{1}{2}A_{QQ}$.

Acknowledgments

The authors would like to thank Professor Yoichiro Nambu for his useful suggestions. The lattice calculations were performed on NEC-SX4 at Osaka University.
