Abstract

Background: Endovascular revascularization has recently been established as a less invasive treatment method for chronic mesenteric ischemia. However, intestinal necrosis caused by distal embolization following this procedure has not been emphasized.

Case presentation: The present report describes a 59-year-old man who was treated with endovascular revascularization for chronic mesenteric ischemia. After the procedure, he was diagnosed with intestinal necrosis caused by distal embolization. Despite emergent bowel resection, he died on postoperative day 109.

Conclusion: Although endovascular revascularization for chronic mesenteric ischemia is less invasive and may be suitable for high-risk patients, attention should be paid to avoid embolic complications that can cause intestinal infarction possibly leading to a fatal condition.

Keywords: Chronic mesenteric ischemia, Endovascular revascularization, Embolization, Bowel necrosis, Embolic protection device

Background

Endovascular revascularization (ER) is an emerging treatment alternative for chronic mesenteric ischemia (CMI) [1]. Although open surgical revascularization (OR) yields a satisfactory outcome with respect to symptom relief and primary patency, it can be associated with perioperative morbidity and mortality. ER is advantageous in that it is less invasive [2,3]. However, procedure-related complications following ER occur in approximately 10% of cases. Of these complications, distal embolization and subsequent bowel necrosis can lead to a fatal condition [4-8]. The present report describes a case of CMI associated with intestinal infarction after ER and discusses the procedure-specific complications.

Case presentation

A 59-year-old man with postprandial abdominal pain, diarrhoea, and vomiting was referred to our hospital. His body mass index was 18.4. His symptoms improved with total parenteral nutrition but relapsed after he resumed his normal diet. He had a history of multiple abdominal surgical interventions. During the past 20 years, he had undergone open drainage for acute pancreatitis, cholecystectomy and choledochotomy for acute cholangitis, cystogastrostomy for pancreatic pseudocyst, and choledocho-jejunostomy for bile duct stenosis. He had a history of hypertension, diabetes, and cervical spondylosis, as well as a history of smoking. An upper gastrointestinal endoscopy showed no ischemic change, whereas total colonoscopy revealed ischemia in the distal ileum and the ascending colon. Enhanced abdominal computed tomography (CT) showed stenosis of the superior mesenteric artery (SMA) and occlusion of the celiac and inferior mesenteric arteries with developed collateral vessels from the SMA and left iliac artery (Figure 1). The patient was diagnosed with CMI caused by splanchnic arterial stenoses and occlusions, and revascularization of the SMA was necessary. We chose ER for this treatment, taking into consideration his poor nutritional condition and hostile abdomen. The root of the SMA was
highly calcified; therefore, we considered angioplasty with stenting to be appropriate. The procedure was performed under local anaesthesia via the left brachial route. The stenosis close to the origin of the SMA was traversed with a 0.014-inch guidewire. After systemic administration of 3000 units of unfractionated heparin, the lesion was predilated, and a stent (Palmaz Genesis, 6 mm × 16 mm, Cordis/Johnson & Johnson, Miami, FL, USA) was placed without apparent difficulty (Figure 2). He subsequently received a continuous infusion of 15000 units of unfractionated heparin for the first 24 hours and 100 mg of aspirin per day.

The patient complained of right upper quadrant abdominal pain after the intervention, and his white blood cell count was elevated to 20 200/μL on the next day. Muscular guarding was present with further elevation of white blood cell count on the second day, and CT revealed small bowel necrosis with intestinal pneumatosis and bloody ascites. Emergency laparotomy was performed, and the necrotic ileum and ischemic ascending colon were totally resected. Post operatively, the patient suffered an ischemic heart attack and liver abscess, which were both treated nonsurgically. Although an ileostomy and a mucous fistula of the colon were viable without ischemia throughout the postoperative course, bacterial translocation from the intestine, which had already been damaged by chronic ischemia before ER, was suspected as a cause of the liver abscess. He died of massive gastrointestinal bleeding on postoperative day 109.

Discussion
Abdominal angina or CMI is characterized by postprandial abdominal pain and weight loss. Insufficient intestinal blood flow causes these symptoms and is usually produced by the obstruction of 2 or 3 splanchnic vessels [7]. The underlying etiology of this disease is atherosclerosis in more than 90% of cases. Other causes include fibromuscular dysplasia, vasculitis (such as Takayasu arteritis, giant cell arteritis, polyarteritis nodosa, systemic lupus erythematosus, and thromboangiitisobliterans), malignancy, and radiation. Patients are initially treated with conservative therapy including bowel resting, smoking cessation, and administration of vasodilator drugs. Revascularization is considered if these conservative treatments fail to relieve the symptoms. Open surgery has been the standard method for revascularization in CMI. On the other hand, since the first report by Furrer et al. on the effectiveness of percutaneous transluminal angioplasty for CMI [2], ER has been considered as the treatment of choice in some cases [9]. Previous studies have reported the equivalent technical success and symptom relief rates, and lower morbidity in ER, compared with OR. Additionally, the primary patency rate is lower in ER than in OR, resulting in more secondary interventions [2,3]. Therefore, ER is currently recommended for high-risk patients [8]. The therapeutic method for CMI should be

Carefully determined, because the treatment outcomes are often affected by systemic cardiovascular comorbidities, as in our patient. Patients treated with ER can have associated procedure-specific complications, and sometimes follow catastrophic courses, as in the present case. Distal embolization and arterial dissection are often critical conditions. Eight cases of distal embolization as a complication of ER for CMI have been previously reported [4-8]. All of these patients underwent bowel resection, and 7 of 8 patients died of postoperative multiple organ failure (Table 1). Bowel necrosis and subsequent sepsis can easily deteriorate the general condition of patients considered high risk for OR, causing 60% of all deaths after ER for CMI [4-8]. Therefore, efforts should be made to prevent embolization.

Little is known about the impact of stent placement in terms of distal embolization. We did not use an embolic protection device (EPD), because there is little evidence showing its efficacy during ER for CMI. An EPD may be useful in some cases with CMI [10,11]. Brown et al. [11] reported the feasibility of routine EPD use because there was no major perioperative morbidity in their endovascular treatment. In percutaneous revascularization and stent placement for renal artery stenosis, several reports have suggested the efficacy of EPDs [12,13]. These studies showed that embolic particles were observed in 60–90% of cases treated for atherosclerotic renal arteries. However, EPD use involves the intrinsic complications of vasospasm, arterial dissection, arterial wall damage, distal hypoperfusion, and even distal embolization [14,15]. Further studies are necessary to verify the usefulness of EPDs in cases with CMI.

Conclusion
Although ER for CMI is less invasive and may be suitable for high-risk patients, attention should be paid to avoid embolic complications.
