Angioedema is a potentially life-threatening adverse reaction to angiotensin-converting enzyme inhibitors and angiotensin receptor blockers. To study the genetic etiology of this rare adverse event, international consortia and multicenter recruitment of patients are needed. To reduce patient heterogeneity, we have standardized the phenotype.

In brief, it comprises swelling in the head and neck region that first occurs during treatment. It should not coincide with urticaria or have another likely cause such as hereditary angioedema.

CONSENSUS PROCESS

In order to study the genetic etiology of rare ADRs, international consortia and multicenter recruitment are needed. The phenotype comprises swelling in the head and neck region induced by ACE inhibitors or ARBs being investigated by the international consortium PREDICTION-ADR, which was funded by the European Union’s Seventh Framework Programme in 2013. To facilitate multicenter recruitment of patients, a meeting was organized to standardize the phenotype of angioedema induced by agents acting on the angiotensin system. A panel of invited experts comprising clinical and basic pharmacologists, internists, immunologists and clinical chemistry scientists, allergists, oto-rhino-laryngology specialists, regulatory agency representatives, and managers of electronic medical record databases convened in Liverpool on 10 December 2013.

DESCRIPTION OF THE PHENOTYPE

Angioedema, also known as angioneurotic edema or Quincke’s edema, is a transient, localized, potentially life-threatening swelling of the deep reticular dermis, subcutaneous or submucosal tissues, and occasionally the viscera. It is caused by vasodilation and increased endothelial permeability, leading to extravasation of fluid into the interstitial compartment. Angioedema can be either hereditary or acquired. Diagnosis of angioedema induced by drugs acting on the angiotensin system is based on the case history and clinical features, and other
causes of angioedema need to be excluded. Supplementary Table S1 online describes the clinical and demographic data recommended to be collected for each patient.

**Pathophysiological mechanism**

Angioedema induced by ACE inhibitors is thought to be mediated by bradykinin and other vasodilating molecules, but the precise pathophysiology has not been elucidated. ACE has two active sites that are able to generate angiotensin II from angiotensin I and degrade bradykinin to inactive metabolites (Figure 1a). Inhibition of ACE will thus decrease both the formation of angiotensin II and the degradation of bradykinin (Figure 1b). Alternative bradykinin inactivating pathways usually step in, but if these pathways are deficient, bradykinin accumulates. Genetic variants in these pathways could explain why only a minority of patients develop angioedema. Variants have been identified in the first intron of the membrane metallo-endopeptidase gene (MME) and upstream of the X-prolyl aminopeptidase 2 gene (XPNPEP2) that encodes aminopeptidase P (APP). However, for the majority of patients, the predisposing factors are unknown.

The pathophysiological mechanism underlying angioedema during ARB treatment is even more unclear (Figure 1c). ARBs have no direct effect on ACE or bradykinin breakdown but have been shown to increase bradykinin levels in hypertensive humans, possibly through indirect inhibition of ACE and metallo-endopeptidase. It is assumed that by blocking the angiotensin type 1 receptor, more circulating angiotensin II is made available for binding to the type 2 receptor. This, in turn, inhibits ACE and metallo-endopeptidase, which can result in increased bradykinin levels.

**Incidence and onset**

ACE inhibitor treatment is the single most common cause of angioedema in the head and neck region in adults, accounting for ~30% of angioedema cases in emergency departments. Angioedema generally occurs within the first 3 months of therapy, but symptoms may appear after many years of treatment. During the first year, the cumulative incidence of angioedema per 1,000 persons was 1.79 (95% confidence interval (CI), 1.73–1.85), with the incidence rate per 1,000 person-years being 4.38 (95% CI, 4.24–4.54) based on an analysis of 1,845,138 patients initiating ACE inhibitor treatment. If the use of an ACE inhibitor is continued after an incident, the rate of recurrent angioedema increases to 187 per 1,000 person-years, with, on average, 11 months to recurrence, according to a study covering 51,752 person-years of

---

**Figure 1** Theoretical effect of agents acting on the angiotensin system. (a) A simplified scheme of the angiotensin–bradykinin pathways. ACE inhibitors inhibit two pathways: the formation of angiotensin II from angiotensin I, and the degradation of bradykinin into inactive peptides. Aminopeptidase P (APP) and membrane metallo-endopeptidase (MME) are alternative pathways to inactivate bradykinin. Accumulation of bradykinin may contribute to the development of angioedema. (c) Mechanism of action of angiotensin II receptor type 1 blockers (ARBs). ARBs block the type 1 receptor site for angiotensin II, which instead may bind to the type 2 receptor. Stimulation of the type 2 binding site results in a bradykinin cascade that inhibits ACE and metallo-endopeptidase (MME), which can lead to increased bradykinin levels. Bradykinin contributes to the therapeutic action of ARBs and may also contribute to the development of angioedema.
ACE inhibitor use. After drug withdrawal, the tendency to develop angioedema usually abates but may persist for months or even years. It is difficult to rationalize how such episodes can occur after stopping the ACE inhibitor, and indeed this is not in accordance with the usual criteria for causality assessment for acutely occurring ADRs. It is possible that the episodes that occur after stopping the ACE inhibitor reflect exacerbation of an intrinsic underlying susceptibility to angioedema, the etiology of which is unclear.

Angioedema during ARB treatment is more infrequent. During the first year, the cumulative incidence of angioedema per 1,000 person-years was 0.62 (95% CI, 0.55–0.69), with the incidence rate per 1,000 person-years being 1.66 (95% CI, 1.47–1.86) in 467,313 patients initiating ARB treatment. ARBs are usually well tolerated in patients with previous general ACE inhibitor intolerance. However, patients who have experienced ACE inhibitor angioedema have been known to develop angioedema when switched to an ARB. Among such patients, the rate of angioedema during ARB treatment is ~4%, according to two meta-analyses, suggesting that a previous episode of ACE inhibitor angioedema can predispose patients to ARB angioedema.

Clinical presentation
Angioedema induced by an ACE inhibitor develops in areas of loose connective tissue over about 4–6 h and usually resolves in 24–48 h. The face, lips, tongue, floor of the mouth, and upper airways are most often affected, and the swelling may be asymmetrical. Symptoms such as a lump in the throat, hoarse voice, and difficulties in swallowing and breathing are signs of impending airway obstruction. ACE inhibitor–induced angioedema rarely presents with urticaria or swelling outside the head and neck region, although gastrointestinal and genital angioedema have been reported. There are no obvious differences in symptoms of angioedema induced by ACE inhibitors and ARBs. Supplementary Table S2 online describes further information to be requested with regard to the reaction.

Risk factors
Minor local trauma, surgical procedures, and dental treatment may trigger angioedema during ACE inhibitor treatment. Smoking and a history of ACE inhibitor–induced cough have also been identified as risk factors. Other risk factors include female gender, African-American ethnicity, chronic heart failure, coronary artery disease, and a history of drug rash and seasonal allergies (Table 1). Due to the rarity of angioedema induced by ARBs, knowledge about risk factors is poor.

Neither sex nor age has been identified as a risk factor. Smoking and a history of ACE inhibitor–induced cough have also been identified as risk factors. Other risk factors include female gender, African-American ethnicity, chronic heart failure, coronary artery disease, and a history of drug rash and seasonal allergies (Table 1).

Differential diagnosis
Other causes of angioedema can be divided by their pathophysiology into (i) hereditary or acquired, mediated by bradykinin or vasoactive molecules; (ii) allergic or pseudoallergic, dependent on direct mast cell degranulation; and (iii) idiopathic angioedema.

Angioedema mediated by bradykinin or vasoactive molecules
Bradykinin-mediated angioedema is characterized by painless swelling without urticaria that responds to treatment with the selective bradykinin B2 receptor antagonist icatibant. Bradykinin-mediated angioedema is not associated with urticaria or other manifestations of histamine release such as hypotension, wheezing, or anaphylaxis.

Hereditary angioedema
This is a rare condition with a prevalence of 1 in 50,000. Patients with hereditary angioedema may present with abdominal pain, obstruction of the upper airways, and swelling of the hands and feet in addition to angioedema at other sites. They do not experience urticaria but may present a transient creeping (serpiginous) skin rash at the leading edge of the angiodematous area. Hereditary angioedema should be suspected in young adults with a family history of angioedema. There are three subtypes of hereditary angioedema. Both types I and II are caused by mutations in the C1 inhibitor gene serpin peptidase inhibitor clade G member 1 (SERPING1) on chromosome 11. Type I is characterized by low circulating levels of C1-inhibitor (C1-INH) and represents 85% of cases. Type II has a functional deficiency of C1-INH, but normal levels, and accounts for 15% of cases. A rare type III is caused by mutations in the coagulation factor XII gene (F12) on chromosome 5. It is found in women with normal levels and function of C1-INH, and is thought to be induced by estrogen.

Acquired angioedema
This is an uncommon form of C1-INH deficiency that is usually associated with B-cell lymphoproliferative diseases such as lymphoma and myeloma, and occasionally
Angioedema. When nonallergic, the mechanism is thought to be mast cell activation that is mediated through the inhibition of cyclooxygenase pathways, resulting in leukotriene synthesis. When nonallergic, the mechanism is thought to be mast cell activation that is mediated through the inhibition of cyclooxygenase pathways, resulting in leukotriene synthesis. When nonallergic, the mechanism is thought to be mast cell activation that is mediated through the inhibition of cyclooxygenase pathways, resulting in leukotriene synthesis.

Angioedema dependent on mast cell degranulation

Mast cell degranulation results in the release of histamine and other inflammatory mediators that increase vascular permeability and lead to angioedema, which is often associated with urticaria and pruritus. Angioedema dependent on mast cell degranulation can be divided into allergic and pseudoallergic types. It usually responds to treatment with antihistamines, corticosteroids, and epinephrine. Elevated levels of histamine and serum tryptase are sometimes found in this type of angioedema when accompanied by systemic features (anaphylaxis).

Allergic angioedema. This is the result of immunoglobulin E (IgE)-mediated mast cell activation and degranulation. IgE-mediated reactions are triggered by specific allergens, and previous exposure is required, but this may be covert. Symptoms do not appear in the absence of the allergens such as food, latex, insect stings, and drugs. IgE-mediated angioedema usually subsides within 24 h, but relapses are common and unpredictable. Typical localization is to the face, particularly the lips and periorbital area; extremities; and genitals. Severe cases manifest with respiratory tract symptoms with rhinitis, wheezing, or stridor, and cardiovascular involvement with tachycardia and hypotension that may evolve into anaphylactic shock.

Pseudoallergic angioedema. This mimics an allergic reaction but is not mediated by IgE. It can be caused by direct mast cell degranulation due to, for example, intravenous radiocontrast media and opiates. Nonsteroidal anti-inflammatory drugs can induce both allergic and more commonly nonallergic angioedema. When nonallergic, the mechanism is thought to be mast cell activation that is mediated through the inhibition of cyclooxygenase pathways, resulting in leukotriene synthesis.
