1. Introduction

Magnetic fields are important in a wide array of different astrophysical systems. In star formation they govern the dynamics at several stages during collapse. They are critical in the launching of jets from a broad range of sources. They also play a major role in the transport of angular momentum in ionized accretion disks due to the magnetorotational instability. Magnetic fields have been largely neglected in galaxy formation simulations, mostly due to the technical difficulties associated with them. It is only until recently that they have begun to be applied (Wang & Abel 2009; Kotarba et al. 2011; Pakmor & Springel 2013; Rieder & Teyssier 2016; Butsky et al. 2017; Su et al. 2017; Pakmor et al. 2017; Steinwandel et al. 2019). The importance of magnetic fields in galaxy formation can be seen from observations of the Milky Way and nearby galaxies, which reveal that the magnetic energy is in equipartition with the thermal and turbulent energies (Boulares & Cox 1990; Beck et al. 1996). This means that they likely have a large dynamical effect on the evolution of the galaxy, adding significant non-thermal pressure that can suppress star-formation (Pakmor & Springel 2013). In addition, it has been shown that magnetic fields have a strong impact on fluid instabilities (Jun et al. 1995; McCourt et al. 2015) which may affect how gas in the intergalactic medium (IGM) accretes onto galaxies and how gas in galactic outflows leaves (or cycles back to) galaxies. The strength and structure of magnetic fields in galaxies also determine the transport of cosmic rays (CRs), which has recently emerged as a promising candidate for driving galactic outflows because they have long cooling time scales (Uhlig et al. 2012; Booth et al. 2013; Pakmor et al. 2016; Butsky & Quinn 2018).

Apart from the improvements in the general method, advances have been made in the MHD extension for SPH (SPMHD). The modern foundation of SPMHD comes largely from the work of Price & Monaghan (2004) which was built on the earlier work of Phillips & Monaghan (1985). The two main technical difficulties to overcome for SPMHD, are the handling of divergence errors and the choice of an artificial resistivity term to capture shocks and discontinuities in the magnetic field. Artificial dissipation terms are required to smooth out discontinuities in any fluid quantity in all numerical hydrodynamics methods. In SPH, this is most commonly achieved via explicit artificial dissipation. To avoid excessive dissipation away from shocks and discontinuities, switches have been developed to limit where the artificial dissipation terms are active. For magnetic fields, newly developed artificial resistivity switches (Price et al. 2018; Tricco & Price 2013) have significantly reduced the amount of dissipation and improved the method in the weak field regime.

Unphysical divergence errors (magnetic monopoles) can arise from the discretization and numerical integration of the MHD equations. Divergence errors in SPMHD for magnetic-dominated scenarios need to be handled with care, as they can produce a negative force between particles which leads to the tensile instability (Monaghan 2000). As such, the force produced from the divergence needs to be partly removed in the strong field regime for the method to remain stable, this breaks momentum and energy conservation in proportion to the divergence error. It is therefore crucial to try to keep the divergence error as close to zero as possible. While grid codes have access to the constrained transport scheme (Evans & Hawley 1988) which ensures a divergence free field up to...
machine precision, it cannot easily be implemented within meshless methods, due to the absence of regular spatial grid surfaces. Generation of divergence free fields in SPMHD have been explored in detail, however all of them suffer from problems. Generation of magnetic fields from Euler potentials ($B = \nabla \alpha \times \nabla \beta$) cannot wind the magnetic field and thereby not produce a dynamo (Brandenburg 2010, Price 2010) showed that vector potential implementations ($B = \nabla \times A$) are plagued with numerical instabilities. However Stasyszyn & Elsner (2015) recently showed that with additional diffusion, smoothing of the magnetic field and enforcing the Coulomb gauge ($\nabla \cdot A = 0$), the vector potential formalism could remain stable for a handful of test cases. Additional testing would be required to determine the robustness of the method. The most popular method to deal with divergence error in meshless methods, is to evolve the magnetic field via the induction equation and then to “clean” the divergence away. In general this is done by introducing a separate scalar field which couples to the induction equation such that it produces a damped wave equation for the divergence error, so the divergence is spread outward like a damped wave. The method was first developed in Dedner et al. (2002) and was improved by Tricco & Price (2012), who introduced a constrained version of the method. This makes sure that the magnetic energy is either conserved or dissipated. This was updated in Tricco et al. (2016) to correctly allow variable cleaning speed, which further improved the method.

These new improvements in artificial dissipation and divergence error controlling have significantly increased the accuracy and convergence of the SPMHD method. There have recently also been implementations of non-ideal MHD in SPMHD (Tsukamoto et al. 2013; Wurster et al. 2014; Tsukamoto et al. 2015; Price et al. 2018), which include Ohmic resistivity, ambipolar diffusion and the Hall effect.

As mentioned previously, the numerical surface tension seen in traditional SPH (TSPH) can be solved by using a different gradient operator (GDSPH) (Wadsley et al. 2017). This substantially improves the accuracy of pressure forces across density jumps and provides a more physical form for the internal energy equation, where it represents a direct discretization of $\frac{\partial S}{\partial t} = -\rho \nabla \cdot \mathbf{v}$ from the Euler equations while retaining all the usual conservation properties. In Wadsley et al. (2017), the authors show that GDSPH, together with an explicit turbulent diffusion term on thermal energy, yields excellent results in fluid mixing test cases such as the Kelvin-Helmholtz instability and the blob test.

In this paper we investigate how SPMHD benefits from the use of GDSPH. As such, we have implemented MHD within the GASOLINE2 (Wadsley et al. 2017) and CHANGA (Menon et al. 2015) codes, which both utilize the GDSPH formalism. GASOLINE2 is a highly parallel, state-of-the-art code for cosmological structure formation simulations and include all the features of modern SPH methods. CHANGA includes all the same SPH methods as GASOLINE2, but is written in an inherently parallel language CHARM++ (Kale & Krishnan 1993) which enables more efficient parallelization. The major difference between the two codes lies in the gravity solver, which is different in CHANGA because it uses an oct-tree rather than an arbitrary binary KD-tree as in GASOLINE2.

This paper is organized as follows. In Section 2 we go through the SPMHD theory and show how the equations can be formulated using the GDSPH approach. In Section 3 we test our implementation on a large suite of standard test cases and in Section 4 we apply the code to an astrophysical application, the collapse of a magnetized cloud. In Section 5 we discuss our results and make some concluding remarks.

2. Theory

In this theory section we show how the MHD equations can be formulated in a conservative way within the GDSPH framework. The development is similar to prior work (Price & Monaghan 2003; Price 2012; Tricco et al. 2016; Price et al. 2018) and we direct the reader to these papers for additional background.

2.1. MHD Theory

The two main equations which are relevant for ideal MHD, are the Lorentz force law and the induction equation. Assuming that the fluid is an ideal conductor ($E = 0$), the Lorentz force law can be written as:

$$ \frac{d \mathbf{v}}{dt} = \frac{1}{\mu_0 \rho} (\nabla \times \mathbf{B}) \times \mathbf{B} = \frac{1}{\mu_0 \rho} \left( -\frac{1}{2} \nabla B^2 + (\mathbf{B} \cdot \nabla)\mathbf{B} \right), $$

(1)

where $\mathbf{v}$, $\rho$, $\mathbf{B}$ and $\mu_0$ is the velocity, density, magnetic field and vacuum permeability respectively. The first term acts like an isotropic magnetic pressure term, while the other term acts like an attractive term along magnetic field lines (tension). Going forward we define code units such that $\mu_0 = 1$. The conservative form of SPMHD is attained by using the stress tensor to describe the momentum equation. Assuming that the magnetic field is divergence free, the MHD stress tensor can be written as:

$$ S^{ij} = -\delta^{ij} \left( \frac{P}{2} + \frac{B^2}{2} \right) + \mathbf{B} \delta^{ij}, $$

(2)

where $P$ is the thermal pressure and $\delta^{ij}$ is the Kronecker delta. The momentum equation can then be written as:

$$ \frac{d \mathbf{v}}{dt} = -\rho \nabla \cdot \mathbf{S} = \frac{1}{\rho} \left( \frac{1}{2} \nabla \left( \frac{P}{\rho} + \frac{B^2}{2} \right) + \left[ (\mathbf{B} \cdot \nabla)\mathbf{B} + \mathbf{B} (\nabla \cdot \mathbf{B}) \right] \right). $$

(3)

There is an extra tension force term which would normally have no effect due to the assumption $\nabla \cdot \mathbf{B} = 0$. However as mentioned in the introduction, this constraint is usually not fully upheld in numerical codes. To avoid numerical instability within SPH, this term needs to be negated when the magnetic pressure exceeds the thermal pressure.

The change in the magnetic field is obtained from the induction equation:

$$ \frac{d \mathbf{B}}{dt} = \nabla \times (\mathbf{v} \times \mathbf{B}) = (\mathbf{B} \cdot \nabla)\mathbf{v} - \mathbf{B} (\nabla \cdot \mathbf{v}), $$

(4)

where the first term affects the magnetic field through shearing motion, while the second will increase the magnetic field when undergoing compression. A combined effect of the two terms is to enhance the field due to compression perpendicular to the field direction (i.e. $B \propto \rho^{2/3}$). Compression in the direction of the field has no effect.
Derivatives within SPH can be discretized in a number of ways, a general formulation is given in section four of Price (2012). The geometric density average force (GDSPH) gives the following symmetric and anti-symmetric gradient operators:

\[
\frac{\nabla A}{\rho} = - (A \nabla 1 + \nabla A) = \sum_b \frac{m_b}{\rho_{ab} d_{rb}^2} (A_a + A_b) \nabla_a \overline{W}_{ab}, \tag{5}
\]

\[
\nabla A = \frac{1}{\rho} (\nabla A - A \nabla 1) = \sum_b \frac{m_b}{\rho_{ab} d_{rb}^2} (A_b - A_a) \nabla_a \overline{W}_{ab}. \tag{6}
\]

Here \( \nabla_a \overline{W}_{ab} \) is a symmetric gradient of the smoothing kernel:

\[
\nabla_a \overline{W}_{ab} = \frac{1}{2} [f_a \nabla_a W(r_{ab}, h_a) + f_b \nabla_b W(r_{ab}, h_b)], \tag{7}
\]

where \( W \) is the smoothing kernel and \( h_a \) is the smoothing length of particle \( a \) and \( r_{ab} = |r_a - r_b| \) is the distance between particle \( a \) and \( b \). And \( f_a \) is a correction term introduced in Wadsley et al. (2017) to ensure that internal energy and density evolve consistently, such that entropy is tightly conserved. To attain a conservative formalism for SPH, the symmetric gradient operator is applied to the equations of motion and the anti-symmetric gradient operator is applied to the internal energy equation. As a consequence, zeroth order errors arise in the equations of motions which will depend on the local particle distribution. A similar improvement can be seen for the linear errors.

A generalized error term for the zeroth order errors is given by:

\[
E_0 = \sum_b \frac{m_b}{\rho_{ab}} (\phi_{ab} + \phi_{ba}^T) \nabla_a \overline{W}_{ab}, \tag{8}
\]

where \( \phi \) is a free function based on scalar quantities of the particles. As shown by \cite{Read2010}, in TSPH \( \phi_{ab} = \frac{\hat{B}_a - \hat{B}_b}{\rho_{ab}} \), while in GDSPH \( \phi_{ab} = 1 \). It is then evident that these errors are more severe at density gradients in TSPH than in GDSPH (where they are explicitly independent of the density gradient). A similar improvement can be seen for the linear errors.

Applying the symmetric gradient operator to the momentum equation (eq. [3]) and the anti-symmetric gradient operator to the induction equation (eq. [4]) gives:

\[
\frac{d\mathbf{v}_a}{dt} = \sum_b \frac{m_b}{\rho_{ab} d_{rb}^2} (S_{ab} \mathbf{v}_a + S_{ba} \mathbf{v}_b) \nabla_a \overline{W}_{ab} + f_{\text{div}, B,a}, \tag{9}
\]

\[
\frac{dB_a}{dt} = \frac{1}{\rho_{ab}} \left[ B_a \left( \mathbf{v}_a \cdot \nabla_a \overline{W}_{ab} \right) - \mathbf{v}_a \left( B_a \cdot \nabla_a \overline{W}_{ab} \right) \right]. \tag{10}
\]

Where \( \mathbf{v}_a = \mathbf{v}_a - \mathbf{v}_b \). The stability term \( f_{\text{div}, B,a} \) is added to avoid the tensile instability. Which can occur due to divergence errors when the magnetic pressure exceeds the gas pressure \( \frac{B^2}{2} > P \) \cite{Phillips1985}. The stability term is defined as:

\[
f_{\text{div}, B,a} = - \hat{B}_a \sum_b \frac{m_b}{\rho_{ab} d_{rb}^2} (\mathbf{B}_a + \mathbf{B}_b) \cdot \nabla_a \overline{W}_{ab}. \tag{11}
\]

\footnote{This can clearly be seen when deriving the SPH equations from the least action principle \cite{Price2012}.}

\footnote{This can be seen as an inherent re-meshing procedure, where the particles try to arrange themselves to maximize the sum of the particle volumes and reach a minimum energy state.}

This basically removes the divergence term \( \left( - \frac{\mathbf{B}}{\rho} \nabla \cdot \mathbf{B} \right) \) from eq. \cite{Borve2001, Price2012}. Removing a term from the conservative momentum equation effectively breaks momentum conservation. However, the error introduced will be proportional to the divergence. To minimize its effect in the weak field regime, we use the scheme from \cite{Borve2004}, with a factor of \( \hat{B}_a = \hat{B}_a \) for \( \beta < 1 \) as advocated by \cite{Tricco2012}:

\[
\hat{B}_a = \begin{cases} 
\hat{B}_a & \beta < 1 \\
\hat{B}_a(2 - \beta) & 1 < \beta < 2 \\
0 & \text{otherwise,}
\end{cases} \tag{12}
\]

where \( \beta = \frac{2P}{\rho} \) is the plasma beta.

### 2.3. Treating discontinuities

When fluid quantities become discontinuous, they are no longer differentiable, which is problematic as differentiability is assumed by the SPMHD equations. Artificial resistivity is required to smooth out discontinuities in the magnetic field which can occur both along and orthogonal to the fluid motion and in both compression and rarefaction. The artificial resistivity can be represented as an isotropic diffusion:

\[
\frac{dB}{dt}_{\text{diss}} = \eta \nabla^2 \mathbf{B}, \tag{13}
\]

where \( \eta \) is a resistivity parameter. We use the Brookshaw method \cite{Brookshaw1985} which estimates the second derivative by using the first derivative kernel and the difference in the field divided by the particle spacing. Following the GDSPH discretization we get:

\[
\frac{dB_a}{dt}_{\text{diss}} = \sum_b \frac{m_b}{\rho_{ab} d_{rb}^2} \left( \frac{\eta_a + \eta_b}{|r_{ab}|} \right) B_{ab} \left( \mathbf{v}_a \cdot \nabla_a \overline{W}_{ab} \right). \tag{14}
\]

Where \( B_{ab} = B_a - B_b \) and \( \mathbf{v}_a \cdot \nabla_a \overline{W}_{ab} \). To conserve energy, the change in the internal energy becomes:

\[
\frac{dB_a}{dt}_{\text{diss}} = - \frac{1}{2} \sum_b \frac{m_b}{\rho_{ab} d_{rb}^2} \left( \frac{\eta_a + \eta_b}{|r_{ab}|} \right) B_{ab} \left( \mathbf{v}_a \cdot \nabla_a \overline{W}_{ab} \right). \tag{15}
\]

To reduce dissipation away from shocks we can introduce a varying and resolution dependent resistivity parameter:

\[
\eta = \frac{1}{2} \alpha_B v_{\text{sig}, B} |\mathbf{r}_{ab}|, \tag{16}
\]

where \( \alpha_B \) is a dimensionless coefficient and \( v_{\text{sig}, B} \) is the signal speed. Proper choice of \( \alpha_B \) and \( v_{\text{sig}, B} \) makes the artificial resistivity second order accurate away from shocks \( \eta \propto h^2 \). We choose to implement the resistivity from Phantom \cite{Price2018} where the signal speed is activated following:

\[
v_{\text{sig}, B} = |\mathbf{v}_a \times \mathbf{f}_{ab}|. \tag{17}
\]

The dimensionless coefficient \( \alpha_B \) is set to a constant. In Phantom this coefficient is set to \( \alpha_B = 1 \), however from our tests we find that \( \alpha_B = 0.5 \) provides sufficient dissipation. This switch was shown to be the least dissipative compared to previous switches, while still capturing the correct magnetic features \cite{Wurster2017}.
2.4. Divergence cleaning

As we discussed in the introduction, divergence errors are generated by the discretization and integration of the MHD equations. Apart from creating an unphysical magnetic field, it also forces us to introduce a stability term (eq. [11]), which breaks momentum conservation in the strong field regime. This makes it crucial to reduce the divergence errors as much as possible. The best way found in SPMHD is by introducing a divergence cleaning scheme (Tricco & Price 2012). In general this is done by introducing a separate scalar field which couples to the induction equation such that it produces a damped wave equation for the divergence error, that is, the divergence is spread outward like a damped wave. In our implementation, we employ the constrained hyperbolic divergence cleaning from Tricco et al. (2016), an improved version of the method presented by Dedner et al. (2002). The constrained hyperbolic divergence cleaning ensures that magnetic energy is either conserved or dissipated. In this method a scalar field $\psi$ is coupled to the induction equation as follows:

$$\frac{d\psi}{dt} = -\nabla \psi. \quad (18)$$

The scalar field $\psi$ evolves according to:

$$c_h \frac{d\psi}{dt} = -c_h \nabla \cdot B - \frac{1}{\tau} \psi - \frac{1}{2} \psi (\nabla \cdot v), \quad (19)$$

where $\tau$ is the decay time and $c_h$ is the wave cleaning speed:

$$c_h = f_{\text{clean}} v_{mhd}. \quad (20)$$

$$v_{mhd} = \sqrt{c_s^2 + v_A^2}, \quad (21)$$

$$v_A = \sqrt{\frac{B^2}{\rho}}. \quad (22)$$

Here $c_s$ is the speed of sound, $v_A$ the Alfvén velocity and $f_{\text{clean}}$ is an overcleaning factor. The $f_{\text{clean}}$ factor can be used to increase the amount of divergence cleaning, however this will reduce the timestep according to $\Delta t \rightarrow \Delta t / f_{\text{clean}}$. Combining the cleaning equation with the induction equation produces a damped wave equation for the divergence (this form assumes constant $c_h$ and $\tau$):

$$\frac{\partial^2 (\nabla \cdot B)}{\partial t^2} - c_h^2 \nabla^2 (\nabla \cdot B) + \frac{1}{\tau} \frac{\partial (\nabla \cdot B)}{\partial t} = 0, \quad (23)$$

which effectively shows that the divergence is spread out and damped. The decay time is given by:

$$\tau_a = \frac{h_a}{c_h v_A \sigma_c}. \quad (24)$$

Here $\sigma_c$ is a dimensional constant and have shown to be optimal with a value of $1$ in 3D. Following Tricco & Price (2012), $\Psi_0$ is discretized using the symmetric gradient operator (eq. [5]) and $\nabla \cdot B$ using the anti-symmetric gradient operator (eq. [6]). Within the GDSPPH discretization, eq. (18) and eq. (19) become:

$$\frac{dB}{dt}_{\phi,a} = - \sum_b m_b \rho_b (\psi_a + \psi_b) \nabla_a \vec{W}_{ab}, \quad (25)$$

$$\frac{d}{dt} \left( \frac{\psi}{c_h} \right)_{\phi,a} = c_h^2 \sum_b m_b \rho_b \nabla_a \vec{W}_{ab} \cdot \frac{\psi_a}{2 c_h} \sum_b m_b \rho_b \nabla_a \vec{W}_{ab} - \frac{\psi_a}{c_h} \frac{\psi_b}{c_h}. \quad (26)$$

The divergence cleaning will dissipate energy from the magnetic field, however this term is so small compared to the other dissipation terms that it is not worth accounting for. One could of course add this energy to heat and conserve energy, however as discussed by Tricco and Price (2012), the removal of magnetic energy and subsequent generation of thermal energy would be non-local due to the coupling of parabolic diffusion with hyperbolic transport. So due to these reasons the energy is simply removed.

To ensure that simulations are not affected by the divergence error we monitor the normalized divergence error:

$$\epsilon_{\text{div},B} = \frac{h_b |\nabla \cdot B|}{|B|}. \quad (27)$$

The mean of this quantity should preferably remain below $10^{-2}$. However regions of locally high divergence error can occur, so careful inspection of the divergence error are required to ensure the quality of simulation.

2.5. Shock capturing

To correctly capture shocks in MHD we need to modify the artificial viscosity term in the momentum equation (see Wadsley et al. 2017) for a detailed description of the artificial viscosity term in GASOLINE2). For MHD the sound speed is replaced by the fast magnetosonic speed (eq. [21]). We also modify the gradient-based shock detector introduced in GASOLINE2, which determines the direction of the shock from the pressure gradient. For MHD we must include the Lorentz force to correctly determine the direction of the shock. A more general way to determine the direction of the shock is to estimate the acceleration of the MHD forces without the dissipation terms before the actual force calculation:

$$\hat{n} = - \left( \frac{\partial f}{\partial \rho} \right)_{\text{no diss}}. \quad (28)$$

This addition improves the behavior of shock detection in convergent flows for MHD. In GASOLINE2 the diffusion of fluid scalar variables such as thermal energy, metals and so forth are modeled using subgrid turbulent mixing (Wadsley et al. 2008; Shen et al. 2010). However we found that in strong shocks like the MHD blastwave, the thermal dissipation is not enough and can lead to incorrect velocity profiles. As such we add a thermal shock dissipation of the form:

$$\frac{du}{dt}_{\text{shock}} = - \sum_b m_b \frac{\hat{u}_{ab} \cdot \nabla \vec{W}_{ab}}{|\bar{r}_{ab}|}, \quad (29)$$

$$d_{\text{shock}} = 16 \bar{h}_{ab} |\bar{u}_{ab}|, \quad (30)$$

Article number, page 4 of 18
the A V parameters are set to $\alpha(A V)$ follows the prescription given in Wadsley et al. (2017),

For the smoothing kernel we use a Wendland C4 kernel

3. Test Problems

In this section we will present the results from our test cases. All the simulations were run with the MHD version of GASOLINE2. To remain consistent and show the production quality of the method we have decided to run all the tests in 3D and with a default set of code parameters (described below). While glass-like initial conditions should always be used to correctly capture the natural state of 3D SPH simulations, we have for the sake of comparison elected to follow the initial setups from other authors, which often use lattice-based initial conditions. Test cases that are originally 1D or 2D are made 3D by extending the non-active dimensions by a set number of particles. By default GASOLINE2 sets the smoothing length based on a fixed number of neighbours, however we found that in very uniform and precise tests, as in the circularized Alfvén wave test, this approach generates small force errors that generate perturbations in the traveling wave. As such, we make the smoothing length directly proportional to the density and simultaneously determine the density and smoothing length using an iterative summation (Springel & Hernquist 2002). We note however that in all other tests, no visible effect was seen. In many of these tests we compare the results to the state-of-the-art SPMHD code PHANTOM, and to the SPH and the new meshless finite mass/volume (MFM/MFV) method of the Gizmo code. The MFM/MFV method utilizes a Lagrangian Godunov type method that employs more complex gradient operators and calculates fluxes from Riemann solvers.

Default set of code parameters:
- For the smoothing kernel we use a Wendland C4 kernel
- (Wendland 1995) with 200 neighbours.
- Our artificial viscosity (AV) follows the prescription given in Wadsley et al. (2017), the AV parameters are set to $\alpha_{\text{max}} = 4$, $\alpha_{\text{min}} = 0$, $\tau = 0.1\pi$ and $\beta = 2$. The artificial resistivity (AR) follows from the method outlined in Section 2.2, and the AR parameter is set to $\alpha_R = 0.5$. The thermal diffusion follows the turbulent mixing model described in Wadsley et al. (2008) and Shen et al. (2010), with the turbulent diffusion coefficient set to $C = 0.03$.

3.1. Circularized polarized Alfvén Wave

The circularized polarized Alfvén wave test was introduced by Toth (2000) and serve as an analytical solution to the ideal MHD equations. Due to the waves being circularized, the gradient in magnetic pressure is zero and the wave should remain the same after each period. This proves to be a useful test for gauging the dissipation and dispersion of the MHD implementation. This test is sensitive to the tensile instability (Price & Monaghan 2005), so it also serves as a good test to see if the stability term (eq. [1]) properly stabilizes the solution. The setup follows Gardiner & Stone (2008) and Price et al. (2018), in which the waves are traveling at an angle of $\theta = 30^\circ$ in respect to the x axis, within a periodic box of length $L = (l, l/2, l/2)$, where $l = 3$. The transverse velocities and magnetic fields are circularized:

$$B_{\perp,1} = v_{\perp,1} = 0.1 \sin (2\pi x_0 / \lambda),$$

$$B_{\perp,2} = v_{\perp,2} = 0.1 \cos (2\pi x_0 / \lambda),$$

$$\mu_{ab} = \frac{\vec{r}_{ab} \cdot (\vec{v}_{ab} \cdot \vec{r}_{ab})}{r_{ab}^2 + 0.01 r_{ab}^2},$$

(31)

Fig. 1. Results of the 3D circularly polarized Alfvén wave test. Top panel: Shows the transverse component of the magnetic field in the direction of propagation, after five periods. The analytical/initial solution is plotted in black, and the simulation results with resolution $[n_x, n_y, n_z] = [128, 74, 78]$ in red and $[n_x, n_y, n_z] = [64, 36, 39]$ in green. Both of these are with Wendland C4 kernel with 200 neighbours. Bottom panel: A convergence study for the Alfvén wave test using different kernels and neighbour numbers. Shows how the $L_2$ error scales with resolution (particles along the x-axis). The code default (Wendland C4 kernel with 200 neighbours) is shown in blue, Wendland C4 kernel with 114 neighbours are shown in orange, Quintic kernel with 114 neighbours are shown in green and the dashed red line shows the curve for second order convergence. Convergence towards the analytical solution for all kernels is close to second order. When the smoothing length becomes comparable to half the wave length of the Alfvén wave, the MHD gradients becomes more ill defined which causes the slower convergence speed for the Wendland kernel ($\bar{R}_{\text{neigh}} = 200$) at low resolution.

while the parallel components are set to:

$$v_{||} = 0 \quad B_{||} = 1.$$

Here $x_0$ is the direction of propagation, and $\lambda = 1$ is the wavelength. An adiabatic EOS ($\gamma = 5/3$) is used with uniform pressure $P = 0.1$ and density $\rho = 1.0$. The particles are set up on a close-packed lattice and the simulation is run for five periods ($t = 5$). We plot the transverse component of the magnetic field in the direction of propagation, showing the results of different resolutions $[n_x, n_y, n_z] = [128, 74, 78]$ and $[64, 36, 39]$ in the up-
per panel of Figure\[1\]. From the results we can see that both the phase and amplitude converge to the analytical solution as we increase resolution. As we have uniform density, there are no differences between GDSPH and TSPH in this case. We also performed a convergence study for this test using different smoothing kernels and neighbour numbers. In the lower panel of Figure\[1\] we show the L1 error norm for the transverse magnetic field at different resolutions, and as we can see all the kernels exhibit second-order convergence. The major outlier is at low resolution for the Wendland C4 kernel with more neighbours. This is caused by the larger smoothing length, which at low resolution becomes comparable to half the wave length of the Alfvén wave. This makes the MHD gradients more ill defined which causes force errors that shows itself predominately as a phase shift in the Alfvén wave as time goes by. The amplitude of the wave is only weakly affected by this. From the bottom panel in Figure\[1\] we can also see that the Wendland kernel has slightly lower convergence speed than the quintic kernel at higher resolution. Despite this result we have chosen to go with the Wendland kernel C4 with 200 neighbors as our code default for the forthcoming tests. In addition, the Wendland kernels tend to make the particle distribution remain well ordered in dynamical conditions, which improves the overall accuracy of the method \cite{Rosswog2015}.

\subsection{3.2. Advection Loop}

The advection current loop test was introduced by \cite{Gardiner2005,Gardiner2008}, in which a weak magnetic loop is advected by a constant velocity field. As the ratio between the thermal pressure and magnetic pressure is massive ($\beta \approx 10^9$), the magnetic field is dynamically unimportant and should simply be advected along the velocity field. This proves to be one of the more difficult tests for grid-based code due to intrinsic dissipation during advection. We follow the setup from \cite{Gardiner2008}, \cite{Hopkins2016} and \cite{Price2018}, and initialize a 3D thin periodic box with length $L = (2, 1, 2 \sqrt[3]{s})$, velocity $v = (2, 1, \frac{3}{2})$ and pressure $P = 1$. The magnetic field inside the loop is determined from the potential $A_z = A_0 R_0 - r$, where $A_0 = 10^{-3}$, $R_0 = 0.3$, and $r = x^2 + y^2$. The face-centered magnetic fields are then $B = \nabla \times A_z = \frac{\partial A_y}{\partial x} (y, -x, 0)$ inside the loop and zero everywhere else. We set up two initial conditions, one with a uniform density $\rho = 1$ with resolution $[n_x, n_y, n_z] = [128, 74, 12]$ and another with a density gradient ($\Delta = 2$) between the inner loop ($\rho = 2$) and outer medium ($\rho = 1$), with resolution $[n_x, n_y, n_z] = [256, 148, 12]$. The particles are set up on a close-packed lattice and the loop is advected for twenty periods with all the default dissipation and divergence cleaning terms turned on. The results of the test can be seen in Figure\[2\] and Figure\[3\]. From the figures we can see that in the case of uniform density the field loop is closely conserved, resulting in only 0.3% reduction in magnetic energy after twenty periods. This is a significant improvement from the advection loop presented in \cite{Price2018}, which starts to degrade after five periods. We have also tested this case using a quintic spline kernel and a smaller number of neighbours similar to \cite{Price2018} but the result appears insensitive to these choices and only a tiny difference can be seen after twenty periods (0.5% instead of a 0.3% decrease in magnetic energy). Without any dissipation and divergence cleaning the advection loop with uniform density can be sustained for thousands of periods, as shown in \cite{Rosswog2007}. This shows a significant advantage for Lagrangian codes compared to Eulerian codes, which suffer from resolution-dependent advection errors when the configuration is not aligned to the grid. In the case of the density gradient, we can see that there is now a faster dissipation of the magnetic energy. The sudden reduction in magnetic energy is largely due to the reordering of the initial particle lattice near the density contrast. Comparing to \cite{Hopkins2016}, we can see that we have a similar reduction in magnetic energy as in the results from the MFM/MFV method at $t = 20$. There is a tiny difference (1%) between GDSPH and TSPH, however this owes itself to the initial reordering, after that we can see that the rate of change in the two discretizations are practically the same. The averaged normalized divergence error, $\langle \epsilon_{\text{div}} \rangle$, is around $10^{-2}$ for both the $\Delta = 1$ case and $\Delta = 2$ case.

\subsection{3.3. Brio-Wu Shocktube}

The Brio-Wu shocktube \cite{Brio1988} is an MHD extension to the classic Sod shocktube test (the hydro setup is the same). It tests how well the implementation can handle different MHD shocks, rarefactions and contact discontinuities. We follow the setup from \cite{Hopkins2016} and \cite{Price2018}.
the development of super-sonic turbulence and the interaction of the different MHD shocks. We setup a 3D thin periodic box with $L = (1.0, 1.0, \sqrt[3]{2} \pi)$ at varying resolutions $[n_x, n_y, n_z] = [128, 148, 12], [256, 296, 12]$ and $[512, 590, 12])$. The test consists of a velocity vortex:

$$v_x = v_y = 0, v_z = v_0(\sin(2\pi(y - y_{min})), \sin(2\pi(x - x_{min})), 0)$$

and a doubly periodic magnetic field:

$$B_x = B_y = B_0(-\sin(2\pi(3/4 - y_{min})), \sin(4\pi(x - x_{min})), 0)$$

where $v_0 = 1, B_0 = 1/\sqrt[4]{\pi}, x_{min} = -0.5$ and $y_{min} = -0.5$. Setting the initial plasma beta $\beta_0 = 10/3$, the initial Mach number $M = v_0/c_s = 1$ and the adiabatic index $\gamma = 5/3$, we get the initial pressure $P_0 = B_0^2\beta_0/2 = 0.133$ and density $\rho_0 = \gamma P_0 M_0 = 0.221$. We show the results of the different resolution runs in Figure [8] after $t=0.5$ (top row) and $t=1$ (bottom row). The test was run with both GDSPH and TSPH, however we found only very small differences between them, which is why we only show the result from GDSPH. This can additionally be seen in Figure [3a] which show the time evolution of the magnetic energy in all of our test cases. From the result at $t=0.5$ we can see that we reproduce the shock structure well and capture the trapped dense filament in the centre of the domain for all resolutions. With increasing resolution, the shock structure and filament become more defined. At $t=1$, a more turbulent flow has developed. Our simulations capture most of the key features and compare well with previous works (e.g. Figure 32 in Price et al. [2018]). However, it appears that our method is unable to develop the central magnetic island, a feature that is supposed to form when the current sheet in the center becomes unstable and reconnects due to the tearing mode instability. This is the case for most previous implementations of SPMHD, however in Wurster et al. [2017] the authors argue that with a less dissipative artificial resistivity switch the magnetic island can be reproduced, and this motivate them to use the signal speed $v_{sig,B}$ given in eq. [17] We use the same switch but the problem remains. Nevertheless, if we compare our evolution of the magnetic energy (the red curve in Figure 6) to theirs (the purple curve) we can see that our simulations are actually less dissipative, likely because we use a smaller resistivity parameter $\alpha_B = 0.5$. It is thus likely that the development of the magnetic island also depends on the other dissipation terms such as AV and artificial conductivity. The mean normalized divergence error in the simulations are of the order $(\epsilon_{div}) = 10^{-3}$ to $10^{-5}$, decreasing with higher resolution.

3.5. MHD rotor

The MHD rotor test was introduced by Balsara & Spicer [1999], which tests the propagation of Alfvén waves generated by a magnetized rotor. We follow the setup from Balsara [2000] and Price et al. [2018], and initialize a 3D thin periodic box of $L = (1.0, 1.0, \sqrt[3]{2} \pi)$ at two resolutions, $[n_x, n_y, n_z] = [128, 148, 12]$ and $[256, 296, 12]$. A rotating dense cylinder ($\rho = 10$) is initiated with cylindrical radius $R = 0.1$, within a surrounding medium ($\rho = 1$). The cylinder is put into rotation with an initial velocity of $v = v_0 \left[-(y - y_0), (x - x_0), 0 \right]$ where $r_{cyl} = \sqrt[x^2 + y^2}$ and $v_0 = 2$. The initial pressure is set to $P = 1$, with an adiabatic index of $\gamma = 1.4$. The initial magnetic field is set to $B = [5/\sqrt[3]{4}, 0, 0]$. The particles are set up on

![Fig. 3. Results from the advection loop test in 3D, showing the time evolution of the magnetic field energy in units of the initial value. After $t = 20$ our uniform case has dissipated about 0.3%, while the cases with the density gradient $\Delta = 2$ have dropped around 5%, which is similar to the dissipation displayed by the MFM/MV method in Hopkins & Raives [2016]. There is a tiny difference between GDSPH and TSPH, however this owes itself to differences in the initial reordering.](image)
Fig. 4. The results from the Brio-Wu shocktube in 3D, with an initial left state \((\rho_L, P_L, v_x, v_y, v_z, B_x, B_y, B_z) = (1, 1, 0, 0, 0, 0.75, 1, 0)\) and right state \((\rho_R, P_R, v_x, v_y, v_z, B_x, B_y, B_z) = (0.125, 0.1, 0, 0, 0, 0.75, -1, 0)\). The figure shows the active region of the shock after \(t = 0.2\), which contains about \(n_x \approx 300 - 400\) particles across the x-direction. The blue line shows the reference solution and the black dots show the result from the GDSPH simulation, while red dots show the result from the TSPH simulation. There are minimal differences between the GDSPH and TSPH result.

Fig. 5. The results from the Orszag-Tang vortex in 3D, which shows rendered density slices \((z = 0)\) at \(t = 0.5\) (top) and \(t = 1\) (bottom) for varying resolution \([n_x, n_y, n_z] = [128, 148, 12], [256, 296, 12]\) and \([512, 590, 12]\) (low to high from left to right). The simulations capture well most of the key features for all tested resolutions. With increasing resolution the flows are more defined and show increased complexity. There are no significant differences between GDSPH and TSPH in this case.
Robert Wissing and Sijing Shen: SPMHD with the geometric density average force expression

Fig. 6. The evolution of the total magnetic energy in units of the initial value for the 3D Orszag-Tang vortex test. We plot the result from three different tested resolutions \([n_x, n_y, n_z] = [128, 148, 12], [256, 296, 12], [512, 590, 12]\) done in GDSPH. We also include a TSPH case with \(n_x = 256\) and the \(n_x = 512\) curve from Wurster et al. (2017) for comparison sake. We can see that there are no visible difference between the TSPH (green curve) and GDSPH (orange curve) cases. From the figure it is also clear that the GDSPH case of \(n_x = 512\) (red curve) is less dissipative than the simulation from Wurster et al. (2017) (purple curve). Significant differences between resolutions can be seen to occur at later times during the evolution.

Fig. 7. The result from the magnetic rotor in 3D, which shows rendered magnetic pressure slices \((z = 0)\) at \(t = 0.15\), for varying resolution \([n_x, n_y, n_z] = [128, 148, 12]\) and \([256, 296, 12]\) and for both GDSPH and TSPH. The plot also shows 30 contours with limits taken to be the same as Tóth (2000) and Price et al. (2018) \((P_{\text{mag}} = [0.25, 0.65])\) for a more direct comparison. We can see that GDSPH develops a larger and broader magnetic pressure peak compared to TSPH.

3.6. Magnetized blastwave

Fig. 8. The result from the magnetized blast in 3D in the 5123 GDSPH run, which shows rendered slices of different fluid quantities at \(t = 0.02\). To the top left we can see the density rendering, top right the kinetic energy density, bottom left the thermal pressure and bottom right the magnetic pressure. The limits are taken to be the same as Stone et al. (2008) and Price et al. (2018) for a direct comparison: \(\rho = [0.19, 2.98], E_{\text{kin}} = [0, 33.1], P = [1, 42.4]\) and \(P_{\text{mag}} = [25.2, 65.9]\). The magnetized blastwave was introduced by Balsara & Spicer (1999) and Londrillo & Del Zanna (2000), in which a central over-pressurized region expands preferentially along the magnetic fields lines. We follow the setup from Stone et al. (2008) and Price et al. (2018), and initialize a 3D periodic box of \(L = [1.0, 1.0, 1.0]\) with uniform density at a resolution of \(N = 512^3\). An inner region of radius \(R = 0.125\) is over-pressurized \((P_{\text{in}} = 100)\) to 100 times the outer pressure, which is set to \(P_{\text{out}} = 1\). The adiabatic index of the gas is set to \(\gamma = 5/3\).

\[\text{Fig. 6. The evolution of the total magnetic energy in units of the initial value for the 3D Orszag-Tang vortex test.}\]

\[\text{Fig. 7. The result from the magnetic rotor in 3D, which shows rendered magnetic pressure slices (z = 0) at t = 0.15, for varying resolution [n_x, n_y, n_z] = [128, 148, 12] and [256, 296, 12] and for both GDSPH and TSPH. The plot also shows 30 contours with limits taken to be the same as Tóth (2000) and Price et al. (2018) (P_{mag} = [0.25, 0.65]) for a more direct comparison. We can see that GDSPH develops a larger and broader magnetic pressure peak compared to TSPH.}\]

\[\text{Fig. 8. The result from the magnetized blast in 3D in the 512^3 GDSPH run, which shows rendered slices of different fluid quantities at t = 0.02. To the top left we can see the density rendering, top right the kinetic energy density, bottom left the thermal pressure and bottom right the magnetic pressure. The limits are taken to be the same as Stone et al. (2008) and Price et al. (2018) for a direct comparison: \(\rho = [0.19, 2.98], E_{\text{kin}} = [0, 33.1], P = [1, 42.4] and P_{\text{mag}} = [25.2, 65.9]\). The magnetized blastwave was introduced by Balsara & Spicer (1999) and Londrillo & Del Zanna (2000), in which a central over-pressurized region expands preferentially along the magnetic fields lines. We follow the setup from Stone et al. (2008) and Price et al. (2018), and initialize a 3D periodic box of \(L = [1.0, 1.0, 1.0]\) with uniform density at a resolution of \(N = 512^3\). An inner region of radius \(R = 0.125\) is over-pressurized \((P_{\text{in}} = 100)\) to 100 times the outer pressure, which is set to \(P_{\text{out}} = 1\). The adiabatic index of the gas is set to \(\gamma = 5/3\).}\]
The initial magnetic field is set to:

\[ B = [10/\sqrt{2}, 0, 10/\sqrt{2}] \]

This sets the initial plasma beta to \( \beta_{\text{pl}} = 2 \) in the inner region and \( \beta_{\text{out}} = 0.02 \) in the outer region. The simulation is run for \( t = 0.02 \) and the result can be seen in Figure \( 8 \). The rendering and limits in the figure are set to the same as the results presented in Tóth (2000) and Price et al. (2018), so that they can be directly compared. We can see that our results agree well with the previous authors, capturing the inner and outer structure of the blast well. There are minimal differences between the GDSPH and TSPH results. The mean normalized divergence error in the simulations are of the order \( (\epsilon_{\text{div}}) = 10^{-5} \).

### 3.7. Kelvin-Helmholtz instability in MHD

Generation of the Kelvin-Helmholtz instability is crucial for efficient mixing in hydrodynamical simulations. Here we look at the same problem but with a magnetic field applied parallel to the flow. This has a stabilizing effect on the shear flow due to the magnetic tension force. We follow the setup from McNally et al. (2012), but extend it to 3D, making a thin periodic box \( L = [1.0, 1.0, \frac{2\pi}{\sqrt{2}}] \), with a resolution of \( [n_x, n_y, n_z] = [256, 296, 12] \). We apply a uniform pressure of \( P = 5/2 \) with an adiabatic index of \( \gamma = 5/3 \). The hot outer stream has a density of \( \rho_{\text{out}} = 1 \) and velocity \( v_{\text{out}} = [-0.5, 0, 0] \). The cold inner stream has a density of \( \rho_{\text{in}} = 2 \) and velocity \( v_{\text{in}} = [0.5, 0, 0] \). A uniform magnetic field is added in the direction of the flow velocity \( B = [0.1, 0, 0] \).

The results for TSPH and GDSPH at \( t = 1.6 \) and 3.2 can be seen in Figure 9. And in Figure 10 we show the particle distribution of the surface boundary at \( t = 3.2 \). The TSPH result exhibits a very gloopy behaviour and shows a decreased growth of the KH mode. A strong artificial surface tension effect can clearly be seen between the hot and the cold phase in Figure 10. With GDSPH this effect is largely eliminated and the growth rate improves significantly. This large improvement in GDSPH lends itself mainly to the reduction of the leading order errors, which we discussed in Section 2.2. Adding turbulent diffusion (i.e., with the code default parameters) further improves the result, because it allows particles to effectively mix/reorder (as shown clearly in the particle distribution near the boundary regions in Figure 10), but the growth rate remains similar to the GDSPH-only case. We note that the sharp contact discontinuities in the initial condition are not smoothed, unlike in McNally et al. (2012). We choose this because it represents an extreme situation for SPH where the initial particle ordering is not optimal (i.e., zeroth order errors are relatively high), and we show that GDSPH performs well even in this extreme case. We have also run the setup using a smoothed contact discontinuity, and this is shown in the rightmost column in Figure 9. The magnetic field effectively uncoils and stretches the vortex, which is in good agreement to the results shown in Hopkins & Raives (2016) with the same setup. Here TSPH and GDSPH develop indistinguishably later until time, where at the end only small differences can be seen. The mean normalized divergence error in the simulations are of the order \( (\epsilon_{\text{div}}) = 10^{-3} \).

### 4. Collapse of a magnetized cloud

In this Section, we apply our method to an astrophysical problem and consider the collapse of a magnetized cloud. In this type of problem involving large dynamic scales, we see a substantial difference between GDSPH and TSPH. A rotating magnetized cloud is allowed to collapse under its own gravity. During collapse the cloud is compressed over several orders of magnitude, testing how the magnetic field develops and interacts with the gas during compression. The collapse is eventually halted by the formation of a disk, which then starts to slowly contract via magnetic braking. As the magnetic field is twisted during the final stages of collapse it eventually launches a jet (Uchida & Shibata 1986; Lynden-Bell 1996; Ustyugova et al. 2000; Nakamura & Meier 2004). The two main jet launching mechanisms are the magneto-centrifugal and the magnetic pressure driven mechanism. With a global poloidal magnetic field as in our model, both of these mechanisms play an important role. The resulting magnetic field structure of the jet consists of a poloidal dominated central core with a surrounding toroidal field which produces a strong current along the jet. We will refer to this magnetic field structure as the magnetic tower. All these key aspects require the code to have excellent angular momentum conservation, small numerical dissipation and maintain low divergence errors (\( \nabla \cdot B \)).

We follow the setup outlined in Hennebelle & Fromang (2008) and Hopkins & Raives (2016) and setup a 3D periodic box \( L = [0.15\text{pc}, 0.15\text{pc}, 0.15\text{pc}] \). A cloud is initiated with a radius of \( R_c = 0.015 \text{pc} \) and a mass of 1 solar mass \( (M_\text{cl} = 1M_\odot) \), within a surrounding medium that has 360 times lower density than the cloud \( (\rho_{\text{out}} = M_\text{cl}/(360V_\text{c})) \). The cloud is put in rotation with an orbital time of \( T \approx 4.7 \times 10^6 \text{yr} \) which correspond to a kinetic over potential energy ratio of about \( E_K/E_P \approx 0.045 \). A constant magnetic field \( B_0 \) is initialized in the direction of the angular momentum vector \( \hat{z} \), and we vary the strength in accordance to different mass-to-flux ratios. The mass-to-flux ratio \( \mu \) is relative to the critical mass-to-flux ratio, \( (M_\text{cl}/\Phi)_\text{crit} \), in which the
Fig. 10. The surface boundary between the high and low density region in the magnetic Kelvin-Helmholtz instability at \( t = 3.2 \). The effect of the numerical surface tension can clearly be seen in the TSPH case, while GDSPH does not suffer from this issue. Adding thermal diffusion allows for local mixing between the cold and hot phase.

Fig. 11. Shows a density rendered slice \( \left( \text{g/cm}^3 \right) \) through the rotation axis, showing the early cloud structure of the strong field case \( \mu = 2 \) before the formation of the disk. As the magnetic field is very strong, accretion will occur primarily along the field lines, creating an elongated cloud structure. Both high resolution cases \((200^3)\) of TSPH and GDSPH creates an elongated cloud structure, while in the low resolution case \((50^3)\) only GDSPH forms the same cloud structure. TSPH instead forms a more compact central cloud, which as a consequence collapses faster than the GDSPH case and the high resolution cases.

The cloud is fully supported by magnetic forces against gravity, i.e.,

\[
\mu = \left( \frac{M_c}{\Phi} \right) / \left( \frac{M_c}{\Phi} \right)_{\text{crit}},
\]

\[
\left( \frac{M_c}{\Phi} \right) = \frac{M_c}{\pi R_c^2 B_0} \quad \left( \frac{M_c}{\Phi} \right)_{\text{crit}} = \frac{c_1}{3\pi} \sqrt{\frac{5}{G}},
\]

Here \( c_1 = 0.53 \) is a parameter that can be determined numerically \((\text{Mouschovias & Spitzer}[1976])\). We then get the corresponding initial magnetic field:

\[
B_0 = \frac{610}{\mu} [ \mu \text{G} ].
\]

The thermal pressure is determined by the following barotropic EOS,

\[
P = c_s^2 \rho_0 \sqrt{1 + \left( \frac{\rho}{\rho_0} \right)^{4/3}},
\]

with \( \rho_0 = 10^{-14} \text{ g cm}^{-3} \) and \( c_s = 0.2 \text{ km s}^{-1} \). We look at five different magnetic flux ratio values in our simulations, from weak to high \((\mu = 75, 20, 10, 5, 2)\). These are run with a moderate resolution of \(50^3\) in the low density region, which correspond to about \(65^3\) particles in the cloud, same as in the setup of \(\text{Hopkins & Raives}[2016]\). These five cases are run with both GDSPH and TSPH until the core has fully collapsed, which is usually around the free fall time \( t_{ff} \approx 4 \times 10^4 \text{ yr} \), but this can vary depending on the initial magnetic field strength. The results of these simulations can be seen in Figure [15] (GDSPH) and Figure [16] (TSPH).

For GDSPH, we see in Figure [15] that jet launching can be seen in the weak field regime \((\mu = 75, 20, 10)\), although very short lived in the case of \(\mu = 75\). It is clear from the poloidal magnetic field and the current density (the fourth and fifth row in Figure [15]) that we have a developed magnetic tower in all these three cases. This is a remarkable achievement, especially for SPMHD, since the amplification of the magnetic field can easily be quenched by numerical dissipation. The jet strength, morphology and velocity structure resemble those in \(\text{Hopkins & Raives}[2016]\) with the same resolution using the MFM/MFV method with more complex gradient operators and Riemann solvers. In contrast, the behavior of TSPH is in agreement with previous findings. In Figure [16] we see neither jet launching nor magnetic tower in the weak-field regime with the fiducial resolution of \(50^3\). This owes itself largely due to numerical dissipation which suppresses field amplification and hinders the formation of a jet. At the time of jet launching, fragmentation of the disc occurs in the two weakest cases \(\mu = 75 \text{ and } 20\) for TSPH, as the magnetic field is too weak to support the disc. For GDSPH it does not occur until a later time in the simulation,
Fig. 12. Magnetic interchange instability in the strong field case ($\mu = 2$) for the GDSPH simulation with $50^3$ resolution. The left panel shows a zoom-in of the disc structure seen face-on in Figure 13 and the right panel depicts the same region at a later time. The white arrows show the direction of velocity and the colour scale indicates density. The instability launches magnetized bubbles in the azimuthal direction. At later times we can see that the central star starts to accrete again along the filamentary structure. These figures can be compared to the results from Krasnopolsky et al. (2012)

however the exact time of fragmentation is heavily dependent on other dissipation terms such as artificial viscosity.

For the more magnetized case with $\mu = 5$ we can see that TSPH successfully develops a jet, however closer inspection on $|B_z|$ in Figure 16 shows that the central portion of the magnetic tower is much less developed, with an order of magnitude smaller strength than the same run with GDSPH. Jet launching is also seen in the GDSPH case with $\mu = 5$ with the magnetic tower intact, albeit weaker and less collimated than in the $\mu = 10$ case. For $\mu = 2$, the collapse proceeds differently in GDSPH and TSPH from an early stage. This can be seen in Figure 11 which shows the density structure of the collapsing cloud in an early stage with different resolutions. As the magnetic field is very strong, accretion will occur primarily along the field lines, creating an elongated cloud structure. While at high resolution ($200^3$) both GDSPH and TSPH runs converge to the correct structure, at the fiducial resolution of $50^3$, only GDSPH shows an elongated cloud. The cloud collapses faster in TSPH, likely due to excessive dissipation.

For $\mu = 2$ we can see that GDSPH does not produce a coherent jet (Figure 15). This is mainly due to the disk being disrupted by the magnetic interchange instability. This instability occurs due to an accumulation of magnetic flux near the accreting protostar, where the magnetic flux that would have been dragged into the protostellar core is redistributed to the surrounding medium by dissipative effects (AR). This builds a large magnetic pressure gradient which, together with the twisted magnetic field, eventually launches highly magnetized bubbles in the azimuthal direction. A density rendering together with a velocity map of the $\mu = 2$ case after the launch of the magnetized bubbles is shown in Figure 12. This is similar to the results seen in simulations using the AMR code Enzo (Krasnopolsky et al. 2012) and in SPH simulations with PHANTOM (Wurster et al. 2017). We would like to stress that, unlike the SPH runs in Hopkins & Raives (2016), the disk disruption is not due to divergence errors, but instead a consequence of the magnetic dissipation. At later times (e.g., right panel of Figure 12), we can see that the protostellar core remains centrally located, which indicates good divergence control and angular momentum conservation. As the formation of the interchange instability is driven by the magnetic dissipation it depends heavily on the choice of AR prescription. Wurster et al. (2017) saw similar magnetic bubbles with the same AR prescription as ours, while other tested AR prescriptions did not launch magnetic bubbles. Additional work will need to be done to determine if this is a real effect or a consequence of the numerical scheme.

To investigate the convergence with resolution, we simulate the $\mu = 10$ case across different resolutions ($12^3, 25^3, 50^3, 100^3$ and $200^3$) for both methods. The results are shown in Figure 17 for GDSPH and Figure 18 for TSPH. Although jet launching occurs at slightly earlier times for higher resolutions, we can see a clear converging pattern in the jet structure in the GDSPH runs. Fully developed magnetic towers and a resolved jet structures are already evident in cases with $25^3$ resolution, and increase in complexity as we increase the resolution. A weak outflow appears even in the lowest resolution of $12^3$. In contrast, the runs with TSPH shows slow convergence. The structure of the magnetic field is severely distorted, and magnetic tower and proper collimated jet are not developed in all cases except the highest resolution. Again, we note that our GDSPH results are very comparable to the MFM/MFV runs in Hopkins & Raives (2016), both in terms of jet properties and converging speed. The magnetic tower structure is also qualitatively similar to the cloud collapse simulation in the weak field regime from the moving-mesh code AREPO (Pakmor et al. 2011), although with a different initial setup.

5. Discussion

In this paper we have presented an SPMHD method, which utilizes the Geometric Density average force discretization (GDSPH) of the MHD equations. GDSPH has been shown in previous work to greatly improve the accuracy near density discontinuities and eliminate the surface tension problem. In the previous sections we have shown that MHD also benefits from this method. For a large part the standard test problems (Section 3.1-3.6) both GDSPH and TSPH handle the problems very well, and the differences between the two methods are minimal. However, when the problem involves mixing such as in the case of Keijn-Helmholtz instabilities, GDSPH shows clear advantages. This is somewhat expected, and in agreement with earlier studies without magnetic fields (Wadsley et al. 2017). However, when we apply the method in the astrophysical test of a collapsing magnetized cloud, we see that GDSPH leads to a significant improvement. GDSPH not only realistically captures the development of a magnetic tower and jet launching in the weak field regime ($\mu \lesssim 10$), but also exhibits fast convergence with resolution. In contrast, TSPH only manages to launch jets in the strong field regime and converges very slowly. We also show that, in the strong field regime, GDSPH converges better than TSPH in accretion time and in the outer cloud structure.

Overall, our new method shows improved or comparable results to previous SPMHD implementations such as in PHANTOM (Price et al. 2018) and in Gizmo (Hopkins & Raives 2016). In many test cases and particularly in the cloud collapse case, GDSPH produces qualitatively very similar result to that of the MFM/MFV method and achieves similar convergence speed. It is worth noting that all the simulations are run in 3D
with the code default parameters listed in Section 3 without any adjustment by hand to specific problems. The success of GDSPH can most likely be attributed to the reduction of SPH “$\epsilon_0$ errors” (eq. 8) by the geometric density average formulation. As discussed in Section 2.2, the advantage of such discretization is more evident when the density gradient is large, such as in the cloud collapse case.

Using the constrained hyperbolic divergence cleaning scheme with variable cleaning speed from Tricco et al. (2016), we can keep the divergence error low in all cases. The mean normalized divergence error, $\langle \epsilon_{div B} \rangle = \langle h|\nabla \cdot B|/|B|\rangle$, is typically of order $10^{-5} - 10^{-3}$. In Figure 13, we show the normalized divergence error maps for several test cases. Again we see that the divergence cleaning works extremely well here, the maximum error is generally around $10^{-5}$. Comparing to Hopkins (2016) (their Figure 4), we find that the errors are smaller than their MFM simulations with the Dedner et al. (2002) cleaning in general, with an exception for the outskirt of the advection loop (where the magnetic field is essentially zero and thus not important for the result). The improvement is probably due to the more advanced constrained cleaning method (Tricco et al. 2016).

The normalized divergence error for the $n = 10$ cloud-collapse case at the jet launching time is shown in Figure 13. Here, the divergence cleaning still performs very well in the disc, along the jets and for the majority of the regions where the outflow interacts with the ambient gas, especially when the divergence error is compared to the total gas pressure (right panel). The result is similar to the Dedner cleaning in Hopkins (2016), although our error is somewhat larger at the tip of the jets where the gas is shocked. However we note that the comparison is not direct in this case as the jets may develop differently. Overall, the result from cleaning is still worse than the constrained transport or constrained gradient schemes (Hopkins 2016). For SPMHD, as shown in Tricco & Price (2012), divergence errors can be reduced to machine precision (or more practically to a certain tolerance value) using cleanup, with the help of a sub-cycling routine. However, local adjustments are required to determine the number of iterations for each particle to efficiently subcycle the cleaning in the simulation. This is because certain regions are more affected than others and because divergence is spread to nearby neighbours. Conceivably, if vector potentials (Stasyszyn & Elstner 2015) could work for a wider range of problems this could be an interesting avenue as well. However, to explore these methods in detail is beyond the scope of this work.

From the tests we can see that using a lower artificial resistivity coefficient ($\alpha_B = 0.5$) than ($\alpha_B = 1$) (Price et al. 2018), works well for all cases. However, the choice of artificial resistivity switch still remains somewhat ad-hoc as it is difficult to accurately detect the MHD discontinuity. A Godunov SPH scheme (Iwasaki & Inutskuh 2011) solves this problem by replacing artificial resistivity with Riemann solvers, which have been shown to produce minimal artificial diffusivity. However this brings with it an increase in computational cost and it is unclear if the extra cost is worth it. Further improvements in the convergence of SPMHD may be found in the use of integral based gradient estimates, which has been shown to be more accurate and less noisy than the standard SPH gradient estimate (García-Senz et al. 2012; Rosswog 2015; Cabezón et al. 2017). This could be especially beneficial for modeling subsonic turbulent flows (Valdarnini 2016). This gradient estimate can easily be implemented within the GDSPH framework and will be investigated in future work.

Recently meshless methods (SPH and MFM) were explored in local 3D simulations of the magnetorotational instability (MRI) (Deng et al. 2019). The authors found that in the vertically stratified MRI simulations, SPH developed an unphysical state with strong toroidal field components and no sustained turbulence. In a forthcoming paper (Wissing et al. in prep.) we will show that GDSPH do not show this unphysical behavior and reproduces the characteristic periodic azimuthal magnetic field pattern (butterfly diagram) of the stratified MRI.

Fig. 13. Shows the normalized divergence error ($\epsilon_{div B} \equiv h|\nabla \cdot B|/|B|$, eq. 27) of the different cases (all in 3D) with GDSPH. From left to right: First: The advection of a current loop with a density ratio of $\Delta = 2$ at $t = 20$ (Section 3.2). Second: The MHD rotor ($n_x = 256$) at $t = 0.15$ (Section 3.3). Third: The Orszag-Tang vortex ($n_x = 256$) at $t = 0.5$ (Section 3.4). Fourth: The MHD blastwave ($n_x = 512^2$) at $t = 0.02$ (Section 3.6). Fifth: The MHD Kelvin-Helmholtz instability ($n_x = 256$) with an initial sharp contact discontinuity at $t = 3.2$ (Section 3.7).
Fig. 14. The normalized divergence error of the magnetized cloud collapse simulation with GDSPH at the jet launching time, $t = t_{ff}$. The mass-to-flux ratio is $\mu = 10$ and the resolution is $10^3$. Left: the normalized divergence error as in \citet[eq. 27]{eq:27}, $\epsilon_{\text{div}} \equiv h |\nabla \cdot B|/|B|$: Right: the divergence error normalized to total gas pressure, $\epsilon_{\text{div}}(1 + \beta)^{1/2} = h |\nabla \cdot B|/|B|^2 (B^2 + 2P)^{1/2}$, where $\beta = 2P/B^2$ is the plasma beta.
Fig. 15. The result of the magnetized cloud collapse for GDSPH at a resolution of $50^3$ particles with varying magnetic flux ratio $\mu$ going left to right from high to low. We show figures at the time of jet formation (around $t = t_f$), which occurs due to the winding of the magnetic field during the collapse, which produces a magnetic tower structure. The top row shows a rendered face-on slice ($L_{xy} = [2000\text{AU}, 2000\text{AU}]$) of the density $[\text{g/cm}^3]$, the rest of the rows show rendered slices through the rotation axis ($L_{xz} = [2000\text{AU}, 2000\text{AU}]$), where the second shows density $[\text{g/cm}^3]$, the third show radial velocity $[\text{km/s}]$, the fourth show the absolute poloidal magnetic field $[\mu\text{G}]$ and the fifth shows the current density $[\text{A/m}^2]$, all quantities are shown in logarithmic scale. We can see that a jet is launched in the cases of $\mu = 75, 20, 10, 5$ while in the case of $\mu = 2$ the interchange instability (see Figure 12) disrupts the disk before jet launching.
Fig. 16. The result of the magnetized cloud collapse for TSPH at a resolution of $50^3$ particles with varying magnetic flux ratio $\mu$ going left to right from high to low. We show figures at the time of jet formation (around $t = t_f$), which occur due to the winding of the magnetic field during collapse, which produces a magnetic tower structure. The top row shows a rendered face-on slice ($L_{xy} = [2000\,AU, 2000\,AU]$) of the density $[g/cm^3]$, the rest of the rows show rendered slices through the rotation axis ($L_{xz} = [2000\,AU, 2000\,AU]$), where the second shows density $[g/cm^3]$, the third show radial velocity $[km/s]$, the fourth show the absolute poloidal magnetic field $[\mu G]$ and the fifth shows the current density $[A/m^2]$, all quantities are shown in logarithmic scale. We can see that TSPH does not form a jet in any of the weak field cases ($\mu = 75, 20, 10$) and there is no sign of a magnetic tower being formed. In the case of $\mu = 5$ we can see a jet being launched, where a current dominated magnetic tower has formed, however the central part of the tower has been completely quenched. The $\mu = 2$ case also launches a jet, but collapses faster than in the high resolution case, which effectively leads to easier jet formation.
Fig. 17. The result of the resolution study of the magnetized cloud collapse for GDSPH with $\mu = 10$. We vary the resolution from left to right (12³, 25³, 50³, 100³, 200³). We show figures at the time of jet formation (around $t = t_{ff}$), which occur due to the winding of the magnetic field during collapse, which produces a magnetic tower structure. The top row shows a rendered face-on slice ($L_{xy} = [2000AU, 2000AU]$) of the density [g/cm³], the rest of the rows show rendered slices through the rotation axis ($L_{xz} = [2000AU, 2000AU]$), where the second shows density [g/cm³], the third show radial velocity [km/s], the fourth show the absolute poloidal magnetic field [$\mu$G] and the fifth shows the current density [A/m²], all quantities are shown in logarithmic scale. We can see a clear convergence with GDSPH. A proper magnetic tower can be seen in all the cases, which increases in complexity as we increase resolution.
Fig. 18. The result of the resolution study of the magnetized cloud collapse for TSPH with $\mu = 10$. We vary the resolution from left to right ($12^3, 25^3, 50^3, 100^3, 200^3$). We show figures at the time of jet formation (around $t = t_f$), which occur due to the winding of the magnetic field during collapse, which produces a magnetic tower structure. The top row shows a rendered face-on slice of the density $[g/cm^3]$, the rest of the rows show rendered slices through the rotation axis, where the second shows density $[g/cm^3]$, the third show radial velocity $[km/s]$, the fourth show the absolute poloidal magnetic field $[\mu G]$ and the fifth shows the current density $[A/m^2]$, all quantities are shown in logarithmic scale. We can see that TSPH converges very slowly and only forms a collimated jet and a proper magnetic tower at the highest resolution.
