Abstract

Background: Child maltreatment is a widespread problem around the world, with an increasing amount of victims both at home and abroad. However, this issue often fails to be properly recognized, and promptly identifying maltreatment remains a challenge. In our study, we observe the clinical factors associated with child maltreatment at a tertiary care children’s hospital.

Methods: We recruited 60 patients from January 2011 to May 2017 who were suspected victims of child abuse or neglect and were admitted to the Pediatric Intensive Care Unit. Patient characteristics, including age, gender, chronic comorbid conditions, immunization schedules, severity of disease, and length of PICU stay, and one-year outcome were recorded and analyzed.

Results: Of the 60 patients enrolled in this study, the median age when the suspected maltreatment event occurred was 9 months old. Our study revealed a higher incidence of underlying disease, new onset seizures, and missed vaccinations in the abused group. The length of hospital stay is 17.5 days and 5 days in the abused group and the neglected group, respectively (P<0.001). The abused group tend to have poor one-year outcome significantly.

Conclusion: Abusive events not only result in harm to children but also because longer hospital stays that become financial burdens in health care. By better understanding the importance of early intervention against abuse, we can take action to save these children and prevent tragedies.

Keywords: Child maltreatment; Child abuse and neglect; Severe inflicted injury

Introduction

Child maltreatment has long been a worldwide problem and can be life-threatening to children. Since the nineteen sixties, relevant authorities in the U.S. have been raising awareness on the issue. Prior to that, children had been viewed as their parents’ property, and no law punished the abusive behavior. In 1946, John Caffey published a report of six infants with subdural hematoma and long bone fractures and indicated a relationship between them and child abuse [1]. In 1962, a landmark year; Henry Kempe and his colleagues published the article, “The battered-child syndrome,” which sparked interest in researching child abuse and brought the subject to national attention [2]. The World Health Organization (WHO) defined child maltreatment, sometimes referred to as child abuse and neglect, as any form of physical and emotional ill-treatment, sexual abuse, neglect, and exploitation that results in actual or potential harm to the child’s health, development, or dignity [3]. Abuse refers to caregivers that carry out acts of physical harm or sexual harassment toward children or acts that have adversely emotional effects on children’s

health and development. Meanwhile, neglect refers to caregivers’ failure to provide an appropriate environment for children’s development, such as health, education, emotional development, nutrition, shelter, and safe living conditions [4]. Based on data collected in the United States from the National Child Abuse and Neglect Data System (NCANDS) of the Children’s Bureau, during the 2015 federal fiscal year (FFY), approximately 683,000 victims of child abuse and neglect were reported nationally, with a victim rate of 9.2 victims per 1,000 children [5]. In Taiwan, according to the Ministry of Health and Welfare, approximately 55,000 victims suspected of child maltreatment were reported in 2016, and only about 9,500 received intervention; most cases were reported by educational staff, followed by the police, social workers, and medical providers. The Centers of Disease and Control (CDC) in Taiwan traced immunization schedules, which revealed children who had been lost or neglected. Child maltreatment not only has the potential to cause death but can also have long-lasting negative effects on psychosocial and behavioral problems [6,7]. Despite widespread concern, child maltreatment is often underestimated. Preverbal children cannot report abusive events and recognizing occult injuries in a clinical setting poses a challenge for medical providers. A caregiver can pretend that child abuse is an accident by caregiver; while an accident can be the result of child neglect. Unreliable accounts from family members and unusual bruises or fractures raise suspicions of abuse. Furthermore, the definition of child maltreatment and parents’ attitudes varies among different cultures and ethnic groups, which has affected the report rate and intervention by authorities [5,8]. More countries highlight the early detection of child maltreatment and aim to educate health care professionals regarding the screening of clinical symptoms and signs, identifying abuse, and making referrals to child protective services. Keeping abused children away from perpetrators is vital for preventing further harm on such children’s physical and psychosocial health. In this study, we compared the characteristics of abused cases to analyze the clinical factors of child maltreatment.

Material and Methods

Patients

Table 1: Demographic data of 60 maltreatment children underwent neglected and abused events.

| Gender (boy/girl) | N (%) | Neglected (n=43) | Abused (n=17) | p-value |
|------------------|-------|-----------------|---------------|---------|
| Gender (boy/girl) | 40/20 | 27/16 | 13/4 | 0.311 |
| Age at injury [months; median (IQR)] | 9 (19) | 10 (21.0) | 8 (21.5) | 0.902 |
| Chronic comorbid conditions [n (%)] | 18 (30) | 7 (16.3) | 11 (64.7) | <0.001** |
| Development delay | 9(15) | 3(7.0)‡ | 6(35.3)‡ |
| Cerebral palsy | 3(5) | 2(4.7) | 1(5.9) |
| Congenital heart disease | 2(3.3) | 1(2.3) | 1(5.9) |
| Hyperactivity disorders | 3(5) | 1(2.3) | 2(11.8) |
| Bed-ridden | 1(1.6) | 0(0) | 1(5.9) |
| No comorbid condition | 42(70) | 36(83.7)† | 6(35.3)† |
| Body height less than 3rd percentile [n (%)] | 16(26.6) | 8(18.6) | 8(47.0) | 0.03* |
| Body weight less than 3rd percentile [n (%)] | 15(25) | 6(13.9) | 9(52.9) | 0.003* |
| POPC score [n (%)] | | | | |
| Favorable (≤2) | 39(65) | 35(81.4) | 4(23.5) | <0.001** |
| Unfavorable (≥3) | 21(35) | 8(18.6) | 13(76.5) |

‡The abused group had significantly more “development delay” patients as chronic comorbid condition
†The neglected group had less chronic comorbid condition significantly
POPC score: Pediatric overall performance category
This retrospective study consisted of 60 patients (Table 1) suspected of being victims of child abuse or neglect at Kaohsiung Chang Gung Memorial Hospital and were admitted to the 20 beds-Pediatric Intensive Care Unit (PICU) from January 2011 to May 2017. These patients, who had failure to thrive, malnutrition, developmental delay, poor personal hygiene, failure/delay to seek medical care (such as immunization schedule, dermatitis, or vision correction), or intracranial hemorrhage or bone fracture caused by low-height falls, were evaluated by doctors, and referrals were made to social workers in cases of suspected abuse or neglect. After interviewing the case and his/her family, we classified cases into the abused group or neglected group based on general appearance, physical examination report, family history, and course of diseases. Then we reviewed patients’ age, gender, general appearance, age when the event occurred, chronic comorbid conditions, immunization schedule, Glasgow Coma Scale (GCS), severity of disease (based on the Pediatric Risk of Mortality (PRISM) score) [9], hemoglobin level at admission, and length of PICU stay. The chronic comorbid conditions observed in this study included developmental delay, cerebral palsy, congenital heart disease, hyperactivity disorder, and bed-ridden status. We define patients that did not receive vaccines pursuant to the recommended schedule as interrupted vaccination, which means missing two shots in a series of the immunization schedule but does not include unintentional delays or deferring vaccines because of illness. Regarding skin lesion-like burns, bullae, and blue-green bruises (excluding traffic accident-related bruise), such lesions are considered red flags for child abuse.

### Intensive care management

Furthermore, we compared patients who received an intubation or operation, had an initial presentation of intracranial hemorrhage, retinal hemorrhage, seizure, wound, bruise, or bone fracture on admission.

### Outcome

Using information contained in the hospital record and telephone follow-up by social workers, we applied POPC score (Pediatric overall performance category) to access the one-year functional outcome of each child approximately. Outcome categories were defined as POPC=1: good overall performance; POPC=2: mild overall disability; POPC=3: moderate overall disability; POPC=4: severe overall disability; POPC=5: coma or vegetative state; POPC =6: brain death [10]. The POPC =1 and 2 were regarded as having favorable outcome, while those who survived with POPC =3, 4, 5 or 6 were considered to have unfavorable outcome. We received approval for this study from the Institutional Review Board (IRB) of Chang Gung Memorial Hospital (IRB number: 201800528B0).

### Statistical analysis

We analyzed data using the Kruskal-Wallis test and pairwise comparisons for continuous variables, and the chi-square test or Fisher’s exact test for categorical variables. The data are presented by percentage, mean, and standard deviation (SD); Ap-value<0.05 is considered statistical significance. All statistical tests were carried out using SPSS 22.0 (SPSS, Inc., Chicago, Illinois).

### Results

#### Characteristics of children

Chronic comorbid condition:
I-developmental delay; II-cerebral palsy; III-congenital heart disease; IV-hyperactivity disorder; V bed-ridden status
AHT: Abusive head trauma

Among the 60 patients recruited for this study, 40 were boys and 20 were girls. The median age when the abused or neglected event occurred was 9 months old [median (IQR): 19]. There were 17 patients were recognized as abused group (shown in Table 3) while other 43 patients were belonged to neglected group according to medical staff’s mandatory reports. The table 1 showed demographic data including 18 patients had chronic comorbid conditions like congenital heart disease, growth retardation, and cerebral palsy, 16 (26.6%) patients were under height (less than 3rd percentile) and 15 (15%) patients were underweight (less than 3rd percentile); Table 2 shows that 51 patients were vaccinated on schedule, 24 patients had intubation, 18 of which had a Glasgow Coma Scale score less than 8. The initial mean hemoglobin level was 10.7±2.5 g/dL, and 21 patients had new onset seizure while hospitalized in the PICU; 33 patients had intracranial hemorrhage, and 22 patients underwent cranial surgery; 16 patients had retinal hemorrhage; 19 patients had visual skin lesions; 15 patients had bone fracture. The mean length of patients’ hospitalization in PICU is 7±10.3 days.

Risk factors
We divided the patients into the abused group and the neglected group and compared the differences between the two groups. The abused group demonstrated a statically significant higher incidence of chronic comorbid conditions (especially in development delay), failure to thrive (body weight and body height less than 3rd percentile) and interrupted vaccination than neglected group (P<0.001 for both; Table 1). The abused group also had more patients diagnosed with seizure upon admission than the neglected group (P<0.001; Table 2). Regarding length of hospital stay, the mean stay lengths are 17.5 days and 5 days in the abused group and the neglected group, respectively (P<0.001; Table 2).

Outcome
All of the children 51(85%) had follow-up either through medical records or telephone follow-up except for 9(15%) death. The one-year outcome POPC score were applied. Using POPC score, 39(65%) patients were belonged to favorable outcome while 21(35%) patients underwent unfavorable outcome. No patients survived in a coma or persistent vegetative state (POPC=5). The post-injury functional outcome in the two groups were shown in Figure 1. We compared the favorable or unfavorable functional outcome in our abused or neglected group. We found the neglected group had significantly favorable outcome (P<0.001; Table 1).
Discussion

The initial presentation of child maltreatment may be subtle or may be catastrophic. In our study, we found that the abused group has more patients diagnosed with skin lesions, seizures on admission, and retinal hemorrhage than the neglected group (P=0.03, P<0.001, and P=0.049, respectively, as shown in Table 2). In a previous study, Maguire et al. analyzed the clinical features of abusive head trauma (AHT) and found that combining intracranial injury with retinal hemorrhage raised the probability of AHT from 4% (intracranial injury only) to 58% however head and/or neck bruising had a less significant relation with AHT. Intracranial injury and the presentation of head and/or neck bruising only elevated the probability of AHT from 4% (intracranial injury only) to 15% [11]. Our study revealed that skin lesions and retinal hemorrhage had significant increased relationship with child abuse, but intracranial hemorrhage did not significantly differ between the two groups. Which correlate the previous studies. O'Neill et al. assessed seizure with continuous electroencephalography (EEG) in patients with traumatic brain injuries and observed that young age and an abusive head trauma mechanism were both strong predictors of seizure (odds ratios [ORs] 8.7 and 6.0, respectively; p < 0.0001 for both) [12]. Child maltreatment has adverse effects on the affected children's physical condition, as well as the community’s health care finance. Our study revealed longer PICU stays for abused children (17.5 days vs. 5 days for abused vs. neglected and accident children, respectively, p=0.001). En-Pei Lee et al. retrospectively reviewed cases of child maltreatment admitted to Chang Gung Memorial Hospital at Linkou from 2001 to 2015 and observed that the abusive trauma group had longer stays in the ICU than the neglectful trauma group (18.2±23.9 days vs. 7.2±6.9 days respectively, p<0.01), and often a worse prognosis [13]. Children who were diagnosed as abused or neglected were more likely to die during hospitalization, have longer hospital stays, and have greater medical expenses [14-18]. These were compatible with our outcome analysis which neglected patients tended to have significantly better outcome and shorter ICU stay. Furthermore, some discharges were delayed despite medical clearance due to a lack of safe deposition [17]. Referral to multidisciplinary child protective service organizations significantly reduces the avoidable days of hospitalization and health care waste [19].

The abused children had a higher probability of chronic comorbid conditions, especially in development delay and interrupted vaccination compared with the neglected children in our study. Delays in seeking medical care raises concerns about potential abuse, [20], while failure to thrive can be a manifestation of child maltreatment [21]. In our study, patients who were failure to thrive also had significant tendency of child abuse. Children with disabilities or chronic illnesses are also at the risk of being abused [22-24]. Demanding special health care may test a caregiver’s patience, and children with disabilities are 3.4 times more likely to be maltreated than children without disabilities [25]. Furthermore, children with disabilities have greater difficulty reporting abusive events and fighting against caregivers. A longitudinal study of low-income children revealed that children with maltreatment reports also had a 74–100% higher risk of hospital treatment for asthma, cardio-respiratory, and non-sexually transmitted infectious disease [26]. While the negative health impact of maltreatment occurs prior to adulthood, it also has life-long consequences. A systemic review and meta-analysis revealed an association between adults’ mental disorder, substance abuse and childhood maltreatment, and some evidence also suggests a significant association between child physical abuse and arthritis, ulcers, and headache/migraine in adulthood [27]. All forms of maltreatment contribute to risk factors of chronic disease and area burden on health economics. Awareness
and early intervention and household visits to children with the risk of being abused can protect children from victimization. Our study has some limitations. First, as a retrospective study, it has recall bias and reverse causality. We were unable to completely obtain some cases’ characteristics and chronic comorbid conditions. The caregivers that may lose patience in dealing with their children’s chronic diseases may have a higher tendency of child maltreatment, while the caregivers’ abuse or neglect of children may worsen children’s diseases. Second, the amount of child maltreatment in our study could be underestimated. Most referrals rely on communities and medical providers, but the Taiwanese culture discourages third-party intervention, and some of the cases are lost during the follow-up period. More studies are needed in the future to ensure that victims are recognized early.

Conclusion

In our study, we found that abused children tend to have a higher incidence of chronic comorbid conditions, seizure, interrupted vaccination, longer length of PICU stay and poor functional outcome. This situation cannot be overemphasized as it affects not only public health but also social welfare and financial burdens. More and more organizations are advocating “early recognition, early referral” and have launched lectures to educate medical professionals. By better understanding the importance of early intervention against abuse, we can take action to save these children and prevent tragedies.
