Abstract

Complete and incomplete fusion cross sections for $^{6}$Li+$^{159}$Tb have been measured at energies around the Coulomb barrier by the $\gamma$-ray method. The measurements show that the complete fusion cross sections at above-barrier energies are suppressed by $\sim$34% compared to the coupled channels calculations. A comparison of the complete fusion cross sections at above-barrier energies with the existing data of $^{11,10}$B+$^{159}$Tb and $^{7}$Li+$^{159}$Tb shows that the extent of suppression is correlated with the $\alpha$-separation energies of the projectiles. It has been argued that the Dy isotopes produced in the reaction $^{6}$Li+$^{159}$Tb, at below-barrier energies are primarily due to the $d$-transfer to unbound states of $^{159}$Tb, while both transfer and incomplete fusion processes contribute at above-barrier energies.

I. INTRODUCTION

Near barrier fusion is governed by the structure of the interacting nuclei and the coupling to the direct nuclear processes, such as inelastic excitation and nucleon transfer [1, 2]. For nuclear systems with tightly bound nuclei, the coupling of the relative motion to these internal degrees of freedom successfully explains the enhancement of fusion cross sections with respect to the 1-D Barrier Penetration Model (BPM) calculations at sub-barrier energies [2]. However, the situation gets more complicated in reactions involving weakly bound nuclei, since they may break up prior to fusion. The interest in understanding the influence of breakup on fusion and other reaction processes has indeed received a fillip in the recent years, especially because of the recent advent of the radioactive ion beam facilities in different laboratories around the world.

Owing to the low intensities of the radioactive ion beams currently available experimental investigation of reaction mechanisms with unstable beams is still difficult, though measurements are being increasingly reported [3–11]. On the contrary, precise fusion cross sections measurements can be carried out with the readily available high intensity beams of weakly bound stable nuclei, \(^\text{6,7Li}\) and \(^\text{9Be}\), which have significant breakup probabilities. Such studies with weakly bound stable projectiles may serve to be an important step towards the understanding of the influence of breakup on fusion process.

During the past few years, the effect of breakup of weakly bound nuclei on the fusion process has been extensively investigated. In fusion measurements of weakly bound stable projectiles with heavy targets [11–22], events corresponding to the complete fusion (CF) of the projectile with the target could be separated experimentally from those resulting due to the incomplete fusion (ICF) process (where part of the projectile is captured by the target). The works show that the CF cross sections are substantially suppressed at above barrier energies, compared to the predictions of the 1-D BPM calculations. This has been attributed to the breakup of the weakly bound projectiles, prior to reaching the fusion barrier.

By contrast, fusion measurements for medium and light mass systems [23–31], where CF and ICF products could not be experimentally distinguished, only total fusion (CF+ICF) cross sections were measured. Such measurements show no significant effect of breakup on total fusion at above barrier energies.
Systematic fusion excitation functions measurement carried out by the characteristic $\gamma$-ray method, for the systems $^{10,11}$B+$^{159}$Tb and $^7$Li+$^{159}$Tb [19], shows that the CF cross sections at above barrier energies are suppressed for the systems $^{10}$B+$^{159}$Tb and $^7$Li+$^{159}$Tb by $\sim$14% and $\sim$26% respectively, with respect to the coupled channels (CC) calculations. Also, the CF suppression was found to be correlated with the $\alpha$-breakup threshold of the projectiles. In the context of these results, it appears worthwhile to measure the CF cross sections for the system $^6$Li+$^{159}$Tb, in view of the fact that $^6$Li has the lowest $\alpha$-breakup threshold (1.45 MeV) amongst the stable projectiles $^6,$ $^7$Li, $^9$Be and $^{10,11}$B. The present work deals with the measurement of CF and ICF cross sections for $^6$Li+$^{159}$Tb at energies around the Coulomb barrier, using the $\gamma$-ray method. To check the consistency of the present results with those of Ref. [19], the reaction $^7$Li+$^{159}$Tb was repeated at a few energies in the present work. Some preliminary results of the measurement have been reported in a conference proceedings [32].

II. EXPERIMENTAL DETAILS

The experiment was performed using the 14UD BARC-TIFR Pelletron accelerator at Mumbai. Beams of $^6$Li in the energy range 23-39 MeV and $^7$Li at energies of 28, 34 and 37 MeV bombarded a self-supporting $^{159}$Tb foil of thickness 1.59±0.08 mg/cm$^2$. To monitor the beam and also for normalization purposes, two Si-surface barrier detectors were placed at ±30° about the beam axis inside a spherical reaction chamber of 22 cm diameter. The total charge of each exposure was measured in a 1 m long Faraday cup placed after the target. The $\gamma$-rays emitted by the reaction products were detected in an absolute efficiency calibrated Compton suppressed clover detector, placed at +125° with respect to the beam direction. An HPGe detector having Be window was placed at −125° with respect to the beam direction, mainly to detect the low energy gamma rays. Both online and offline $\gamma$-spectra were taken during the runs, using the Linux based data acquisition software LAMPS [33]. The absolute efficiencies of the $\gamma$-ray detectors were determined using the standard calibrated radioactive sources ($^{152}$Eu, $^{133}$Ba, $^{209}$Bi, $^{60}$Co, $^{137}$Cs) placed at the same geometry as the target. The target thickness was determined using the 137.5 keV ($7/2^+\rightarrow3/2^+(g.s.)$) Coulomb excitation line of $^{159}$Tb. The same target was used for all the beam exposures. So to minimize the accumulation of radioactivity in the target, the target irradiations were carried out from the
III. DETERMINATION OF COMPLETE FUSION YIELDS

The compound nuclei $^{165}$Er and $^{166}$Er formed following the CF of $^{159}$Tb with $^6$Li and $^7$Li, respectively, decay predominantly by neutron evaporation. This is also predicted by the compound nuclei $^{165}$Er and $^{166}$Er formed following the CF of $^{159}$Tb with $^6$Li and $^7$Li.

A typical $\gamma$-ray addback spectrum from the clover detector, at the bombarding energy of 39 MeV, is shown in Figs. 1(a-b). The nuclei produced in the lowest beam energy onwards, a typical $\gamma$-ray addback spectrum from the clover detector, is shown in Figs. 1(a-b).
the statistical model calculations done using the code PACE [34]. In the measured energy
range the evaporation of two to five neutrons occurs, resulting in the formation of $^{163-160}$Er
and $^{164-161}$Er evaporation residues (ERs) for the reactions $^6$Li+$^{159}$Tb and $^7$Li+$^{159}$Tb,
respectively.

In determining the ER cross sections, the online spectra were mostly used. But as and
when required, the offline-spectra were also used. It needs to be mentioned here that in sit-
tuations where the ERs are stable, only the in-beam $\gamma$-ray spectroscopy method can be used.
However, in cases where the unstable ERs undergo further radioactive decay to populate
the excited states of their daughter nuclei, which in turn decay to their ground states by
emitting $\gamma$-rays, one can also use the off-beam $\gamma$-ray method, if the situation is favourable.
In the present work, this could be done only for the $4n$ channel residual nucleus, $^{161}$Er
with a half life ($T_{1/2}$) of 3.21 hours, produced in the reaction $^6$Li+$^{159}$Tb. The off-beam $\gamma$-ray
method could not be used for the ER $^{163}$Er ($T_{1/2}= 75$ mins.), as 99.9% of $^{163}$Er undergoes
EC decay to ground state of $^{163}$Ho. Also, as the same target was used for all the irradiations,
the off-beam method could not be used for the ER $^{160}$Er, having $T_{1/2}= 28.58$ hours which
is substantially large compared to the data accumulation times (typically $\sim$1-2 hours).

While analyzing the data from the clover detector, the addback spectra were used.
Wherever possible, the cross sections obtained from the clover detector spectra were
compared with those from the HPGe detector spectra, and they were found to be in good
agreement.

The $\gamma$-ray cross sections ($\sigma_\gamma$) were obtained from the relation

$$\sigma_\gamma = \frac{N_\gamma}{(\epsilon_\gamma N_B N_T)}$$

where $N_\gamma$ is the number of counts under the $\gamma$-ray peak, $\epsilon_\gamma$ is the absolute full energy peak
detection efficiency of the detector for the specific $\gamma$-ray, $N_B$ is the total number of beam
particles incident on the target and $N_T$ is the number of target nuclei per cm$^2$. The quantity
$N_B$ was determined by dividing the charge $Q$ collected in the Faraday cup by the equilibrium
charge value $\bar{Z}e$, obtained from Ref. [35]. The total systematic uncertainty in the $\gamma$-ray cross
sections, arising because of the uncertainties in $N_B$, $N_T$ and $\epsilon_\gamma$, is $\sim$8%. This is added in
quadrature to the statistical error in $N_\gamma$ to get the total error in $\sigma_\gamma$.

For the even-even ERs ($^{164,162,160}$Er), the cross sections were extracted from the extrap-
FIG. 2: (Color online) Ratio of individual channel cross sections to the total channel cross sections as a function of the centre-of-mass energy for the reaction $^6\text{Li}+^{159}\text{Tb}$. The errors are statistical only. The dashed lines are drawn to guide the eye.

FIG. 3: (Color online) Complete fusion cross sections as a function of the centre-of-mass energy for the reaction $^6\text{Li}+^{159}\text{Tb}$. The error bars indicate the total errors. The solid line is the coupled channels calculation multiplied by the factor of 0.66.
olated value of the intensity at J=0 obtained from the measured γ-ray intensities (after correcting for the internal conversion) for various transitions in the ground state rotational band [19]. For the odd-mass ERs (163,161Er) the cross sections were obtained by adding the cross sections of the γ-rays corresponding to the transitions from the excited states to the ground states of the nuclei, as done by Broda et al. [36]. In such cases, however, direct population of the ground states of the nuclei could not be considered. Nevertheless, the direct feedings to the ground states are expected to be substantially small in this mass and energy region, except at very low bombarding energies. In fact, in the present work this has been checked for the ER 161Er, produced in the reaction 6Li+159Tb, as both in-beam and off-beam γ-ray method could be applied to measure its production cross sections at low bombarding energies. It was observed that the cross sections, obtained from the in-beam γ-rays of 161Er (where direct population of the ground state is not included) and those from the off-beam γ-rays of 161Ho, following EC decay of 161Er, (which obviously includes direct ground state population of 161Er) are practically same. This shows the ground state contribution to be rather small and can safely be ignored in the evaluation of the CF cross sections. The CF cross sections for both reactions were obtained from the sum of the 2n−5n ER cross sections.

Figure 2 shows the individual xn channel cross sections normalized to the CF cross sections (fractional channel cross sections) for the reaction 6Li+159Tb. The measured CF cross sections, along with the total errors, for the reaction 6Li+159Tb are plotted in Fig. 3. The CF cross sections for 7Li+159Tb, measured at a few bombarding energies in the same setup, are seen to agree well with the earlier measurements [19,36], thus enabling a reliable comparison of the present results with the earlier ones.

IV. COUPLED CHANNELS CALCULATIONS

To interpret the measured fusion excitation function in a theoretical framework, the realistic coupled channels (CC) code CCFULL [37] was used to calculate the fusion cross sections for 6Li+159Tb. The initial input potential parameters (V₀, r₀, and a) were obtained from the Woods-Saxon parametrization of the Akyüz-Winther (AW) potential [38], and are shown in Table I. The table also shows the corresponding uncoupled fusion barrier parameters (V₀, R₀, and ℏω). As CCFULL cannot handle shallow potential, a deeper potential was used. This modified potential was derived keeping the diffuseness parameter fixed at a=0.85
fm, following the systematic trend of high diffuseness required to fit the high energy part of the fusion excitation functions \[39\]. To obtain the appropriate potential, the parameters \(V_0\) and \(r_0\) were varied accordingly so that the corresponding 1-D BPM cross sections agree with those obtained using the AW potential parameters at higher energies \[19\]. The modified potential used for the CC calculations, and the corresponding uncoupled barrier parameters are given in Table I. Using the modified potential parameters, the 1-D BPM calculations were done using the code CCFULL, in the no coupling limit and the results are shown by the dotted line in Fig. 3. The CF cross sections at below-barrier energies are seen to be enhanced and the cross sections at above-barrier energies are found to be reduced compared to the 1-D BPM calculations. The enhancement at below-barrier energies may be because of the fact that the target \(^{159}\)Tb is a well deformed nucleus.

The effect of target deformation on the fusion cross sections was calculated by including coupling to the ground state rotational band of the target nucleus. As described in Ref. \[19\], for the odd-A nucleus \(^{159}\)Tb, the excitation energies and deformation parameters were taken to be the averages of those of the neighbouring even-even nuclei \(^{158}\)Gd and \(^{160}\)Dy. The energy states, in the ground state rotational band of the corresponding average spectrum \((\beta_2=0.344 [40] and \beta_4=+0.062 [41])\), upto \(12^+\) were included in the calculations. Projectile excitation was not included in the calculations. It needs to be mentioned here that \(^6\)Li has a ground state with non-zero spin \((1^+)\) and spectroscopic quadrupole moment of \(-0.082\) fm\(^2\), and has an unbound first excited state \((3^+)\) at \(2.186\) MeV. But coupling to the unbound first excited state of \(^6\)Li with such ground state properties, along with the rotational coupling to the target excited states could not be included in the CCFULL calculations.

The dashed line in Fig. 3 shows the CC calculations that include rotational coupling to the inelastic states of the target. The calculations, though reproduce the low energy part of the data reasonably well, overestimate the high energy part of the data. The little difference that can be seen at the lowest energy could be due to the projectile effect, which could not be considered in the calculations, as mentioned. At above barrier energies, where coupling is not expected to play any significant role, the CF cross sections are found to be suppressed compared to the CC calculations.

As CC model cannot yet separate CF and ICF, the measured CF cross sections can only be compared with the calculated total fusion cross sections. So in order to have an estimate of the extent of CF suppression compared to the total fusion cross sections, the CC calculations
TABLE I: The parameters for AW and modified CC potentials, along with the corresponding derived uncoupled barrier parameters $V_b$, $R_b$, and $\hbar \omega$.

| System       | Potential | $V_0$  | $r_0$  | $a$   | $V_b$  | $R_b$  | $\hbar \omega$ |
|--------------|-----------|--------|--------|-------|--------|--------|-----------------|
| $^6\text{Li}+^{159}\text{Tb}$ | AW        | 46.40  | 1.18   | 0.62  | 24.89  | 10.60  | 4.85            |
|              | CC        | 128.0  | 0.98   | 0.85  | 24.48  | 10.53  | 4.15            |
| $^7\text{Li}+^{159}\text{Tb}$ | AW        | 46.43  | 1.18   | 0.62  | 24.70  | 10.69  | 4.48            |
| $^{10}\text{B}+^{159}\text{Tb}$ | AW        | 54.54  | 1.18   | 0.64  | 40.71  | 10.79  | 4.68            |
| $^{11}\text{B}+^{159}\text{Tb}$ | AW        | 54.54  | 1.18   | 0.64  | 40.34  | 10.89  | 4.42            |

for $^6\text{Li}+^{159}\text{Tb}$ were scaled so as to reproduce the high energy part of the measured CF excitation function. Agreement could be achieved only if the calculated fusion cross sections are scaled by a factor of 0.66, and the resulting scaled calculations are shown in Fig. 3 by the solid line. The CF suppression factor ($F_{\text{CF}}$) for the system is thus 0.66±0.05, where the uncertainty of ±5% has been estimated, resulting from the overall errors in the measured fusion cross sections. The CF suppression of 34±5% thereby obtained at above barrier energies for $^6\text{Li}+^{159}\text{Tb}$ agrees with the value reported for the heavier systems $^6\text{Li}+^{208}\text{Bi}$ [14] and $^6\text{Li}+^{208}\text{Pb}$ [16] and is also in close agreement with the suppression of 32±5% reported for $^6\text{Li}+^{144}\text{Sm}$ [22].

V. COMPARISON OF SUPPRESSION WITH OTHER SYSTEMS

The $F_{\text{CF}}$ for $^6\text{Li}$ induced reactions on different targets are compared in Fig. 4(a), using the present data and those reported in the literature [14, 16, 22]. The dotted line has been drawn in the figure only to guide the eye. It appears that the $F_{\text{CF}}$ for $^6\text{Li}$ induced reactions are almost independent of the atomic number ($Z_T$) of the target nucleus, in the heavy mass region. However, more values of $F_{\text{CF}}$ for $^6\text{Li}$ induced reactions, especially with targets of lower $Z_T$ are required before drawing any definite conclusion. Figure 4(b) compares $F_{\text{CF}}$ for the reactions $^6\text{Li}+^{159}\text{Tb}$, $^7\text{Li}+^{159}\text{Tb}$ [19] and $^{10}\text{B}+^{159}\text{Tb}$ [19] as a function of the $\alpha$-separation energies (S.E.$_{\alpha}$) of the projectiles. Like $^6\text{Li}+^{159}\text{Tb}$, a ±5% uncertainty has also
FIG. 4: (Color online) (a) CF suppression (%) as a function of atomic no. $Z_T$ of target for the $^6$Li-induced reactions involving different targets. The reactions considered are $^6$Li incident on $^{144}$Sm [22], $^{159}$Tb (present work), $^{208}$Pb [16], and $^{209}$Bi [14]. The dotted line is drawn to guide the eye. (b) CF suppression(%) as a function of $\alpha$-separation energies (S.E.\(_\alpha\)) of the projectiles in reactions with the target $^{159}$Tb. The reactions considered are $^{10}$B+$^{159}$Tb [19], $^7$Li+$^{159}$Tb [19] and $^6$Li+$^{159}$Tb (present work).

been estimated for F\(_{CF}\) of $^7$Li+$^{159}$Tb and $^{10}$B+$^{159}$Tb reactions. The plot shows that there is a correlation between F\(_{CF}\) and S.E.\(_\alpha\). But more such measurements, including reactions with unstable projectiles, are needed to understand the nature of the correlation.

Figure 5 compares the reduced fusion cross sections $\sigma_{fus}/R_b^2$ as a function of $E_{c.m.}/V_b$ for different projectiles in logarithmic scale (a) and linear scale (b). The parameters $V_b$ and $R_b$ used for the reduction are those deduced from the AW potentials, and are listed in Table I. The CF cross sections for $^{11,10}$B+$^{159}$Tb and $^7$Li+$^{159}$Tb were obtained from Refs. [19, 36]. It can be seen from Fig. 5(a), that at the lowest energies the CF cross sections of $^6,7$Li+$^{159}$Tb are enhanced compared to those of $^{10,11}$B+$^{159}$Tb reactions. This enhancement,
FIG. 5: (Color online) A comparison of the reduced complete fusion excitation functions for the systems $^{10,11}$B+$^{159}$Tb [19] and $^7$Li+$^{159}$Tb [19, 36] with those of the present measurements for $^6,7$Li+$^{159}$Tb. The errors are statistical only.

which could be due to the effect of the projectiles $^6,7$Li, was also observed while comparing the measurements with CCFULL calculations [Fig. 3 and Ref. [19]]. For the reaction $^6$Li+$^{159}$Tb, this has already been discussed in Sec. IV. For the reaction $^7$Li+$^{159}$Tb, the deformation of $^7$Li needs to be considered in the calculations [19], but both projectile and target deformations can not be included simultaneously in the CCFULL calculations.

Figure 5(b) shows that as one moves from the projectile $^{11}$B to $^6$Li, i.e. as the projectile $\alpha$-breakup threshold decreases, the CF cross sections are observed to be more and more suppressed. A comparison with the CCFULL calculations has shown that the measured CF cross sections for $^{10}$B+$^{159}$Tb, $^7$Li+$^{159}$Tb [19] and $^6$Li+$^{159}$Tb are suppressed by $\sim 14\%$, $\sim 26\%$ and $\sim 34\%$ respectively. This certainly shows that the CF supression is correlated with the $\alpha$-breakup threshold of the projectile. Lower the $\alpha$-breakup threshold, larger is the CF suppression. Thus the CF suppression can be attributed to the loss of flux from the fusion channel due to the breakup of the loosely bound projectiles, and hence at least
a major part of this suppression should be the ICF cross sections of the reactions. Also, if one looks carefully into Fig. 5(b), it appears that higher the α-breakup threshold of the projectile, higher is the energy where the CF suppression starts. However, more such systematic measurements, especially with unstable beams, are required for confirming this observation.

VI. INCOMPLETE FUSION

In order to have a complete picture of the fusion process in the reaction $^6\text{Li}+^{159}\text{Tb}$, besides CF cross sections, it is also important to measure the ICF cross sections. As discussed in the previous section, a major part of the observed reduction in CF is expected to be due to the ICF process.

In the γ-ray spectra, besides the γ-ray lines of the Er nuclei resulting from CF, the γ-ray lines corresponding to Dy and Ho isotopes produced via the ICF processes were also observed. In the reaction $^6\text{Li}+^{159}\text{Tb}$, the Dy nuclei are produced by the capture of the lighter projectile fragment, $d$, following $^6\text{Li}$ breakup, by the target $^{159}\text{Tb}$ and subsequent emission of neutrons. Similarly, the Ho nuclei are formed by the capture of the heavier projectile fragment, $α$, by $^{159}\text{Tb}$, followed by neutron emission. The ICF cross sections are shown in Fig. 6. The cross sections of the ICF products were determined in a similar way as that for the CF residues. The $αn$, $α2n$ and $α3n$ channels, following the capture of $d$ by $^{159}\text{Tb}$, are seen to be the dominant ICF channels. On the other hand, only γ-lines corresponding to $^{161}\text{Ho}$ nucleus resulting from the $α+^{159}\text{Tb}$ ICF process, followed by $2n$ emission, could be identified in the spectra. However, the ICF contribution of $^{161}\text{Ho}$, plotted in the figure, partly includes the contribution of $^{161}\text{Ho}$ produced via the EC decay of $^{161}\text{Er}$ CF residue. Nevertheless, it is clear that the contribution of $^{161}\text{Ho}$ formed in the ICF process is relatively much less compared to Dy isotopes. A possible explanation of this could be given on the basis of Q-values of the reactions. It is to be noted that the Q-value for the reaction $^{159}\text{Tb}(^6\text{Li},α)^{161}\text{Dy}$ is +10.2 MeV, while it is −2.2 MeV for the reaction $^{159}\text{Tb}(^6\text{Li},d)^{163}\text{Ho}$. This indicates that the former channel corresponding to ICF process, where the $α$-particle is emitted with the $d$ being captured by the target is more favoured compared to the latter. Our measurement on the systems $^7\text{Li}+^{159}\text{Tb}$ and $^{10}\text{B}+^{159}\text{Tb}$ reported earlier also showed similar result.

It needs to be mentioned here that the ICF cross sections for Dy isotopes also include
FIG. 6: (Color online) The ICF/transfer cross sections measured for the reaction \( ^6\text{Li} + ^{159}\text{Tb} \). The cross sections corresponding to the \( \alpha n \), \( \alpha 2n \) and \( \alpha 3n \) channels, following \( d \)-capture by the target, and the cross sections corresponding to the \( d2n \) channel, following \( \alpha \)-capture by the target are shown.

Contributions from transfer of \( d \) from projectile \( ^6\text{Li} \) to the higher excited states of the target since in the present \( \gamma \)-ray measurement it was not possible to distinguish between the two events. Also, the single-proton stripping reaction \( ^{159}\text{Tb}(^6\text{Li},^5\text{He})^{160}\text{Dy} \), with Q-value +2.836 MeV, if occurs will lead to the same \( ^{160}\text{Dy} \) nucleus. Hence the contribution from \( ^{160}\text{Dy} \) nuclei via \( p \)-transfer, if any, is also included in the \( \alpha n \) channel cross section.

A careful insight into Fig. 6 shows appreciable cross sections for Dy nuclei, even at energies below the barrier where CF shows no suppression (Fig. 3). This is perhaps because of the fact that at below-barrier energies, it is essentially the transfer of \( d \) to the unbound states of \( ^{159}\text{Tb} \) (one-step process), followed by the emission of neutrons, that produces the Dy isotopes. In a simplistic picture, this can be understood by considering the optimum Q-value \( (Q_{opt}) \) associated with a transfer reaction. The ground state Q-value \( (Q_{gg}) \) for the \( d \)-transfer reaction \( ^{159}\text{Tb} (^6\text{Li},\alpha)^{161}\text{Dy} \) is +10.2 MeV, and \( Q_{opt} \) for the transfer process, say at \( E_{c.m.} = 22 \) MeV and 25 MeV are calculated [42] to be −7.1 MeV and −8.1 MeV, respectively. The excitation energy \( (\epsilon^*) \) in \( ^{161}\text{Dy} \) to which the \( d \)-transfer is energetically favoured is given by
Q_{gg} - Q_{opt}. Thus at $E_{c.m.} = 22$ MeV and 25 MeV, $\epsilon^* = 17.3$ MeV and 18.3 MeV, respectively, thereby showing that the $d$-transfer to $^{159}\text{Tb}$ will energetically favour the production of $^{161}\text{Dy}$ nuclei in the unbound states. Unlike transfer, at below-barrier energies, the breakup fragments may not have sufficient energy to overcome the Coulomb barrier and get further captured by the target (two-step process). By contrast, at above-barrier energies the breakup fragments will have sufficient energy to undergo further fusion with the target and hence at such energies the ICF (breakup-fusion) process, along with $d$-transfer, lead to the production of Dy nuclei. It is mainly the ICF (breakup-fusion) yield (which could not be separated from transfer in the present measurement) that contributes to the reduction of CF at above barrier energies. Similar argument also holds true for the Ho nuclei. Unfortunately, only one Ho isotope, namely $^{161}\text{Ho}$ could be identified in the present work and that too had an admixture due to the contribution from $^{161}\text{Ho}$ nuclei resulting from the EC decay of $^{161}\text{Er}$ residue. So nothing conclusive could be said about Ho nuclei. Detailed exclusive measurements aimed at disentangling ICF and transfer yield, though difficult, are indeed necessary to see how much of the reduction in CF is accounted for by the ICF process.

VII. SUMMARY

The CF cross sections for the reaction $^6\text{Li} + ^{159}\text{Tb}$ have been measured at energies around the Coulomb barrier, using the $\gamma$-ray method. CC calculations using the code CCFULL were done to calculate the total fusion cross sections. The calculated fusion cross sections had to be scaled by a factor of $0.66 \pm 0.05$ to reproduce the measured CF cross sections at above barrier energies. The above-barrier CF suppression has been attributed to the breakup of the loosely bound $^6\text{Li}$ nucleus. The CF suppression of $\sim 34\%$ for $^6\text{Li} + ^{159}\text{Tb}$ when compared to the values of $\sim 26\%$ and $\sim 14\%$ for $^7\text{Li} + ^{159}\text{Tb}$ and $^{10}\text{B} + ^{159}\text{Tb}$ respectively, convincingly shows that the CF suppression is correlated with the $\alpha$-separation energy of the projectile. Lower the $\alpha$-breakup threshold of the projectile, larger is the CF suppression. At energies below the barrier, enhancement of CF cross sections could be reasonably well reproduced by considering the deformation of the target.

The nuclei produced via the ICF process in the reaction $^6\text{Li} + ^{159}\text{Tb}$ were also identified and their cross sections have been determined. Similar to $^{10}\text{B} + ^{159}\text{Tb}$ and $^7\text{Li} + ^{159}\text{Tb}$, the present measurement also shows that the $\alpha$-emitting channel is the favoured ICF process.
in reactions of projectiles, having low $\alpha$-breakup thresholds, with $^{159}$Tb target.

At below barrier energies, the Dy isotopes are primarily produced by the $d$-transfer to the unbound states of $^{159}$Tb, while at above barrier energies both transfer and ICF processes contribute to their production.

Further investigation of the light particles emitted in reactions involving loosely bound projectiles, in conjunction with the results presented here, may lead to a better understanding of the mechanisms involved in such reactions.

Acknowledgments

We are grateful to Prof. B.K. Dasmahapatra for valuable discussions and advices at various stages of the work. We thank Mr. P.K. Das for his earnest technical help during the experiment. We would also like to thank the accelerator staff at the BARC-TIFR Pelletron Facility, Mumbai, for their untiring efforts in delivering the beams.
