Abstract: Increase in conversion efficiency from a femtosecond optical pump into broadband terahertz (THz) radiation is currently an essential issue since it boosts THz source performance for medicine and security applications. An air-plasma based THz radiation from a two-color femtosecond filament is the most efficient gas-based THz emitter, with a dipole local source having a maximum on the beam propagation axis. In this work, we show the novel advancement to THz yield increase with preservation of the forwardly directed dipole radiation. The two-color THz source can be enhanced if the filament plasma channel is placed into an external electrostatic field (DC bias), which is parallel to the second harmonic polarization direction. In the experiment, we produce a plasma channel from 800-nm, ∼50-fs, 2-mJ pulse with 200 µJ of 400-nm, ∼50-fs mixed with the pump, and allocate it between the electrodes carrying 7-kV/cm static field. Time-domain measurements and 3D+time simulations of THz waveforms from the two-color DC-biased filament show that the THz emission is the superposition of the THz waveforms generated in the 800 + 400-nm filament without a DC-bias and in the 800-nm (without 400-nm) plasma channel biased by 7-kV/cm static field. The additivity of the two local dipole THz sources is possible if the majority of free electrons are produced by the pump pulse.

Keywords: broadband THz pulse; methods of THz generation; DC-biased filament; two-color filament; interplay between THz local sources

1. Introduction

The plasma channel of a femtosecond laser filament [1-3] in air or atmospheric density gases is a promising source of terahertz (THz) radiation [4,5]. A single-color femtosecond plasma burst [6] or a more extended filament plasma channel emits radially polarized THz waves, ref. [7] typically registered in the focusing geometry. Breaking a single filament symmetry through an external electric field [8] or an optical pulse at another central wavelength [9,10] boosts the THz yield and paves the way to medical and security applications of THz spectroscopy [11,12].

Hereafter, we will refer to these two schemes of enhanced (as compared with a single-color plasma channel case) THz yield as the DC-biased ($\omega + DC$) and two-color filamentation, respectively. Linearly polarized THz radiation is typically detected from both the DC-biased ($\omega + DC$) and the two-color filaments [13,14]. Mixing of the pump pulse with its second harmonic, also known as the two-color $\omega + 2\omega$ filamentation, is recognised as one of the most efficient ways to generate THz from femtosecond gas plasmas [15,16]. For the mid-infrared air-based $\omega + 2\omega$ filament, the conversion efficiency to THz range reaches several percents [17-20].
The interplay between different mechanisms of THz generation in the filament has been studied for more than ten years. The interference in spatial domain between the radially and linearly polarized THz emission from DC-biased filament was reported in [13, 21, 22] for an external field of about 1 kV/cm. For the electric field strength of 5 kV/cm and larger, the linearly polarized THz emission dominates. The competition between the mechanisms of THz generation in DC-biased filament was recently experimentally studied in Ref. [23]. The analysis of THz spectra measured by electro-optical sampling shows that the balance between the sources of radially and linearly polarized THz emission occurs for the electrostatic field of 300 V/cm [23].

The joint effect of the external DC bias and the second harmonic on THz yield, or, in other words, THz generation from a DC-biased two-color \((\omega + 2\omega + DC)\) filament, has been experimentally studied in Ref. [15]. In the case of an external electrostatic field orthogonal to the \(\omega\) pulse polarization, Wang et al. [15] suggested that the THz emission could be the sum of two components: one generated by two-color \((\omega + 2\omega)\) laser-induced filamentation and the second induced by the DC electric field. To provide a well-controlled comparison of THz signal from \(\omega + 2\omega\) and \(\omega + DC\) filaments, Thomson et al. [24] superimposed the THz waveforms measured for \(\omega + 2\omega + DC\) filament with opposite polarities to the DC-bias, assuming that THz signals produced with and without external electrostatic field are added coherently. This method suggests that half a sum of two THz waveforms, obtained for the opposite directions of the external electrostatic field, highlights the contribution from the \(\omega + 2\omega\) source. In Ref. [25] the \(\omega + 2\omega + DC\) filament was shown to be a promising tool for THz generation with tunable spectrum. Besides, control of the THz spectrum width and modulation is important for the "false" absorption frequency identification when performing THz spectroscopy, especially when the reflection from the layered structures is considered [12]. In atmospheric air, the tunability of the THz spectrum from a DC-biased plasma channel cannot be large, because the DC field is limited by static breakdown threshold. However, this method can be improved by considering gases with variable density or even liquids. Indeed, impressive conversion from \(\omega + 2\omega\) to THz radiation was found in the insulator liquids [26], which have a higher breakdown threshold, thus providing a lot more freedom for spectral shaping using DC bias.

In this work, we experimentally study the THz emission from the DC-biased two-color \((\omega + 2\omega + DC)\) filament with the DC field parallel to polarization of the second harmonic and orthogonal to the fundamental light field polarization. In this case, the THz emission of both \(\omega + DC\) and \(\omega + 2\omega\) sources is polarized along the DC field. Terahertz waveforms measured in the temporal domain are found to be the superposition of electromagnetic fields emitted by the air-based plasma in the presence of the second harmonic pulse and the DC bias. Numerical \((t, r) + z\) simulations based on the Unidirectional Pulse Propagation Equation (UPPE, [27]) and performed separately for \(\omega + DC\), \(\omega + 2\omega\) and \(\omega + 2\omega + DC\) sources in the conditions of the experiment reveal that biasing the two-color pulse with the DC field results in linear addition (superposition) of the THz waveforms.

The paper is organized as follows. Section 2 describes the experimental setup capable of switching the electrostatic field on and off. In the same Section 2, the 3D+time numerical approach to propagate the light field in air and to obtain the THz waveforms self-consistently from the simulations is presented. In Section 3, the measured and simulated waveforms from \(\omega + 2\omega\), \(\omega + DC\) and \(\omega + 2\omega + DC\) are compared and discussed. Section 4 concludes the paper.

2. Materials and Methods

2.1. Experimental Setup

Figure 1 shows the scheme of the experimental setup. Ti:Sapphire laser system Spectra Physics Spitfire Pro XP delivered the pulses with the horizontal polarization centred at a wavelength of 800 nm with the energy up to 2.7 mJ, for a duration of 50 fs (full width at half maximum, FWHM) and a beam diameter of 12 mm (at \(e^{-2}\) level) at 1-kHz repetition rate. The pulse energy was reduced down to 2 mJ by the half-wave plate and the Glan–
Taylor prism. The beam was focused by the lens with a focal length of 300 mm forming a ≈15-mm filament in free air (humidity of 30% at 23 °C). Two copper 40 × 15 mm² plane electrodes with a gap of 10 mm between them were set parallel to the optical table so that the filament was burnt in the center between them in the transverse direction and closer to the registration system in the longitudinal direction in order to avoid the reflection of THz radiation from the electrodes surface. A voltage of $U_{DC} = 7$ kV applied to the electrodes formed a vertically directed field with a strength of $E_{DC} = 7$ kV/cm. To generate the second harmonic and form a two-color filament, the β-barium borate (BBO) crystal (I-type, 100-µm thickness, 10% efficiency) was inserted into the pump beam after the lens. The BBO crystal was adjusted to maximize the second harmonic yield, so, the 400-nm radiation has the vertical polarization, i.e., perpendicular to the 800-nm pump and parallel to the external DC bias. For single-color experiments, the BBO crystal was removed from the optical path. Thus, our experimental setup allowed us to study the THz waveforms in three cases:

(a) = $ω + DC$: DC-biased single-color filament, when BBO crystal was removed from the optical path;

(b) = $ω + 2ω$: two-color filament, when the voltage on the electrodes was turned off ($U_{DC} = 0$);

(c) = $ω + 2ω + DC$: DC-biased two-color filament.

In all cases, the THz radiation had linear vertical polarization. Thus, in our setup the superposition of THz waveforms generated according to $ω + DC$ and $ω + 2ω$ mechanisms could be observed.

For our purposes, a coherent THz detection technique is required. Among the three widely used methods, namely, photoconductive antenna detection [28,29], THz Air Breakdown Coherent Detection (THz–ABCD) [30], and electro-optical sampling (EOS) [31], the latter is best suited for our study. Indeed, the photoconductive antennas are regularly employed with MHz repetition rate laser systems, and would not have enough sensitivity for the kHz source we have. ABCD works very well with the two-color scheme, while the DC-biased filament produces THz wave with lower frequency, which is not properly detected by THz–ABCD setups. Furthermore, the THz–ABCD method requires a high-power probe pulse and an additional DC supply, which can produce distortions for the one used to bias the filament (and vice versa). In turn, EOS has excellent sensitivity, and the frequencies below 3 THz are present in both two-color- and DC-bias-generated THz pulses. To obtain waveforms of the THz electric field, we used a standard time–domain system.
(TDS), which consists of the ZnTe crystal (10 × 10 × 0.5 mm³, (110) cut), the quarter-wave plate, the Glan–Taylor prism, and two photodiodes (Figure 1). The THz field induces birefringence in ZnTe crystal, so the probe pulse attains ellipticity proportional to the field strength. After passing through the quarter-wave plate, the probe pulse is divided by the Glan–Taylor prism and is registered by the photodiodes. The difference in the photodiode signals characterizes the birefringence induced in the crystal and, therefore, the THz field strength. By scanning the delay between the optical pump generating the THz wave and the probe pulse, we obtain a THz waveform. This TDS is sensitive to the radiation in the spectral range from ~0.2 to ~3 THz. Two 50-mm diameter Teflon lenses with focal distances of 100 and 60 mm collimated the THz emission from the filament and focused it onto the ZnTe crystal. Weak THz radiation of unbiased single-color filament [6] was below the registration threshold of our THz detection system. However, either the 7-kV/cm static field or the second harmonic with ~200 µJ of energy increased the THz yield up to the level of detection by TDS.

All the optical elements presented in Figure 1 were fastened and preserved their positions during the experiment. Only the BBO crystal was removed from the optical path in the case of ω + DC (a), and the mirrors of the delay line were moved. Therefore, the collection angles of THz radiation were the same throughout the experiment, and we can compare the measured waveforms in the three cases: ω + DC, ω + 2ω and ω + 2ω + DC.

2.2. Simulations

Filamentation and THz generation in the conditions of our experiment (moderate focusing with a numerical aperture of ~0.02) can be simulated using Unidirectional Pulse Propagation Equation (UPPE, [27]). The spatio-temporal spectrum \( \mathcal{E}(\omega, k_r, z) = \mathcal{F}[\mathcal{E}(t, r, z)] \) represents the electric field \( \mathcal{E}(t, r, z) \) of the laser pulse together with all the secondary emission (emerging terahertz and optical harmonics). Here, \( \mathcal{F} \) denotes a Fourier–Hankel transformation from the spatio-temporal domain \( (t, r, z) \) to the frequency-angular domain \( (\omega, k_r, z) \). Although the most rigorous description of a nonlinear source term requires the solution of the Schrödinger [32] or Maxwell–Bloch Equations [33], the decomposition of the medium susceptibility into the response of bound and free electrons (or intra- and inter-band responses) is successful for THz generation simulations in gases [34] and transparent condensed media [26], and can even be applied to metals [35]. To decrease the computational costs, we follow this simplified approach. The external electrostatic field \( E_{DC} \) is introduced into UPPE as the nonlinear susceptibility modification of the medium [36]. With this modification the third-order polarization is given by:

\[
P(t) = \chi^{(3)} \left[ (\mathcal{E}(t) + E_{DC})^3 - E_{DC}^3 \right],
\]

where \( \chi^{(3)} \) is the third-order susceptibility of air. The transient photocurrent obeys the equation

\[
\frac{\partial J_e}{\partial t} = \frac{e^2}{m_e} N_e(t)(\mathcal{E}(t) + E_{DC}) - \nu_c J_e,
\]

where \( e \) and \( m_e \) are electron charge and mass, respectively, \( \nu_c = 5 \text{ ps}^{-1} \) is the collision rate. The absorption current \( J_e \) [37] does not require modification because the influence of the external electrostatic field on the plasma density \( N_e \) is negligible. The density of free electrons \( N_e \) was calculated from the rate equations for the major air components: molecular nitrogen (78%) and molecular oxygen (22%).

The nonlinear terms are calculated in time domain and substituted into UPPE:

\[
\left( \frac{\partial}{\partial z} + ik_z \right) \mathcal{E} = -\frac{2\pi i}{e^2 k_z} \left( \omega^2 \mathcal{F}[P] - \mathcal{F} \left[ \frac{\partial J_e}{\partial t} \right] - i\omega \mathcal{F}[J_0] \right),
\]
where \(k_z = \sqrt{n^2(\omega)\omega^2/c^2 - k_0^2}\), \(n(\omega)\) is the refractive index of dry air, and \(c\) is the speed of light. The derivative \(\partial J_r/\partial t\) is used as it vanishes at the right boundary of the temporal domain \(t \to +\infty\), whereas the photocurrent \(J_r\) does not.

The simulations of THz generation from femtosecond filament were carried out in the experimental conditions for 800-nm pump pulse with the energy of 2 mJ, FWHM duration of 50 fs and beam diameter of 1 cm. We simulated three different THz sources implemented in three different experimental schemes designed in our lab. These schemes are mixing the pump and electrostatic field \(\omega + DC\), the pump and its second harmonic \(\omega + 2\omega\), and the pump and the second harmonic in the presence of an electrostatic field \(\omega + 2\omega + DC\). For the \(\omega + DC\) scheme, the THz source was a single-color filament biased by the external electrostatic field \(E_{DC} = 7\) kV/cm. The \(\omega + 2\omega\) case corresponds to the two-color filament formed by mixing the 800-nm pump pulse with its second harmonic (wavelength of 400 nm, energy of 200 μJ, FWHM duration of 35 fs and the same beam shape as the pump). The \(\omega + 2\omega + DC\) case was a combination of the previous two schemes, i.e., we simulated THz generation in the DC-biased two-color filament in which the second harmonic and the external field \(E_{DC}\) were the same in value and direction as in the \(\omega + 2\omega\) and \(\omega + DC\) cases. To reproduce geometrical focusing with a focal length \(f = 30\) cm, we multiplied the initial field by the phase factor \(\exp[i\omega^2/(2c f)]\) in \((\omega, r, z)\) domain. We propagated the pulse linearly from the lens at \(z = 0\) to the front edge of the electrodes at \(z_0 = 26\) cm (as in [38]) in order to decrease the computational cost. Starting from \(z_0\) the nonlinear Equation (3) was solved.

Since the spectrum of THz radiation from DC-biased single-color filament covers the range up to a few terahertz [8,13,39], the simulations require the spectral resolution of the order of 0.01 THz. To reduce the computational resources, we utilized the non-uniform frequency grid, which consists of two equidistant sub-grids with different steps of \(0.02\) THz in the range from 0 to 85 THz and of \(0.1\) THz) in the range from 0 to 85 THz and of \(\approx 0.07\) THz in the remaining frequency space up to 2.75 PHz [36].

3. Results and Discussion

Figure 2 shows the measured THz waveforms (upper row) and the spectra of THz radiation reconstructed from these waveforms (dots, middle row). Panels (a)–(c) in Figure 2 correspond to \(\omega + DC\), \(\omega + 2\omega\) and \(\omega + 2\omega + DC\) schemes of THz generation, respectively. The simulated THz spectra are shown in Figure 2 (middle and lower row) by solid curves. In reasonable agreement between the numerical and experimental results, the spectrum of THz radiation generated from a DC-biased single-color (\(\omega + DC\)) filament is localized at \(\nu \lesssim 1\) THz (Figure 2a). In the experiment, strongly divergent low-frequency (\(\nu \approx 0.1\) THz) spectral components escape the Teflon lenses and do not enter the TDS detector. Owing to this effect, the maximum of the experimental spectrum was achieved at \(\nu \approx 0.4\) THz, while the simulations predicted the spectral maximum at much lower frequencies.

In the case of the \(\omega + 2\omega\) filament, the experimentally obtained and simulated spectra are much broader than in the \(\omega + DC\) one (cf. Figure 2a,b). The spectrum reconstructed from the measured THz waveform is limited by the ZnTe phonon band at \(\nu \gtrsim 3\) THz [40]. The simulated spectrum goes down very slowly and has a width of about the inverse pulse duration in agreement with the previous studies [41]. The low-frequency part of the experimentally obtained THz spectrum qualitatively agrees with the simulated one (Figure 2b).

The spectrum of THz radiation generated in a DC-biased two-color filament (\(\omega + 2\omega + DC\), see Figure 2c) combines the characteristics of \(\omega + DC\) and \(\omega + 2\omega\) spectra considered above. This is clearly pronounced in the higher-frequency range \(\nu \gtrsim 1.5\) THz. The spectrum of THz radiation generated according to the \(\omega + 2\omega + DC\) scheme extends up to 3 THz and the spectral intensity at 2 THz constitutes \(10^{-2}\) of the spectrum maximum (Figure 2c). Without the second harmonic field, the spectral intensity at 2 THz is of the order of \(10^{-3}\) of the spectrum maximum (Figure 2a). This wide high-frequency wing in Figure 2c originates due to the 800-nm pump pulse mixing with the second harmonic pulse.
as seen from the $\omega + 2\omega$ spectrum in Figure 2b. However, the direct intensity summation of the THz spectra in the $\omega + DC$ and $\omega + 2\omega$ schemes does not exactly reproduce the THz spectrum corresponding to the $\omega + 2\omega + DC$ scheme. We suggest that superposition of THz waves should be considered in the temporal domain. Therefore, we will study the partial contributions of the THz waveforms from the $\omega + DC$ and $\omega + 2\omega$ sources into the overall THz emission from the $\omega + 2\omega + DC$ filament.

Figure 2. Upper row: measured waveforms of THz radiation emitted from (a) red, $\omega + DC$) DC-biased single-color filament, (b) blue, $\omega + 2\omega$ two-color filament and (c) orange, $\omega + 2\omega + DC$) DC-biased two-color filament. Middle row: THz spectra in the cases shown in upper row; (dots) THz spectra obtained from the measured waveforms; (solid lines) simulated THz spectra integrated over the overall transverse domain. Lower row: the simulated THz spectra from the middle row in the extended frequency range till $\nu = 30$ THz and normalized.

As all the experimentally obtained waveforms were measured in the same conditions, they have the same scale and can be quantitatively compared with each other, see Figure 3a. The simulated on-axis waveforms processed by the bandpass filter $0.2 \text{ THz} < \nu < 3 \text{ THz}$, which roughly reproduces the spectral sensitivity of TDS, are plotted in Figure 3b. The rectangular filter cannot fully reproduce the TDS transfer function and spatial convolution with the probe beam, so the simulated waveforms in Figure 3b reproduce the measured ones in Figure 3a qualitatively. This reproduction includes the main physical characteristics of the waveforms, such as the correct relation between the amplitudes, the frequency content and the temporal shape of waveforms obtained from the $\omega + DC$, $\omega + 2\omega$ and $\omega + 2\omega + DC$ sources (Figure 3a,b, cf. the curves with the same colors). Note, in particular, the shorter period of THz field oscillations as the $2\omega$ pulse is added to the filament (cf. red and blue curves in Figure 3a,b).

To clarify the origin of the THz radiation from the two-color filament placed into the electrostatic field, we subtract the $\omega + 2\omega$ waveform, obtained without the DC field, from the $\omega + 2\omega + DC$ waveform. This subtraction was performed for both measured and simulated waveforms (Figure 3c,d, black curves). As the next step, we plot the measured THz waveform, obtained without the second harmonic pulse, i.e., in $\omega + DC$ case, on the same panel as the result of subtraction (Figure 3c, cf. red and black curves). Similar comparison was done for the simulated $\omega + DC$ curve (Figure 3d, cf. red and black curves). In both the experiment and the simulations the difference between the result of $\omega + 2\omega$
waveform subtraction from the $\omega + 2\omega + \text{DC}$ waveform and the $\omega + \text{DC}$ waveform is ~8%. Thus, the THz field from a two-color filament placed into the electrostatic field is the superposition of THz fields from the two-color dipole source and DC-biased filament plasma dipole source.

![Image](image_url)

**Figure 3.** (a) Measured and (b) simulated waveforms of THz radiation generated from a two-color filament ($\omega + 2\omega$, blue curves), a DC-biased single-color filament ($\omega + \text{DC}$, red) and a DC-biased two-color filament ($\omega + 2\omega + \text{DC}$, orange). (c,d) Replica of $\omega + \text{DC}$ waveform (red) compared to the difference between $\omega + 2\omega + \text{DC}$ and $\omega + 2\omega$ waveforms (black is orange minus blue) in (c) the experiment and (d) simulations.

To confirm our proposition, let us perform the analysis based on the material equations for the atmospheric density gas ionized by a femtosecond pulse. The main source of THz radiation in this underdense plasma is transient photocurrent $J_\omega$ [42]. Let the laser field $E(t)$ consist of the fast oscillating components only: the 800-nm pump and its second harmonic, i.e., $E(t) = E_{2\omega}(t) + E_{\omega}(t)$. The part of the transient photocurrent $J_\omega$ responsible for the generation of odd harmonics satisfies Equation (2) with $E_{\text{DC}} = 0$ and $E(t) = E_{\omega}(t)$. The remaining part of the transient photocurrent $J_e - J_\omega$ provides for the generation of THz radiation (and other even optical harmonics). For $\omega + \text{DC}$, $\omega + 2\omega$ and $\omega + 2\omega + \text{DC}$ mechanisms of THz generation in the filament, the equations for the remaining part of the photocurrent following from Equation (2) are, respectively:

$$\frac{dJ_{\text{DC}}}{dt} = \frac{e^2}{m_e} N_e(t) E_{\text{DC}} - v_e J_{\text{DC}}, \quad (4a)$$

$$\frac{dJ_{2\omega}}{dt} = \frac{e^2}{m_e} N_e(t) E_{2\omega}(t) - v_e J_{2\omega}, \quad (4b)$$

$$\frac{dJ_{2\omega+\text{DC}}}{dt} = \frac{e^2}{m_e} N_e(t) [E_{2\omega}(t) + E_{\text{DC}}] - v_e J_{2\omega+\text{DC}}. \quad (4c)$$

Plasma density $N_e$ does not depend significantly on either the external DC field $E_{\text{DC}}$ or on the electric field of low-intensity second harmonic $E_{2\omega}$ (cf. red and blue curves in Figure 4). Therefore, Equation (4c) is the sum of Equations (4a) and (4b), so, $J_{2\omega+\text{DC}} = J_{\text{DC}} + J_{2\omega}$, i.e., the THz source terms in DC-biased two-color ($\omega + 2\omega + \text{DC}$) filament are additive. According to Equation (3), the additivity of THz source terms corresponds to the interference of the THz fields induced by them and the superposition of the measured and simulated THz waveforms.
4. Conclusions

In conclusion, we have shown experimentally and numerically that THz radiation from a two-color filament can be further enhanced by imposing the electrostatic field over the plasma channel with the direction parallel to the second harmonic pulse polarization. The physical reason for THz radiation enhancement is superposition of THz waveforms produced in the two-color filament and in the plasma channel biased by a DC electric field. The additivity of the two local dipole THz sources is possible if the majority of free electrons in the filament plasma channel is produced by the optical field of the fundamental harmonic. The superposition of THz waveforms observed by us could serve as a tool for THz pulse shaping in a DC-biased two-color filament, especially in the media with higher breakdown voltage (pressurized gases or liquids).
