Recently, remarkable progress has been made in nanozyme research due to the rapid development of nanomaterials. Two-dimensional nanomaterials such as metal nanosheets, graphene-based materials, transition metal oxides/dichalcogenides, etc., provide enhanced physical and chemical functionality owing to their ultrathin structures, high surface-to-volume ratios, and surface charges. They have also been found to have high catalytic activities in terms of natural enzymes such as peroxidase, oxidase, catalase, and superoxide dismutase. This review provides an overview of the recent progress of nanozymes based on two-dimensional nanomaterials, with an emphasis on their synthetic strategies, hybridization, catalytic properties, and biomedical applications. Finally, the future challenges and prospects for this research are discussed.

Keywords: two-dimensional, nanomaterials, nanozyme, catalysis, biomedical

INTRODUCTION

Enzymes are catalysts that speed up almost all biochemical reactions in cells. They have some inherent defects that make them unfavorable in large-scale applications. Since the fascinating discovery of enzymatically active Fe₃O₄ nanoparticles (NPs) for immunoassay (Gao et al., 2007), the last decade has witnessed great advances in nanozyme research (Wei and Wang, 2013; Huang et al., 2019; Jiang D. W. et al., 2019), deriving from the growth of nanoscience and developments in technology. Various types of catalytic nanomaterials (NMs), primarily zero-dimensional (0D) NPs based on metals [e.g., Pt (Ju and Kim, 2015)], bimetallic compounds [e.g., AuPt (He et al., 2010)], metal oxides [e.g., Co₃O₄ (Mu et al., 2013)], and metal chalcogenides [e.g., CuS (He et al., 2012)], have been extensively explored to mimic peroxidases (PODs), oxidases (ODs), catalases (CATs), and superoxide dismutases (SODs) for biomedical applications. Despite much progress in the structural design of 0D nanozymes, there are still several obvious drawbacks. Firstly, most metal-based NPs are often used in a disposable manner, which inevitably causes either economic concerns for the precious metals used or environmental issues due to the pollution and toxicity of these heavy metals (Zhang T. et al., 2014). Secondly, it is known that NPs tend to agglomerate because of huge surface energy, which decreases catalytically active sites, impairing catalytic performance (Yang et al., 2004). Lastly, the inherently imperfect surface accessibility of 0D nanostructures is unfavorable and it is difficult to fully exert the biocatalytic capacity to mimic enzymes (Maromeze et al., 2016). Therefore, researchers should develop nanozymes with novel types of structures and functionalities, a significant research frontier in the nanozyme area.
Two-dimensional (2D) NMs within general sheet-like structures are a newly emerging but very important class of materials. Their lateral dimensions are generally one or several orders of magnitude larger than the thickness, with typical morphologies of nanosheets (NSs), nanoribbons, nanoplates, and nanowalls (Zhang, 2015). Different from their 0D counterparts, 2D NMs with these unique shapes could render large specific surface and distinctive physicochemical attributes, especially in terms of extraordinary surface chemistry, due to the exposure of most of the atoms in 2D NMs on their surface. Initial work about layered materials focused on MoS$_2$, dating back nearly half a century (Gan et al., 2017). A surge of interest and studies on 2D NMs started after the discovery of graphene in 2004 (Novoselov et al., 2004). Since then, a host of 2D NMs, including layered double hydroxides (LDHs) (Harvey et al., 2016), transition metal dichalcogenides (TMDs) (Zhu et al., 2013), ultrathin metal NMs (Huang et al., 2011), transition metal oxides (TMOs) (Zhou et al., 2017), Xenes (e.g., black phosphorus) (Khan et al., 2020), metal carbides/nitrides (MXenes) (Jiang C. M. et al., 2019), graphitic carbon nitride (g-C$_3$N$_4$) (Yang et al., 2013), hexagonal boron nitride (h-BN) (Chen M. M. et al., 2017), and metal-organic frameworks (MOFs) (Ding et al., 2017), have attracted considerable attention in numerous research fields, such as sensing, catalysis/electrocatalysis, batteries, electronics/optoelectronics, supercapacitors, and biomedical areas.

In terms of mechanical, chemical, and optical attributes, the potential biocompatibility and degradability, 2D NMs have been enthusiastically researched in various biomedical fields including biosensing (Oudeng et al., 2018), antibacterial agents (Lu et al., 2017), bioimaging (Ma D. T. et al., 2020), and cancer therapy (Kong et al., 2017). Also, with a single-atom layer or several-atoms-thick layers, 2D NMs possess the highest specific surface areas among all known materials, thus they have large reservoirs and abundant anchoring sites to load and deliver therapeutic agents (Qian et al., 2017). Moreover, the planar structure endows them with unusual properties including light/ultrasonic/magnetic responses and biological behaviors (e.g., endocytosis, biodistribution, biodegradation, and excretory pathways), which evokes the broad interest in developing 2D NMs as biomaterials (Chimene et al., 2015).

The rapid development of 2D NMs as versatile biomaterials has benefited from significant research progress in graphene, especially its bulk-quantity production and surface functionalization to improve its water solubility (Li et al., 2008; Sun et al., 2008), which paved the way for graphene to be potentially utilized for biomedical purposes. Meanwhile, it should be pointed out that, the success of 0D nanozymes in biomedical applications has promoted the exploration of the enzymatic properties of other nanostructures. As the first example of the employment of 2D NMs to mimic enzymes, the carboxyl-modified graphene oxide (GO) NSs were found to be able to mimic horseradish peroxidase (HRP), which were further developed as a glucose biosensor based on POD-like activity (Song et al., 2010). Later, a large number of 2D NMs with enzymatic activities have been successively reported and become a new type of enzyme-mimic, hereafter referred to as 2D nanozymes.

To our knowledge, despite many reviews (Huang et al., 2016; Agarwal and Chatterjee, 2018; Chen Y. et al., 2018; Dong et al., 2018; Merlo et al., 2018; Tao et al., 2019; Yan et al., 2019; Zhang X. L. et al., 2019; Ren et al., 2020) on the outstanding biomedical performance of 2D NMs, few of them have emphasized enzymatic properties, which are of significant importance to the development of 2D NMs. In this mini-review, we aim to highlight recent progress in 2D NMs with enzymatic properties for biomedical applications. Firstly, we briefly introduce crystal structures, synthesis, and hybridization strategies for 2D NMs. Then, we discuss the enzyme-like activities of 2D NMs. In the following, we summarize the recent advances of 2D nanozymes in diversified biomedical applications, ranging from biosensors, antibacterial agents, and antioxidants to therapeutics (Figure 1). Finally, we share our insights into the development prospects and challenges of 2D nanozymes.

![Figure 1](image-url) Two-dimensional NMs with enzyme-like activities for biomedical applications.

**CRYSTAL STRUCTURES, SYNTHESIS, AND HYBRIDIZATION STRATEGIES OF 2D NMs**

**Crystal Structures of 2D NMs**

In essence, the unusual physicochemical attributes of 2D NMs largely depend on their atomic arrangements, which have been clarified in detail elsewhere (Butler et al., 2013; Zhang, 2015; Tan et al., 2017). Despite multifarious composition and structural differences, 2D NMs can be generally categorized as layered and non-layered (Hu et al., 2019). For the former, each in-plane atom connects to the neighboring ones through strong chemical bonding in every layer. The layers, however, stack together via weak van der Waals (VDW) interaction (Bhimanapati et al., 2015). A typical layered compound is graphite, in which each
atom covalently bonds to three adjacent atoms in planes by σ-bond but weak VDW interaction exists between layers (Allen et al., 2010). LDHs, TMDs, g-C3N4, h-BN, Xenes, MXenes, and MOFs, also have a graphite-like crystallite structure. By contrast, the non-layered NMs crystallize in three dimensions by atomic/chemical bonds to form bulk crystals, which typically include 2D metals, metal oxides/chalcogenides, and others (Tan and Zhang, 2015). Relying on the specific arrangement of atoms, coordination modes between atoms, or stacking order between layers, these non-layered NMs can crystallize into different crystal phases, which greatly affect their attributes and functionalities (Tan et al., 2017).

**Synthetic Approaches of 2D NMs**

The top-down and bottom-up methodologies, as two types of commonly used approaches to the synthesis of 2D NMs, are well-summarized in the literature (Chen et al., 2015; Tan et al., 2017). The former is based on direct cleavage of bulk precursors, aiming to break weak VDW interaction between layers in 2D NMs by various driving forces, typically mechanical/liquid-phase/ion-intercalation and exfoliation (Zeng et al., 2011; Huo et al., 2015; Yi and Shen, 2015). Notably, these methods are only suitable for layered materials. They are relatively simple but suffer from certain disadvantages and limitations. Take synthesis of MoS2 NSs for example, mechanic exfoliation (Novoselov et al., 2005) is limited by low throughput, thereby making it unsuitable for most biomedical applications: Li-intercalation process not only requires a long time (e.g., 3 days) and high temperature (e.g., 100°C) but results in semiconducting-to-metallic phase-transition of MoS2 bulk (Yuwen et al., 2016); liquid exfoliation proposes difficulties in removing high-boiling organic solvents (Coleman et al., 2011).

Contrarily, the bottom-up methods usually begin with small organic or inorganic molecules/atoms, employing crystal growth/assembly into a 2D ordered structure, which includes classical chemical vapor deposition (CVD) (Shi et al., 2010) and wet-chemical synthesis (hydro-/solvo-thermal (Duan et al., 2014; Huang et al., 2014) and the self-assembly (Wu et al., 2015) of crystals, etc.). Since the bottom-up methods are based on the chemical reactions of certain precursors in given synthetic systems, they are more versatile than the top-down methods in enabling access to all types of 2D NMs. Despite the above protocols, it is still challenging to develop an appropriate strategy to synthesize 2D NMs with controlled and desirable structural parameters so as to satisfy the specific requirements.

**Hybridization of 2D NMs**

It is known that the hybridization of 2D NMs with functionalized species is an effective strategy to extend and expand their functionalities, which could potentially make them suitable for practical applications. Numerous functionalized species (e.g., atoms, ions, molecules, polymers, and nanostructures), have been modified onto/into 2D NMs by various methods such as doping, adsorption, electrodeposition, covalent functionalization, chemical reduction, and self-assembly (Guan and Han, 2019). For example, to improve water dispersibility and the stability of pristine MXenes NSs in a physiological solution for biomedical applications, Shi’s group reported modification of Ti3C2 NSs with soybean phospholipid by adsorption (Lin et al., 2017). The functionalized materials were found to possess enhanced permeability, stable circulation, and retention ability. In a similar study by Geng’s group, titanium carbide NSs terminated with Al(OH)3−4, obtained by intercalation of Ti3AlC2 bulk with tetramethylammonium (TMAOH) were modified with polyethylene glycol (PEG) molecules. The functionalized NSs demonstrated excellent stability in various physiological solutions, which were further developed as promising photothermal therapeutic agents (Xuan et al., 2016).

A variety of 0D metal NPs-functionalized 2D NMs have also been reported by different groups, including 0D/2D nanostructured Au/GO (Tao et al., 2013), Au/MOF (Huang et al., 2017a), and Pt/black phosphorus (Ouyang et al., 2018). In recent studies, the *in-situ* growth method was also adopted by different groups for the synthesis of Pt/h-BN (Ivanova et al., 2019) and “naked” Au NPs on g-C3N4 NSs (Wu et al., 2019), via the reduction of metal precursors on NSs with various reducing agents like NaBH4, ascorbic acid, etc. Our group also constructed a variety of 0D/2D heterostructures, including PtAg NPs-decorated MoS2 NSs through the hydrothermal process (Cai et al., 2016), Pt NPs-covered CuO NSs by NaBH4 reduction (Wang X. H. et al., 2017), and IrO2 NPs-modified GO (Sun et al., 2020) and reduced GO (rGO) (Liu X. L. et al., 2019) NSs by electrostatic adsorption/hydrothermal treatment. The modification of NPs onto 2D NMs could not only prevent NPs from aggregation but inhibit the restacking of NSs, which could facilitate practical applications. However, to access these nanocomposites, a multi-step procedure was generally required for synthesis. In a recent study, our group reported a one-pot fabrication of PtRh NPs-modified Rh NSs (Cai et al., 2019). During the synthesis, Pt atoms/clusters as seeds were first formed by reduction of Pt precursors (H2PtCl6·H2O), which promoted the reduction of Rh precursors (Rh(acac)3) to form PtRh NPs and directed formation of Rh NSs around PtRh NPs. In another work, our group demonstrated the one-pot synthesis of Pd NPs-modified NiCl2 NSs, by using a three-step process of “*in situ* reduction-oxidation-assembly” (Cai et al., 2018a). Notably, the pre-preparation and/or functionalization of NSs as well as immobilization of NPs on NSs, generally involved in conventional synthetic protocols, were unnecessary in the above studies.

**ENZYMATIC PROPERTIES OF 2D NANOZYMES**

**POD- and OD-Like Properties**

PODs and ODs are a class of known oxidative enzymes in biosystems, which activate H2O2 and O2 to catalyze the oxidation of respective substrates under mild conditions (Wei and Wang, 2013; Huang et al., 2019; Jiang D. W. et al., 2019). To evaluate the POD-/OD-like activity of 2D NMs, catalytic oxidations of enzymatic chromogenic substrates like 3,3′,5,5′-tetramethylbenzidine (TMB), which are often carried out in acidic media and produce colored products (Equation 1), are...
chosen as a probe reaction by most researchers (Gao et al., 2007; Song et al., 2010; Tao et al., 2013; Cai et al., 2016, 2018a; Huang et al., 2017a; Wang X. H. et al., 2017; Ouyang et al., 2018; Ivanova et al., 2019; Liu X. L. et al., 2019; Wu et al., 2019; Sun et al., 2020). The reaction process is tracked by UV-Vis spectroscopy and the color variation of the reaction solution can be easily observed by naked eyes.

Since the first report of GO NSs as a 2D POD-mimic by Qu's group (Song et al., 2010), similar observations were obtained from other types of 2D NMs, which also exhibited typical Michaelis-Menten kinetics during POD-catalysis. The apparent kinetic constant ($K_m$) and maximum reaction rate ($V_{max}$), as two important parameters related to enzyme-catalysis, could be determined from the Lineweaver-Burk plot. The constant $K_m$ characterizes the binding affinity of a substrate to the enzyme, in which a lower $K_m$ value means the higher affinity. Table 1 lists the kinetic parameters of typical 2D NMs as POD-mimics based on GO (Zhang L. N. et al., 2014; Sun et al., 2020) or rGO (Liu X. L. et al., 2019), TMDs (Lin et al., 2014a,b; Chen T. M. et al., 2017; Huang et al., 2018; Wu et al., 2018; Feng et al., 2020), LDHs (Zhan et al., 2018; Yang et al., 2020), g-C$_3$N$_4$ (Darabdhara et al., 2019), MOF NSs (Chen J. Y. et al., 2018), h-BN (Ivanova et al., 2019), metal oxides (Wang X. H. et al., 2017; Li et al., 2019), and metallic NSs (Wei et al., 2015; Cai et al., 2018b, 2020).

In an earlier study on the POD-like properties of TMDs, Guo's group reported that the commercially obtained MoS$_2$ NSs by solution-based exfoliation gave a $K_m$ value of 0.0116 mM with H$_2$O$_2$ as substrate, far lower than those of HRP (3.7 mM) (Gao et al., 2007) and Fe$_3$O$_4$ NPs (154 mM) (Gao et al., 2007), suggesting good affinity of as-obtained materials toward H$_2$O$_2$ (Lin et al., 2014a). The authors also found the POD-catalysis of Mo$_2$O$_5$ NSs was efficient over a broad pH range (2.0–7.5), wider than those of GO NSs and several 0D NPs [e.g., Fe$_3$O$_4$ (Gao et al., 2007), Co$_3$O$_4$ (Mu et al., 2012), and ZnFe$_2$O$_4$ (Su et al., 2012)]. In a recent study, Wang's group synthesized Mo$_2$S$_2$ NSs using a hydrothermal method, followed by the treatment of N$_2$ plasma, producing N-doped Mo$_2$S$_2$ NSs (Feng et al., 2020). With H$_2$O$_2$ as a substrate, the as-obtained materials not only gave a much lower $K_m$ value (0.4459 mM) compared to that of the undoped ones (2.0828 mM), but presented a larger $V_{max}$ value ($4.348 \times 10^{-8}$ M s$^{-1}$) than that of undoped NSs ($1.346 \times 10^{-8}$ M s$^{-1}$), suggesting enhanced affinity and the activity of NSs by N-doping. The N$_2$ plasma treatment efficiently increased the surface wettability and affinity of pristine NSs, thus improving the access of the electrons and substrates of catalytic reactions. In another study, Da's group synthesized a series of metal NPs (e.g., Au, Ni, and AuNi NPs) decorated g-C$_3$N$_4$ NSs by a solvothermal method (Darabdhara et al., 2019). With a substrate of either TMB or H$_2$O$_2$, the bimetallic nanocomposites gave both lower $K_m$ values and larger $V_{max}$ values (Table 1) than those of monometallic ones, indicating better affinity and POD-like activity by introducing bimetallic NPs into g-C$_3$N$_4$ NSs. Similar observations were obtained by Pt/CuO (Wang X. H. et al., 2017), IrO$_2$/rGO (Liu X. L. et al., 2019), Pd/NiCl$_2$ (Cai et al., 2018a), and PtM/MoS$_2$ (M = Ag, Cu, and Au) (Cai et al., 2016, 2017; Qi et al., 2016) as reported by our group.

Compared to the layered NM-based POD-mimics, non-layered examples are few. In a study by our group, the Pd NSs were prepared in CH$_3$COOH by bubbling of CO gas, followed by Galvanic replacement of Au$^{3+}$ ions to obtain Au NPs decorated Pd NSs (Cai et al., 2020). When TMB and H$_2$O$_2$ respectively acted as a substrate, the as-obtained nanocomposites afforded two large $V_{max}$ values (19.65 $\times 10^{-8}$ and 8.19 $\times 10^{-8}$ M s$^{-1}$), an ~2-fold enhancement in those of Pd NSs (7.01 $\times 10^{-8}$ and 4.02 $\times 10^{-8}$ M s$^{-1}$). In another study, Zheng's group synthesized ultrathin Pd NSs with a thickness below 10 atomic layers in the presence of PVP and a halide salt, followed by coating Pt nanodots onto the Pd NSs by reduction of Pt(acac)$_2$ with hydrazine hydrate in DMF solution (Wei et al., 2015). As listed in Table 1, compared to Pd NSs, the as-prepared nanocomposites gave lower $K_m$ values and larger $V_{max}$ values, demonstrating superior affinity and activity. To further make a meaningful comparison of catalytic efficiency between Pd NSs and the nanocomposites, the catalytic rate constant ($K_{cat}$) was introduced by the authors, which was calculated from the equation $K_{cat} = V_{max}/E$, where $E$ is the concentration of the catalyst. With either TMB or H$_2$O$_2$ as a substrate, the obtained $K_{cat}$ value for the nanocomposites was appropriately two times larger than those of Pd NSs. However, compared to several NPs such as Fe$_3$O$_4$ NPs (Gao et al., 2007), the catalytic efficiency of the nanocomposites is not high enough. In an interesting study, our group presented superior POD-catalysis of single-layer Rh NSs synthesized via the solvothermal method (Cai et al., 2018b). The obtained $K_m$ values for Rh NSs that were comparable to those of HRP (Gao et al., 2007), while the $V_{max}$ value for Rh with H$_2$O$_2$ as the substrate was exceptionally larger than those of HRP (Gao et al., 2007), Rh NPs (Choleva et al., 2018), and layered NMs based on GO (Gao et al., 2007), and TMD-based NSs (Lin et al., 2014a,b; Chen T. M. et al., 2017; Wu et al., 2018). Moreover, the obtained $K_{cat}$ value for Rh NSs to H$_2$O$_2$ was 128 times, 323 times, and 34 times larger than those of HRP (Gao et al., 2007), Rh NPs (Choleva et al., 2018), and few-layer Pd NSs (Wei et al., 2015), respectively. This high activity could be attributed to the large number of exposed active Rh atoms that were coordinately unsaturated, which facilitated efficient interaction with reactants during catalysis. The Rh NSs also demonstrated satisfactory chemical/thermal stability.

Previous studies revealed that POD-catalysis generally involves two types of pathways: (1) the generation of reactive oxygen species (ROS) including hydroxyl radicals (-OH) (Song et al., 2010; Lin et al., 2014a; Wei et al., 2015; Wang X. H. et al., 2017; Cai et al., 2018a), and (2) electron-transfer (ET) process (Cai et al., 2018b, 2020). The former is believed to undergo a radical chain mechanism, in which the O-O bonds

(Continued)
of H$_2$O$_2$ molecules are broken to generate ·OH radicals, which subsequently oxidize the substrates. In a representative example, Yang’s group found that after the coverage of Au NPs onto the g-C$_3$N$_4$ NSs (Wu et al., 2019), the generation of ·OH radicals remarkably increased during catalysis, evidenced by electron spin resonance (ESR). The increase in ·OH radicals could be attributed to the synergistic effect of Au NPs and g-C$_3$N$_4$ NSs, which enhanced the POD-catalysis. By contrast, for the latter, the 2D NMs mediate ET between the substrates and H$_2$O$_2$ molecules, instead of ROS generation. Take the Au NPs coated Pd NSs reported by our group (Cai et al., 2020) for example, with the introduction of Au atoms, the electronic structure of Pd NSs was modified, which subsequently caused a change in the catalytic pathway of Pd NSs (i.e., from ·OH generation to rapid ET process).

Different from PODs, ODs catalyze oxidations with O$_2$ as the oxygen source (generally in the open air), instead of unstable H$_2$O$_2$. The potential oxidative damage of biological species by H$_2$O$_2$ could also be avoided by the use of O$_2$. The metal oxide NSs like MnO$_2$ NSs (Liu et al., 2017; Yan et al., 2017; Ge et al., 2019) were found to exhibit OD-like activities, with the merits of operational simplicity and fine compatibility. Besides, good stability of MnO$_2$ NSs as OD-mimics was also found by several research groups. For example, Dyson’s group synthesized the MnO$_2$ NSs by exfoliation of bulk δ-MnO$_2$ in BSA aqueous solution (Liu et al., 2017). After storage for 3 months, no significant loss in the activity of NSs was observed. Similar findings were obtained from Rh NSs (Cai et al., 2018b) and PtRh/Rh nanocomposites (Cai et al., 2019). In some studies, the OD-catalysis was believed to go through the generation of ROS such as superoxide ions (O$_2^-$), via cleavage of O-O bonds in O$_2$ molecules (Cai et al., 2019; Ge et al., 2019).

Notably, besides temperature and substrate concentration, the POD/OD-like activities of 2D nanozymes greatly depend on system pH (often around 4 is efficient), which is similar to the 0D examples and enzymes. Thus, to facilitate their application in biosystems, it is highly desirable to develop 2D nanozymes with a wide range of pH, especially at neutral pH. In an early study, Qu’s group synthesized the lysozyme-stabilized Au clusters on GO NSs (Au/GO), which exhibited good catalytic activity over a broad pH range, even in physiological pH (Tao et al., 2013). Compared to that at pH 3.0, the POD-like activity of Au/GO remained about 82% at pH 7.0. In a recent study, Kim’s group reported the rosette-shaped C$_3$N$_4$ by the polymerization reaction between cyanuric acid and melamine, followed by calcination (Heo et al., 2020). Due to larger surface area and higher porosity, the activity of as-prepared materials was appropriately 10-fold higher than that of conventional bulk-C$_3$N$_4$. Interestingly, the maximal activity was shown at pH 8.0, and over 80% of the activity relative to the maximum activity remained across a pH range of 6.0–9.0.

Although numerous 2D nanozymes exhibited high activity, the catalysis is also lacking selectivity, similar to the 0D ones. To this end, Lee’s group synthesized the N- and B-codoped rGO NSs, which showed high efficiency in POD-catalysis, nearly 1000-fold higher than that of undoped rGO (Kim et al., 2019). More importantly, no OD-like activity was observed for the as-prepared materials, suggesting high selectivity. The same group also provided another valuable example, in which the Fe-N$_4$ single site, resembled the heme cofactor present in HRP, was embedded in graphene to obtain the Fe-N-rGO nanocomposites (Kim et al., 2020). Intriguingly, the nanocomposites not only showed a remarkable enhancement in catalytic efficiency, up to approximately 700-fold higher than that of undoped rGO but had excellent selectivity toward H$_2$O$_2$. The single-atom nanozymes (SAzymes), as a very new concept in the nanzyme field (Jiao et al., 2019), could open a window to develop a new type of highly active and selective 2D hybrid nanozymes at the atomic scale.

### SOD- and CAT-Like Properties

Contrary to oxidative biocatalysts, SODs and CATs are a type of antioxidant enzyme, which plays an essential part in maintaining redox balance in living organisms by scavenging excess ROS (Liu Y. et al., 2014). There are three forms of human SODs [i.e., cytosolic CuZn SOD, mitochondrial Mn SOD, and extracellular SOD, of which the first is the most studied (Korschelt et al., 2017)]. In a typical cycle of CuZn SOD (Yu et al., 2014; Korschelt et al., 2017), the metal Cu center shuttles between the Cu$^{2+}$/Cu$^+$ redox states (Equations 2, 3), catalyzing the disproportionation of O$_2^-$ into O$_2$ and H$_2$O$_2$ under neutral conditions (Equation 4).

\[
\text{O}_2^- + \text{Cu}(II) \rightarrow \text{O}_2 + \text{Cu}(I) \quad (2)
\]

\[
\text{O}_2^- + \text{Cu}(I) + 2\text{H}^+ \rightarrow \text{H}_2\text{O}_2 + \text{Cu}(II) \quad (3)
\]

\[
2\text{O}_2^- + 2\text{H}^+ \rightarrow \text{H}_2\text{O}_2 + \text{O}_2 \quad (4)
\]
Following a similar mechanism to that described above, several NMIs based on V$_2$O$_5$ nanowires (Vernekar et al., 2014) and CeO$_2$ NPs (Korsvik et al., 2007) have displayed intrinsic SOD-like activities. The polyvinylpyrrolidone (PVP)-modified Nb$_2$C NPs obtained by liquid-phase exfoliation (Ren et al., 2019) also provide an interesting example of SOD-mimics. By density functional theory (DFT) calculations together with the characterization of active intermediates via X-ray photoelectron spectroscopy (XPS) and X-ray diffraction (XRD) analysis, the authors discovered the SOD-like activity of Nb$_2$C NPs originated from the surface oxidation process, in which Nb$_2$O$_5$ forms as catalytically active species.

CATs accelerate the dismutation of H$_2$O$_2$ into O$_2$ and H$_2$O, often in the reaction solutions at a high pH (Wei and Wang, 2013; Huang et al., 2019; Jiang D. W. et al., 2019). Previous studies have revealed that the CAT-like activities of 0D metal oxide NPs originated from ion pairs (catalytic sites in two different oxidation states), such as Co$^{2+}$/Co$^{3+}$ (Mu et al., 2013), Fe$^{2+}$/Fe$^{3+}$ (Lin and Gurol, 1998), and Mn$^{3+}$/Mn$^{4+}$ (Hasan et al., 1999). Take Co$_3$O$_4$ NPs (Mu et al., 2013) for example, the catalytic mechanism can be described as follows. Under alkaline conditions, it is believed that there is a larger concentration of perhydroxyl anions (OOH$^-$) in the reaction system (Equation 5) (Mu et al., 2013). Since OOH$^-$ radicals are more nucleophilic than H$_2$O$_2$ molecules, they could readily interact with Co(III) centers (Equation 6) to generate Co(II) species and release -OOH radicals (Equation 7), while H$_2$O$_2$ molecules were activated by Co(II) center to produce -OH radicals (Equation 8). The coupling reaction of the generated -OH and -OOH radicals gave water and oxygen as final products (Equation 9).

$$\text{H}_2\text{O}_2 + \text{OH}^- \rightarrow \text{OOH}^- + \text{H}_2\text{O}$$  \hspace{1cm} (5)
$$\text{Co(III)} + \text{OOH}^- \rightarrow \text{Co(II)} \cdot \text{OOH}$$  \hspace{1cm} (6)
$$\text{Co(II)} \cdot \text{OOH} \rightarrow \text{Co(II)} + \cdot\text{OOH}$$  \hspace{1cm} (7)
$$\text{Co(II)} + \text{H}_2\text{O}_2 \rightarrow \text{Co(III)} + \cdot\text{OH} + \text{HO}^-$$  \hspace{1cm} (8)
$$\cdot\text{OH} + \cdot\text{OOH} \rightarrow \text{H}_2\text{O} + \text{O}_2$$  \hspace{1cm} (9)

The above mechanism could also apply to 2D counterparts. For example, Jiang’s group prepared MnFe LDHs by simple co-precipitation, which exhibited intrinsic CAT-like activities (Ruan et al., 2018). The authors explained that both the Mn$^{3+}$/Mn$^{4+}$ and Fe$^{3+}$ species exhibited catalytic activity toward H$_2$O$_2$, which could be used for H$_2$O$_2$ decomposition to generate oxygen in cancer tissues, to enhance the effect of oxygen-dependent photodynamic therapy (PDT). In another study, besides the metal center shuttling during catalysis, Zheng’s group demonstrated the role of ligands in the CAT-like activity of MOF NSs. The Cu MOF NSs were synthesized based on the coordination reaction between the Cu$^{2+}$ ions and isophthalic acids as ligands, with different substituent groups (e.g., -CH$_3$, -NO$_2$, -OH, and -NH$_2$) at 5-position (Wang et al., 2019). The authors found that the CAT-like activity of as-obtained materials was related to the charge density around Cu atoms in the NSs, in which the nitro-functionalized NSs exhibited the highest activity. Since the nitro group is an electron-drawing group while other groups are electron-donating ones, the positive charge density around Cu atoms for the nitro-modified NSs was the highest, which was favorable for the binding of H$_2$O$_2$ as an electron donor.

It is also of note that several 2D NMIs were found to have multiple enzymatic activities. For example, Yang’s group found that the few-layer MoS$_2$ NSs prepared by liquid-exfoliation exhibited ternary activities (POD-, OD-, and CAT-like activities) (Chen T. M. et al., 2018). As discussed above, these enzymatic activities could be closely associated with specific reaction conditions especially system pH, in which the acidic conditions are usually favorable for POD/OD-mimic catalysis (Qi et al., 2016; Cai et al., 2017; Darabdhara et al., 2019; Feng et al., 2020), while a high pH is beneficial to CAT-catalysis (Liu Y. et al., 2014; Ruan et al., 2018; Wang et al., 2019). Due to the use of various 2D NMIs in biomedical fields, for a meaningful discussion of enzyme-like activity, the reaction parameters, nature of materials (e.g., morphology, structure, composition, and size), capping agents, and surface charge, are believed to be taken into account (Cai and Yang, 2020).

**BIOMEDICAL APPLICATIONS OF 2D NANOZYMES**

**Toxicology of 2D NMIs**

To access the full potential of 2D NMIs for practical applications, it is necessary to know their toxicity, including in vitro cellular uptake, location, toxicity, in vivo biodistribution, degradation, and excretion. However, to date, few studies have highlighted biocompatibility.

The in vitro biocompatibility of graphene-based materials, as the oldest and most studied 2D examples, was found to be highly related to their structural/compositional parameters and physicochemical properties, such as morphology, size, layer numbers, hydrophobicity/hydrophilicity, dispersion, and concentration (Ghosal and Sarkar, 2018). For example, hydrophobic and large-size graphene had higher cytotoxicity than hydrophilic and nanosized counterparts (Sukumar et al., 2020). Cui’s group found that the cytotoxicity of GO was affected by their concentration, in which the presence of GO with a low concentration (<10 µg mL$^{-1}$) slightly decreased the viability of human fibroblast cells (<20% when exposed for 4 days), but high concentrations of graphene (>50 µg mL$^{-1}$) showed obvious cytotoxicity even after only 1 day of exposure (>20%) (Wang et al., 2011). This was caused by the agglomerates of the physiological medium formed between GO layers via π - π interactions. Since the aggregated macroparticles could not enter into the cells, they became entrapped on the cell membrane and gave rise to cytoskeleton disruption, membrane deformation, and an increase in intercellular stress, ultimately resulting in cell death. In addition, Koyakutty’s group observed that the cytotoxicity of pristine graphene could be improved by carboxyl functionalization (Sasidharan et al., 2011). As the concentration of pristine graphene increased from 0 to 300 µg mL$^{-1}$, the viability of Vero cells decreased remarkably. A lower concentration of pristine graphene (100 µg mL$^{-1}$) resulted in
the death of appropriately 50% of cells, which further increased to about 60% at 300 µg mL⁻¹. Contrarily, the functionalized graphene showed negligible effects on the viability, even at the highest concentration studied. In another study by the same group, functionalized hydrophilic graphene was found to be favorable for macrophage cell (RAW 264.7) uptake (Sasidharan et al., 2012), distinct from the hydrophobic pristine graphene. The pristine graphene was primarily accommodated at the cell surface and induced ROS-mediated apoptosis when the concentration was above 50 µg mL⁻¹, which has not been found for functionalized graphene at a higher concentration of 75 µg mL⁻¹. Despite enhanced cytocompatibility by surface functionalization, all forms of graphene-based materials could lead to ROS generation in mammalian cells, which should be carefully taken into account for biomedical applications (Liao et al., 2011; Gollavelli and Ling, 2012).

In an earlier study on the in vivo biodegradability of graphene, Koyakutty's group revealed that time-bound spectral alternations using confocal Raman imaging, such as the formation of the defective D’ band, widening of D and G bands, and increase in ID/IG ratio of pristine graphene, embedded in different organs (e.g., lung, liver, kidney, and spleen of mice) over a time of 8–90 days (Girish et al., 2013). These observations arose from the increase in structural disorders in graphene phagocytosed by macrophages. The most enhanced amount of disorder, which was observed for the spleen bound samples, caused complete amorphization after 90 days of intravenous injection. In another study, after intravenous GO administration, the accumulation of GO was increased largely in the lung and liver for a longer time (Liu et al., 2012). GO NSs accumulated because of the possible instability and nonspecific binding of GO with different proteins. Since the blood initially flowed to the lung, more GO NSs were accumulated in the lung than other organs. Dash's group investigated the effect of GO and rGO on blood platelet functions (Singh et al., 2011). In this study, the GO sheet was found to cause strong aggregatory responses in platelets by activating a family of Src kinases, which further led to the release of calcium from intercellular compartments. Moreover, this study revealed that, due to charge distribution on the surface of GO NSs, the intravenous administration of GO in mice could trigger pulmonary thromboembolism. By contrast, rGO was unable to effectively activate platelets because of reduced charge density on the graphene surface.

The exploration of TMDs in biomedical areas began in 2013–2014. Similar to graphene-based materials, after surface modification, several members of TMDs also showed good in vitro biocompatibility. A relevant example is the WS₂ NSs prepared by Liu's group using the Li ions insertion method (Cheng et al., 2014). Without surface modification, the authors found that the WS₂ NSs exhibited obvious toxicity toward 4T1 (murine breast cancer cells), HeLa (human epithelial carcinoma cells), and 293T (human embryo kidney cells) after incubation for 24 h. At a high concentration of 0.1 mg mL⁻¹ of WS₂ NSs, only about 50% of cells were alive; however, after modification with PEG, the as-obtained NSs demonstrated no significant cytotoxicity under the same conditions. Contrarily, without surface functionalization, Zhao's group prepared the WS₂ NSs by H₂SO₄ intercalation and exfoliation in an aqueous solution, which showed low toxicity toward HeLa cells (Yong et al., 2014). The cell viability remained high (above 85%) even at a high concentration (0.2 mg mL⁻¹). The authors outlined that the biocompatibility of unmodified WS₂ NSs could be attributed to a mild aqueous phase in synthesis, in which the toxic organic solvents/chemicals were unnecessary. Using a similar method, Zhao's group prepared MoS₂ NSs, followed by coating with chitosan (Yin et al., 2014). Even at a high concentration up to 0.4 mg mL⁻¹, the as-obtained NSs demonstrated low cytotoxicity against KB (human epithelial carcinoma cell line) and Panc-1 (pancreatic carcinoma, epithelial-like cell line). The functionalized NSs also showed negligible hemolysis of red blood cells (RBCs), suggesting good blood compatibility. The above studies revealed that the in vitro toxicity of TMDs could be affected by synthetic methodology, surface chemistry, and specific cells. For the investigations on in vivo biocompatibility, Liu's group evaluated the toxicity of PEGylated WS₂ NSs (Cheng et al., 2014) toward Balb/c mice, by hematoxylin and eosin (H&E) assay, serum biochemistry assay, and complete blood panel test. In their study, no obvious abnormal behavior of mice at the dose of 20 mg kg⁻¹ was observed during the assay (45 days after photothermal therapy). In a similar study by the same group, the PEGylated MoS₂ NSs also demonstrated no obvious toxicity against Balb/c mice, at a relatively lower dose of 3.4 mg kg⁻¹ (Liu T. et al., 2014). However, to fully understand their potential toxicity/metabolism in longer terms, more studies are needed.

Compared to graphene-based materials and TMDs, the biocompatibility/biosafety of other 2D NMs especially Xenes, MXenes, and ultrathin metallic NSs, is less explored. Considering these structural and compositional differences, their solubility, biodegradation, and biocompatibility could be different from each other. Presently, the evaluations of in vitro/vivo biocompatibility of these materials are in progress (Wang S. G. et al., 2020). Despite the low toxicities of several types of 2D NMs [e.g., MnO₂ (Gao et al., 2020), g-C₃N₄ (Liang et al., 2017), and H-BN (Mateti et al., 2018)] exhibited in preliminary investigations, it is too soon to confirm the biosafety of 2D NMs at this stage. Thus, careful systematic tests on their toxicity are required before practical applications can be developed.

Biomedical Applications of 2D Nanozymes Biosensors
The accurate determination of biologically important analytes is of significance for clinical diagnosis. The colorimetric method, as an appealing one for point-of-care (POC) applications with many merits (e.g., low cost, simplicity, and practicality), has attracted considerable interest in biosensing (Song et al., 2011).

With good stability and adjustable catalytic activities, 2D NMs provide useful platforms for in vitro colorimetric detection. Recently, the assays for various bioanalytes like small molecules, cancer cells, and ions, have been proposed based on POD-like activities of 2D NMs (Table 2). As a typical example, the colorimetric assays for glucose have been largely developed based
on a host of 2D NMs and their hybrids, including graphene derivatives [e.g., GO (Song et al., 2010), FePd/rGO (Yang et al., 2019)], TMDSs [e.g., MoS$_2$ (Lin et al., 2014a), WS$_2$ (Lin et al., 2014b), WSe$_2$ (Chen T. M. et al., 2017), VS$_2$ (Huang et al., 2018)] and their hybrids [e.g., PtAg/MoS$_2$ (Cai et al., 2016), NiFe/LDHs (Zhan et al., 2018), and metallic NSs-based hybrids [e.g., Au/Pd (Cai et al., 2020) and Pt/Pd (Wei et al., 2015)]. Some of them showed excellent analytic performance (e.g., wide linear detection range, high sensitivity, and selectivity) for glucose detection and demonstrated practicality and superiority for real samples. However, it is noteworthy that these materials could only be employed to mimic PODs and that glucose oxidase (GOx) was required for detection, since it catalyzed the aerobic oxidation of glucose to generate H$_2$O$_2$. Intriguingly, Zhang’s group proposed a non-enzyme colorimetric assay for glucose based on GOXs- and the POD-like activities of Au/MOF, which catalyzed cascade reactions for detection (Huang et al., 2017a). The multifunctional enzymatic properties of

### TABLE 2 | Summary of several typical 2D nanozymes for colorimetric detection of various target analytes.

hybridized 2D NMs provide valuable opportunities to develop advanced biosensors.

By taking advantage of POD-/OD-like activity of 2D NMs, the colorimetric assays for other analytes like AA (Wang X. H. et al., 2017; Sun et al., 2020), biothiols [e.g., GSH (Liu et al., 2017; Ge et al., 2019; Liu X. L. et al., 2019), cysteine (Liu X. L. et al., 2019), and homocysteine (Liu X. L. et al., 2019)], xanthine (Cai et al., 2018b; Wu et al., 2018; Li et al., 2019), dopamine (Dutta et al., 2015; Ivanova et al., 2019), cholesterol (Zhang et al., 2017), acetylcholinesterase (Yan et al., 2017), cancer cells (Tao et al., 2013; Zhang L. N. et al., 2014; Qi et al., 2016), ions [e.g., S2− (Liu et al., 2020), Fe2+ (Wang et al., 2016), and Pb2+ (Tang et al., 2020)], have also been established by different groups. The colorimetric biosensing based on 2D nanozymes continues to be a rapidly growing field.

Antibacterial Agents

The POD-like activities of 2D NMs have gained ever-increasing interest in antibacterial applications. For example, Yang’s group prepared MoSe2 NSs by exfoliation of bulk MoSe2 powder in the aqueous solution of carboxyl-modified silk fibroin under sonication conditions (Huang X.-W. et al., 2017). In their study, a high concentration of H2O2 (100 mM) alone was required to eliminate most Gram-negative bacteria E. Coli, while only 100 μM H2O2 could display excellent antibacterial activity in the presence of MoSe2 NSs (50 μg mL−1). The effectiveness of a combination of MoSe2 NSs and H2O2 was further verified for disinfection and healing of Kunming mice with infected skin wounds. The study provided a type of TMD-based antibacterial agents with the usage of low-dose H2O2, which potentially avoid the harmful side effects of high-dose H2O2 in traditional medical therapy. Similarly, Yin’s group (Ma D. Q. et al., 2020) and Gu’s group (Wang T. et al., 2020) respectively reported good antibacterial efficacy of lysozyme-modified MoS2 NSs and N-doped MoS2 or WS2 NSs, against E. Coli and Gram-positive Bacillus subtilis. The POD-mimics catalyzed H2O2 decomposition to generate ·OH radicals, which promoted bacteria-infected wound healing. Several 2D hybrid NMs like Au/g-C3N4 (Wang Z. Z. et al., 2017) also showed potential in antibacterial agents.

Recently, Qu’s group constructed a self-activated cascade reagent based on GOx-adsorbed 2D Cu-TCPP(Fe) MOF NSs (Figure 2A), which was used together with glucose in the antibacterial system (Liu X. P. et al., 2019). The authors also created the wound model on the back of Kunming mice and prepared a MOF/GOX-band-aid for the in vivo bacterial study (Figure 2B). The principle was based on the consecutive reactions, in which GOX firstly catalyzed the oxidation of glucose to gluconic acid and H2O2, which was further catalytically decomposed into ·OH radicals by MOF NSs as a POD-mimic, thus leading to an antibacterial effect and ultimately, wound healing (Figure 2C). In the in vitro antibacterial investigation, the group (glucose + MOF/GOX) led to high bacteria inactivation rates, up to 88% and 90 % for E. Coli and S. aureus, respectively. By contrast, for the control groups including (1) PBS, (2) glucose, (3) glucose + MOF, and (4) MOF/GOX, the viabilities remained above 50% for the two bacteria. In the in vivo antibacterial study, the bacteria for the group (glucose + MOF/GOX-band-aid) were decreased to 9.1%; however, the bacteria for the control group (glucose + GOx-band-aid) were only decreased to 56.5%. These results showed high antibacterial activity of MOF/GOX. More interestingly, since H2O2 is an oxidant that was continuously produced by oxidation of glucose in the cascade catalysis, the study provided a benign antibacterial system to avoid the direct introduction of highly concentrated H2O2.

Antioxidants

2D NMs had important applications in antioxidants. Table 3 shows a summary of 2D nanozymes as antioxidants. Typical examples include GO NSs (Halim et al., 2019), Se NPs in situ grown on GO NSs (Huang et al., 2017b), and MoS2 NSs prepared by sonication-assisted exfoliation (Chen T. M. et al., 2018). In another example, the different TMDs (WS2, MoSe2, and WSe2) were functionalized with an amphiphilic poly(e-caprolactone)-b-PEG (PCL-b-PEG) diblock copolymer, which efficiently captured mitochondrial and intracellular ROS and reaction nitrogen species (RNS) like ·NO radicals, of which the WS2 NSs displayed the best performance (Yim et al., 2020). With effective scavenging of ROS and RNS as well as suppression of inflammatory cytokines of WS2 NSs, the survival rate of the septic mice remarkably increased to 90%.

Chen’s group found that the PVP-functionalized Nb3C NSs could greatly reduce ROS generation caused by ionizing radiation, thereby providing a kind of antioxidant based on 2D nanozymes for radioprotective applications (Ren et al., 2019). Wang’s group also demonstrated the potential of Se-modified g-C3N4 NSs against oxidative stress (Cao X. N. et al., 2020).

Therapeutics

A new hotspot in nanozyme research is the integration of enzymatic properties for therapy. Using an in situ growth strategy, Liu’s group fabricated Pt NPs decorated on the surface

of black phosphorus (BP) NSs, obtained by the liquid exfoliation method (Figure 3A) (Ouyang et al., 2018). The as-obtained BP NSs were freestanding with several hundred nanometers (Figure 3B), while the Pt NPs had an average size of approximately 4.2 nm (Figure 3C), with the crystal lattice fringe of 0.223 nm of (111) plane. The element distribution was further obtained from high-angle annular dark-field scanning TEM (HAADF-STEM) image (Figure 3D) and element maps (Figures 3E,F). The as-obtained Pt/BP nanocomposites integrated CAT-like activity of Pt NPs and photodynamic therapy (PDT) activity of BP NSs, in which the Pt NPs catalytically decomposed the accumulated H₂O₂ in tumors to relieve tumor hypoxia (Figure 3A). In the in vitro antitumor experiment, the BP NSs alone only reduced 26% of cell viability under near infrared (NIR) light irradiation, while about 65% of tumor cells were dead after the treatment of the Pt/BP. The result showed that the elevated O₂ level caused by CAT-catalysis of Pt NPs remarkably improved the PDT efficiency of BP NSs. Moreover, as a result of the Pt/BP treatment, the overexpression of hypoxia-inducible factor-1α (HIF-1α), which is associated with therapy resistance in tumor cells, was significantly down-regulated, since the intensity of fluorescence appeared on the tumor slices of mice was decreased by 64% in the immunohistochemical staining experiment. The down-regulation of HIF-1α by the Pt/BP decreased the tumor apoptotic resistance, which ultimately enhanced the therapeutic effect in the in vivo antitumor experiment, in which the growth of the tumor was completely regressed by the treatment of Pt/BP, while the treatment of BP NSs alone only led to a decline in about 47% of average tumor size.

By using a similar in situ growth method, Sun’s group synthesized Pt NPs coated 2D MOF, that is, Sm-modified tetrakis(4-carboxyphenyl)porphyrin (Sm-TCPP), which afforded a multifunctional nanozyme with excellent tumor specificity for enhanced PDT efficiency (Cao Z. G. et al., 2020). In their study, the Pt NPs acted as a CAT-mimic, catalyzing over-expressed H₂O₂ in a tumor microenvironment (TME) into O₂. The generated O₂ was further catalytically transformed to O¹O₂ by Sm-TCPP, owing to its high ROS generation capacity under light irradiation.

PROSPECT AND CHALLENGES

This review has undertaken a summary of recent progress in developing 2D NM with enzyme-like activities for diversified biomedical applications. The continuous advancement of nanoscience and nanotechnology in relation to 2D NM will offer great opportunities to develop new types of nanozymes with varied functionalities in the future. Meanwhile, the exploration of new biocatalytic properties and integration of enzymatic activities of 2D NM with other nanostructures like 0D NPs have potentially limitless applications in biomedical areas, and more fundamental technological breakthroughs in 2D nanozymes are expected in the near future.

Despite the many achievements that have been made in research on 2D nanozymes, studies on this field are still in the initial stages and future studies must address some challenges. Firstly, compared to 0D NPs with easy preparation, it is challenging to achieve the controlled synthesis of 2D NM with uniform thickness, desirable size, and colloidal stability. Despite great success in creating layered materials by the top-down methods, there are still some obvious shortcomings. A typical example is the synthesis of TMDs for biomedical applications, in which the liquid exfoliation and chemical intercalation methods were adopted in most studies. Although the former had a high yield with simple operations, the morphologies of the obtained products had a lack of uniformity, often involving a mixture of single and few-layer sheets with different lateral dimensions (Agarwal and Chatterjee, 2018). Despite the more uniform single-layer NSs created by the latter, it both brought structural and electronic deformations and involved toxic reagents. The chemical intercalation process was highly sensitive to the environment and time-consuming. Therefore, it is still desirable to develop an efficient method to prepare TMDs. Another example is the metallic NSs. Bearing lots of unsaturated atoms, the ultrathin metallic nanostructures are difficult to stabilize, because metal atoms readily form 3D close-packed crystals. Despite tremendous efforts in the synthesis of metallic NSs by bottom-up protocols, the formation mechanism in most reports was proposed based on a simple correlation between a few synthetic parameters and the final shape, in which several characterization techniques (e.g., TEM, XRD, etc.) were employed to identify reaction intermediates, were formed either at certain time intervals or in the control experiments (Chen Y. et al., 2018). However, there is not enough evidence relating to authentic reactive species during synthesis. Therefore, to better understand the formation process (e.g., nucleation, growth, and assembly) of metallic NSs for synthesis, it is essential to carry out
more in situ studies on the morphological evolution toward the 2D structure.

Secondly, despite the fascinating enzymatic properties of numerous 2D NMs, few studies on the in-depth catalytic mechanism are available. At present, it is still difficult to predict the nanozyme activity of 2D NMs for a specific structure. It is also difficult to achieve the best performance (e.g., activity and selectivity) for a specific application in biomedical areas, and hard to design the desired 2D nanozymes with optimal structures. Fundamentally, the missing link of structure-property relationship is largely because the enzyme-catalysis mechanism of 2D NMs remains unclear. For example, we must ask what the true active sites of 2D NMs and catalytically active intermediates during enzyme-catalysis are. In this regard, a deeper understanding of the catalytic mechanism of 2D nanozymes could benefit from in situ experimental studies and theoretical calculation by establishing appropriate models for catalysis, which are beneficial to the structural design of 2D nanozymes.

Thirdly, unlike 0D nanosystems, the biocompatibility and environmental stability of 2D NMs remains largely unknown, to date. Despite numerous studies on the biocompatibility of graphene-based NMs and TMDSs, evaluations of the toxicity of other types of 2D NMs are urgently required. The solubility, biodegradation, and biocompatibility of 2D NMs could be different from each other due to differences in their structure, composition, the methodology of synthesis and functionalization, and the cells studied. Therefore, it is hard to speculate whether a specific 2D NM is toxic or not. Their toxicity (both short-term and long-term), cellular-uptake mechanism, and the metabolic pathways of 2D NMs should be systematically tested for clinical trials.

Finally, it is acknowledged that many of the current applications of 2D nanozymes that display an outstanding performance are just proof-of-concept and have only been performed in laboratories. A number of reports fail to examine processability, scale-up possibility, and cost. The long-term stability and durability of 2D nanozymes are also less explored by researchers. Accordingly, there is still a long way to go before 2D nanozymes can be implemented in practical applications, which ultimately require interdisciplinary collaboration from chemistry, materials science, and biology.
