Highlights

- A soluble form of mouse Neuropilin1 (msNRP1) has been cloned in a lentiviral vector
- msNRP1 was successfully secreted by the transduced HEK293T in the supernatant
- msNRP1-containing supernatant inhibited growth cone collapse activity of Semaphorin 3A

Plain Language Summary

Multiple Sclerosis (MS) is an inflammatory disease of the central nervous system. In MS, axons of neuronal cells become demyelinated, and remyelination process is also defective. In fact, oligodendrocyte precursor cells must survive, proliferate, and migrate towards demyelinated neurons and differentiate into mature oligodendrocytes to produce myelin and repair the neurons. Semaphorin 3A (Sema 3A) is a molecule that reduce the remyelination by preventing oligodendrocyte precursor cells to proliferate, migrate towards lesions, and differentiate into mature oligodendrocyte.

We successfully produced mouse soluble Neuropilin 1 (msNRP1), that can bind Sema 3A and inhibit its activity. Then, the msNRP1 was used inhibit the activity of Sema 3A. Neural cells of dorsal root ganglia was cultured in presence of Sema 3A with and without msNRP1. We observed that when msNRP1 was added to the neuronal cells culture, the growth cones were able to form. On the other hand, the growth cones collapsed when msNRP1 was not added to the cultures.

This finding is important in terms of MS treatment. Remyelination is defective in MS patients, and axons are progressively demyelinated. Finding a molecule that can prevent demyelination and enhance remyelination will be of great importance for MS treatment and improvement of their condition.

Abstract

**Background:** Semaphorin 3A (Sema 3A) is a secreted protein, which plays an important part in the development of the nervous system. It has collapse activity on the growth cone of dorsal root ganglia. After the development of the nervous system, Sema 3A expression decreases. Neuropilin 1 is a membrane receptor of Sema 3A. When semaphorin binds to neuropilin 1, the recruitment of oligodendrocyte precursor cell to the demyelinated site decreases. In Multiple Sclerosis (MS), Sema 3A expression increases and inhibits
oligodendrocyte precursor cells differentiation. Therefore, remyelination of axons would be impaired. We hypothesized that function of Sema 3A can be inhibited by neutralizing its binding to membrane NRP1.

**Materials and methods:** we cloned a soluble form of mouse neuropilin 1 (msNRP1) in a lentiviral vector and expressed the recombinant protein in HEK293T cells. Then, the conditioned medium of the transduced cells was used to evaluate effects of the msNRP1 on the inhibition of Sema 3A-induced growth cone collapse activity. Dorsal root ganglion explants of timed pregnant (E13) mice were prepared. Then, growth cone collapse activity of Sema 3A was assessed in the presence and absence of msNRP1-containing conditioned media of transduced and non-transduced HEK293T cells. Comparisons between groups were performed by one-way ANOVA and Post Hoc Tukey tests.

**Results:** msNRP1 was successfully cloned and transduced in HEK293T cells. The supernatant of transduced cells was concentrated and evaluated for the production of msNRP1. ELISA results indicated that transduced cells secreted msNRP1. Growth cone collapse assay showed that Sema 3A activity was significantly reduced in the presence of the conditioned medium of msNRP1-transduced HEK293T cells. On the other hand, conditioned medium of non-transduced HEK293T cells could not effectively prevent Sema 3A growth cone collapse activity.

**Conclusion:** Our results indicated that msNRP1 was successfully produced in HEK293T cells. The secreted msNRP1 effectively prevented Sema 3A collapse activity. Therefore, it seems that msNRP1 can be used to increase remyelination in MS lesions although more studies using animal models are required.

**Keywords:** Multiple Sclerosis, Neuropilin-1, Semaphorin 3A, Remyelination

**Introduction**

The class 3 of Semaphorins (Sema 3s) are secreted proteins in vertebrates. There are seven members of semaphorins (Sema 3A - Sema 3G) which have pivotal roles in the nervous system development (Montolio et al., 2009). Semaphorin 3A (Sema 3A) is the prototype
of this class. It was isolated from chicken brain for the first time and named collapsin 1 since it had collapse activity on Dorsal Root Ganglion (DRG) growth cones (Luo, Raible, & Raper, 1993). Neurons of both the peripheral nervous system (PNS) and the central nervous system (CNS) express Sema 3A during the development of nervous system. Sema 3A becomes less abundant and more confined to particular regions of adults CNS. However, its expression increases in CNS conditions (De Winter et al., 2002; Good et al., 2004; Joyal et al., 2011; Körner et al., 2016) such as Multiple Sclerosis (MS) (Costa et al., 2015; Williams et al., 2007) as it was shown in animal models and human samples.

Multiple Sclerosis (MS) is an inflammatory demyelinating disease of CNS. To remyelinate axons in MS, oligodendrocyte precursor cells (OPCs) must survive, proliferate, and migrate to lesions and differentiate into mature oligodendrocytes that produce myelin (Reviewed by Franklin, 2008). Remyelination defects might exist at any step in this process. Sema 3A increases in grey matter neurons, astrocytes, and microglial cells that surround or reside in active inflammatory lesions both in MS patients and experimental models of demyelination (Williams et al., 2007). Researches have demonstrated that sema 3A inhibits the recruitment of oligodendrocyte precursor cell to the demyelinated site (Piaton et al., 2011). It also prevents the differentiation of OPCs to myelinating oligodendrocyte cells (Syed et al., 2011). On the other hand, Sema 3A disrupts the interaction of PP2A serine/threonine phosphatase and VE-cadherin in endothelial cells. This disruption can weaken tight junctions and increase vascular and thus Blood Brain Barrier (BBB) permeability (Le Guelte et al., 2012). Increased permeability of BBB facilitates the access of immune system components to CNS. This, in turn, results in disease severity and progression. Therefore, Sema 3A acts like Vascular Endothelial growth factor (VEGF) in MS pathology. Sema 3A signaling is mediated by two important molecules: (i) Neuropilin-1 as binding receptor and (ii) Plexins as signal transducing receptors.

Neuropilin-1 (NRP1) is a type-1 membrane glycoprotein. It also has four soluble forms in human (Cackowski, Xu, Hu, & Cheng, 2004; Rossignol, Gagnon, & Klagsbrun, 2000). The membrane form has a short cytoplasmic domain and an extracellular component. The former has no apparent signaling motif. The latter consists of a1/a2, b1/b2, and c domains. The a1/a2 domains bind to Sema 3, and the b1/b2 domains bind to Sema 3 and VEGF.
In transgenic mice, NRP-1 overexpression was shown to result in embryonic lethality, neuronal guidance defects, and vascular formation (Kitsukawa, Shimono, Kawakami, Kondoh, & Fujisawa, 1995). NRP-1 disruption in mice is also embryonic lethal due to defective neuronal patterning and inadequate vascularization (Kitsukawa et al., 1997). The soluble isoforms have conserved extracellular domains. These domains are ligand binding domains. However, c-domain, transmembrane, and intracellular domains are lacking. A mouse hepatic sNRP1 isoform has been cloned by Panigrahy and colleagues. Their experiments showed that this endogenous inhibitor of angiogenesis may regulate VEGF or Hepatocyte Growth Factor bioavailability during normal growth and development (Panigrahy et al., 2014). In addition, Gagnon et al studied human soluble s11NRP1. They showed that s11NRP1 antagonized VEGF binding and consequently induced apoptosis in tumor cells. Their data suggested that soluble NRP1 and membrane-bound NRP1 have opposite functions (Gagnon et al., 2000).

Gene therapy is one of the leading areas of multiple sclerosis research. A suitable protein for MS gene therapy should have two characteristics: (i) it should be able to induce axons remyelination by OPCs recruitment/differentiation (ii) it should be able to reduce BBB permeability in order to restrict immune system access to the CNS. Therefore, in the present study, we investigated the inhibition of Semaphorin 3A growth cone collapse activity by mouse soluble Neuropilin-1 in vitro.

Materials and Methods

1) Lentiviral vector construction

A murine soluble Neuropilin 1 (msNRP1)-expressing lentiviral vector (Lv-SFFV-msNRP1) was constructed based on the LeGO-iG2 plasmid (Weber, Bartsch, Stocking, & Fehse, 2008) from AddGene. The msNRP1-coding sequence fragment was reverse transcribed from total RNA extracted from C57BL/6 mouse liver tissue. Subsequently, specific forward (F:5' GCTGAATTCATGGAGAGGGCTGCCGTT 3') and reverse primers (R:5' AGCAGGCCTCAGATAAGTATGTGAGCCCTTGTGC 3') containing the restriction site for EcoR I and Stu I enzymes, were used to amplify the fragment. The
amplified DNA fragments were then purified from agarose gel and cloned into a pLeGO-iG2, downstream of the Spleen Focus Forming Virus (SFFV) promoter. The recombinant plasmid was verified using PCR-Sanger sequencing as well as restriction digestion analysis.

For lentiviral vector packaging, HEK293T cells were transfected with pLeGO-SFFV/msNRP1-IRES-EGFP or pLeGO-SFFV/IRES-EGFP (the control vector), psPAX2, and pMID2.G plasmids in presence of Lipofectamine 2000 (Thermo Fischer Scientific, USA). Forty-eight hours after transfection, culture medium containing lentiviral particles (Lv-SFFV-msNRP1 and Lv-SFFV-eGFP) were collected, passed through a 0.45 µm, and concentrated by ultracentrifugation at 82000 g for 2 hours.

2) Production of sNRP1 by HEK293T cells
To produce sNRP1 from the sNRP1-lentiviral vectors, HEK293T cells were plated on T75 flasks and cultured at 10⁴ cell/cm² density in complete DMEM (INOCLON, Iran) containing 10% FBS (Gibco, Thermo Fischer Scientific, USA), 1x PenStrep (INOCLON, Iran), and 25mM HEPES (INOCLON, Iran). At 50 to 60% confluence, the culture medium was replaced with fresh DMEM containing 5 µl/ml of concentrated Lv-SFFV-msNRP1 particles, 5% FBS, 8 µg/ml polybrene (Sigma-Aldrich, USA), and 25mM HEPES (INOCLON, Iran). In control flasks, the medium was supplemented with the Lv-SFFV-eGFP particles. Twenty-four hours after incubation of the cells, old medium was replaced with fresh DMEM containing 5% FBS and 25mM HEPES.

Every 24 hours, the supernatant of the transduced and non-transduced cells were collected for 72 hours and pooled after centrifugation at 800 g for 5 minutes. The molecular mass of the murine sNRP1 is estimated as 50-90 kDa (R Mamluk, Klagsbrun, Detmar, & Bielenberg, 2005). Therefore, supernatant samples were first concentrated on 50 kDa MWCO Amicon Ultra-15 devices (Merck Millipore, Germany) through 15 minutes centrifugation at 5000 g. Concentrated samples were then subjected to a second concentration step on 100 kDa MWCO Amicon Ultra-4 device (Merck Millipore, Germany) and centrifuged for 10 minutes at 5000 g. The total concentration factor was estimated at 20 times. The flow-through was aliquoted and kept at -20 °C.
The levels of concentrated and non-concentrated sNRPI secreted from HEK293T cells was measured using Mouse Neuropilin-1 PicoKine ™ ELISA Kit (Boster Biological Technology, China) according to the manufacturer's instructions. The differential absorbance reads of 450-570 nm on an automated Microplate Reader (BioTek Instruments, USA) analyzed with the Gen5 software (BioTek Instruments, USA) was used to measure sNRPI concentration.

3) Dorsal root ganglion explants culture

Dorsal root ganglion (DRG) explants were isolated and cultured according to the protocol described by Wang & Marquardt (Wang & Marquardt, 2012) with slight modifications. Briefly, DRGs were isolated from timed pregnant (E13) mice under the sterile condition and plated on pre-coated coverslips with poly L-lysine (Sigma-Aldrich, USA) (1 mg/ml) and laminin (Sigma-Aldrich, USA) (100 μg/ml). Explants were grown for 20 hours in a defined medium (DM), consisting of Neurobasal medium (Gibco, Thermo Fisher Scientific, USA) supplemented with 2mM L-Glutamine (INOCLON, Iran), 2x B-27 (Gibco, Thermo Fisher Scientific, USA), 1x PenStrep, and 10 ng/ml Nerve Growth Factor (NGF) (R&D systems, USA).

4) Growth cone collapse assay

To assess semaphorin 3A (Sema 3A) inhibition by sNRPI, five study groups were defined in which DRG explants were exposed to conditioned media (CM) supplemented or not with 100 ng/ml Sema 3A (R&D System, USA). Conditioned media was the concentrated cell culture supernatant (DMEM containing 5% FBS and 25mM HEPES) of transduced HEK293T, as previously mentioned, supplemented with 2mM L-Glutamine, 2x B-27, and 1x PenStrep.

To do so, DRG explants were first washed with pre-warmed PBS (INOCLON, Iran) and then incubated with a pre-warmed CM supplemented or not with 100 ng/ml Sema 3A for 30 min at 37°C. Incubation of DRG explants with the defined media (DM) (without NGF) contained or not 100 ng/ml Sema 3A (controls). Before adding to cultured DRG explants,
CMs and DMs were incubated for 30 min at 37°C in order to facilitate binding of Sema 3A to sNRP1. DRG explants were then stained with Alexa Fluor 488 phalloidin (Thermo Fischer Scientific, USA) for 4 hours at room temperature following fixation, permeabilization, and blocking according to the previously described method (Wang & Marquardt, 2012). Coverslips containing DRG were mounted using ProLong Gold antifade reagent (Thermo Fischer Scientific, USA).

5) Imaging and quantification

Fluorescent images were captured on an upright BX51 fluorescent microscope (Olympus, Japan) equipped with cell∧A Imaging software (Olympus, Japan). For the quantification of collapsed growth cones, 10 DRG explants from each experimental group in which at least 40 single identifiable growth cone per DRG had been analyzed, were scored as collapsed (growth cones without lamellipodia or with < 2 filopodia or bullet shaped) and non-collapsed (growth cones with the presence of lamellipodia and/or ≥ 2 filopodia) as described by Kapfhammer and colleagues (Kapfhammer, Xu, & Raper, 2007). Data are presented as the percentage of collapsed growth cones to the total number of scored growth cones per DRG.

6) Statistical analysis

Values were expressed as mean±standard error and comparisons were performed by one-way ANOVA and Post Hoc Tukey tests. P values < 0.05 were considered significant. All analyses were performed using the SPSS 22.0.

Results

1) Murine sNRP1 is secreted from Lv-SFFV-msNRP1 transduced HEK293 cells

Lentiviral vectors were used to engineer HEK293T cells for the continuous production of msNRP1. To transduce the cultured HEK293T, two recombinant lentiviral vectors expressing GFP (Lv-SFFV-eGFP) or GFP and murine sNRP1 (Lv-SFFV-msNRP1) were
used (figure 1A). Forty-eighth hours post-transduction, the transduced cells were monitored under a fluorescent microscope for the expression of GFP. As shown in figure 1B, approximately 70 percent of the transduced cells seemed to express GFP, compared to non-transduced cells. Transduction does not seem to affect the cell’s morphology when examined under phase contrast microscopy (figure 1B). In parallel, the amount of msNRP1 in the supernatant of the transduced and non-transduced HEK293T cells was measured. Unlike the non-transduced and Lv-SFFV-1eGFP-transduced cells from which no msNRP1 signal was detected, almost 100 ng/ml msNRP1 was detected in the supernatant of Lv-SFFV-msNRP1-transduced HEK293Ts (figure 1C). These data indicate that constructed Lv-SFFV-msNRP1 vectors successfully transduced HEK293T cells for the effective expression and secretion of murine sNRP1.
Figure 1: A) Lentiviral vectors used in this study. LeGO/msNRP1 (left) is the recombinant vector containing msNRP1 and GFP coding sequences. sNRP1 and GFP are connected by IRES sequence. Both coding
sequences are under the control of a single SFFV promoter. LeGO/EGFP (right) is the control vector, which contains only GFP coding sequence. B) HEK293T cells after transfection. HEK293T cells transduced with LeGO/msNRP1 (left), LeGO/EGFP(middle), and non-transduced cells (right). GFP expression (green) indicates that HEK293T cells were successfully transduced with the lentiviral vectors (left and middle). Non-transduced cells do not show GFP expression (right). C) msNRP1 concentration in the supernatant of transduced and non-transduced cells. ELISA results indicated that the supernatant of non-transduced cells and Lv-SFFV-1eGFP-transduced cells had no detectable msNRP1. The supernatant of Lv-SFFV-msNRP1-transduced cells contained nearly 100 ng/mL of msNRP1. ***: p< 0.001

2) sNRP1 is able to inhibit Sema 3A-induced growth cone collapse activity

To investigate sNRP1 capability of inhibiting the Sema 3A-induced growth cone collapse activity, dorsal root ganglion (DRG) explants from E13 mouse embryos were cultured and treated with Sema 3A, in the presence or absence of sNRP1. The study groups included DRGs treated with conditioned media from non-transduced and lentivirus vectors transduced HEK293T cells and defined media (with and without Sema 3A). Figure 2 shows fluorescent images of DRG explants stained with Alexa Fluor 488 conjugated phalloidin for the detection of collapsed growth cones. The treatment of DRG with Sema 3A-supplemented supernatant of non-transduced and Lv-SFFV-eGFP vector-transduced HEK293T cells caused a large number of growth cones to be collapsed. On the other hand, the incubation of DRG with CM from Lv-SFFV-msNRP1 vector-transduced HEK293T led to the collapse of few numbers of growth cones compared to the above-mentioned groups (Figure 2).
Figure 2. Growth cone collapse activity assay. A and E show DRGs treated with DM without Sema 3A and CM+Sema 3A, respectively. Growth cones are not collapsed since either Sema 3A was not added to DRGs (A) or msNRP1-containing CM inhibited Sema 3A binding to membrane NRP on DRGS. Arrowheads show the growth cones. B to D show DRGs treated with either Sema 3A-containing DM, Sema 3A-containing non-transduced cells’ CM, or Sema 3A-containing GFP-transduced cells’ CM, respectively. The number of collapsed growth cones in B-D is significantly higher than that of A and B since there was no msNRP1 in the media to inhibit Sema 3A activity. Arrows show the collapsed growth cones.

Quantification of collapsed growth cones revealed that the treatment of DRGs with Sema 3A in DM or with Sema 3A-free DM caused the growth cones to be collapsed up to 79% and 12%, respectively (figure 3, p < 0.001, compared to Sema 3A supplemented DM). Treatment of DRGs with Sema 3A-supplemented CM of non-transduced and Lv-SFFV-eGFP vector transduced HEK293T cells has led to a collapse of approximately 47% and 43% of growth cones, respectively, with no significant difference between these two groups, as expected (figure 3, p > 0.05). However, when cultured DRGs were treated with CM containing Sema 3A and msNRP1, 27.7% of growth cones were collapsed. There were significant differences between groups treated with CM of non-transduced (p < 0.01) or Lv-SFFV-eGFP vector transduced cells (p < 0.05) (figure 3). On the other hand, the difference in the collapse of growth cones between Lv-SFFV-msNRP1 vector transduced HEK293T CM and Sema 3A-free DM groups were not significant (p= 0.07). As a result, the present study suggests that endogenous sNRP1 protein in mice is able to inhibit collapse activity of Sema 3A in vitro.
Figure 3. Quantification of collapsed growth cones in the groups. Growth cone collapse was 12% in DRGs treated with DM without Sema 3A while 79% collapsed growth cones were observed when DRGs were treated with Sema 3A-containing DM (DM S3A). Treatment of the DRGs with the CM of non-transduced cells, LeGO/EGFP-Transduced cells, and LeGO/sNRP1-Transduced cells resulted in 47%, 43%, and 27.7% growth cone collapse, respectively. ***: p< 0.001, **: p<0.01, *: p< 0.05

Discussion

We cloned a soluble form of neuropilin 1 (sNRP1) containing a1/a1-b1/b2 domains. HEK293T cells were transduced with the lentivirus containing sNRP1. ELISA results showed that the sNRP1 was expressed in HEK293T cells. Conditioned medium of
transduced HEK293T cells was used to investigate if it can bind Sema 3A and inhibit Sema3A-induced growth cone collapse. The results showed that the conditioned medium containing sNRP1 could reduce growth cone collapse of Sema 3A.

Neuropilins are important receptors that participate in several signaling pathways including class III semaphorins and VEGF pathways (Chen, Chedotal, He, Goodman, & Tessier-Lavigne, 1997; Gluzman-Poltorak, Cohen, Herzog, & Neufeld, 2000; Kolodkin et al., 1997; R. Mamluk et al., 2002). NRPs are transmembrane ligand-binding receptors. When NRPs are bound with their ligand, they bind to their co-receptors which are responsible for signal transduction. One of these co-receptors is PLXN, which is recruited to NRPs when the ligand is Sema 3A (Soker, Miao, Nomi, Takashima, & Klagsbrun, 2002). Overall, NRPs play a part in various biological processes such as angiogenesis, tumor development, and neuronal guidance during nervous system development or its regeneration (reviewed in (Pasterkamp & Giger, 2009)).

Researchers have previously cloned and produced recombinant NRP or NRP inhibitors to prevent transmembrane NRP signal transduction. In 1999, Renzi and colleagues showed that antibodies against NRP1 could inhibit NRP1 downstream signaling (Renzi, Feiner, Koppel, & Raper, 1999). Regarding VEGF-NRP interaction, various studies have shown that natural soluble forms of NRP act as ligand-scavengers and antagonized VEGF in vivo (Gagnon et al., 2000; Rossignol et al., 2000). We used a simple yet functional approach to prevent Sema 3A inhibitory effects on growth cones. We cloned only the a1/a2-b1/b2 fragment, which is an alternatively spliced natural form of NRP. Then, HEK293T cells were transduced and the conditioned medium was concentrated. ELISA results on the conditioned medium confirmed the successful expression of the cloned fragment of NRP1 (soluble NRP1).

Other researchers have explored non-NRP compounds to inhibit Sema 3A-NRP1 interaction. Montolio and colleagues showed that SICHI peptoid could inhibit Sema 3A binding to NRP1 (M. Montolio et al., 2009). Cackowski et al, also found that two soluble forms of NRP1 (SIII NRP1 and SIV NRP1). They showed that these sNRP1s can antagonize Sema 3A- and VEGF-165-dependent cellular activities (Cackowski et al, 2004).
Studies show that membrane NRP1 is a receptor for Sema 3A. NRP1⁺ cells migrate in response to locally secreted Sema 3A. Dejda et al, showed that genetic ablation of NRP1 and therapeutics that trap NRP1 can reduce immune cell recruitment to lesion site and neovascularization in retinopathies (Dejda et al., 2014). In MS lesions, the level of Sema 3A increases, recruits, and activates NRP1⁺ cells to the lesion site, which ultimately results in the complications of MS (Williams et al., 2007). We hypothesized that collapse activity of Sema 3A can be inhibited by neutralizing its binding to membrane NRP1. Thus, we used a soluble form of NRP1 which competitively binds to Sema 3A and prevents it from binding to cell surface NRP1.

We demonstrated that NRP1-containing conditioned media could effectively bind Sema 3A and prevent growth cone collapse of DRGs.

In conclusion, our results suggest that soluble NRP1 can bind Sema 3A and inhibit Sema 3A-dependent NRP1 signaling. Therefore, sNRP1 is probably effective in neuronal remyelination in MS lesions. However, mouse models of MS are needed in order to evaluate effects of sNRP1 systemic administration.

**Ethical Considerations**

**Compliance with ethical guidelines**

All procedures of the study have been approved by Ethics Committee of Zanjan University of Medical Sciences, Zanjan, Iran (ZUMS.REC.1394.264), and have been confirmed to the provisions of the Declaration of Helsinki.

**Funding**

This work was financially supported by Cancer Gene Therapy Research Center, Zanjan University of Medical Sciences, Zanjan, Iran [grant number: A-12-65-8].

**Conflict of interest**

The authors declare that there is no conflict of interest.

**Acknowledgements**

The authors should also thank Dr. Tina Shahani for technical supports, and Dr. Vahid Kia for revising the English language of the manuscript.
