Autoimmune atrophic gastritis: current perspectives

Abstract: At present there is no universally accepted classification for gastritis. The first successful classification (The Sydney System) that is still commonly used by medical professionals was first introduced by Misiewicz et al in Sydney in 1990. In fact, it was the first detailed classification after the discovery of Helicobacter pylori by Warren and Marshall in 1982. In 1994, the Updated Sydney System was proposed during the International Workshop on the Histopathology of Gastritis followed by the publication in The American Journal of Surgical Pathology by Dixon et al. Using the new classification, distinction between atrophic and nonatrophic gastritis was revised, and the visual scale grading was incorporated. According to the Updated Sydney System Classification, atrophic gastritis is categorized into multifocal (H. pylori, environmental factors, specific diet) and corpus-predominant (autoimmune). Since metaplasia is a key histological characteristic in patients with atrophic gastritis, it has been recommended to use the word “metaplastic” in both variants of atrophic gastritis: autoimmune metaplastic atrophic gastritis (AMAG) and environmental metaplastic atrophic gastritis. Although there are many overlaps in the course of the disease and distinction between those two entities may be challenging, the aim of this review article was to describe the etiology, epidemiology, pathogenesis, diagnosis, clinical manifestations and treatment in patients with AMAG. However, it is important to mention that H. pylori is the most common etiologic factor for the development of gastritis in the world.

Keywords: autoimmune gastritis, pernicious anemia, gastric carcinoid

Epidemiology

The prevalence of pernicious anemia (PA; one of the distinctive manifestations of autoimmune metaplastic atrophic gastritis (AMAG)) is ~0.1% in the general population and ~2% in those older than 60 years.1 For many years, it was suggested that PA is the disease of elderly females of Northern European ethnicity. Subsequently, it was shown that the prevalence of PA is similar among all populations (white, African American and non-white Hispanic).2 Based on the analysis of the data from 156 patients affected by PA, in 1978, Carmel and Johnson3 concluded that black women develop PA at younger age than women of all other races (53±16 years, p<0.001). Similar to other autoimmune conditions, AMAG is more common in females than in males (3:1 ratio). Strong association between AMAG and other autoimmune disorders has been well documented.4 It is believed that AMAG and PA might be underdiagnosed in all parts of the world. One of the explanations could be the fact that almost all forms of micro- and macrocytic anemia are treated with iron, folic acid and cobalamin without further...
identifying the etiology of the anemia. Moreover, in many cases, biopsy samples of the gastric mucosa are inadequate or taken from the wrong location.5

Pathogenesis
The understanding of the pathogenesis of AMAG is somewhat challenging for several reasons: 1) the prevalence of AMAG is relatively low, 2) in many cases there is a concurrent Helicobacter pylori-induced gastritis and 3) no or minimal manifestations are present in early stages of the disease. Nevertheless, we know that both genetic and environmental factors play a role in the development of autoimmune gastritis. Using murine models, it was possible to discover autoimmune gastritis susceptibility genes (Gasa1, 2, 3 and 4) on chromosomes 4 and 6 and H2 region. Interestingly, three of these genes are located on the same locus as non-obese diabetic mouse diabetes mellitus (DM) susceptibility genes, which could explain the strong association between AMAG and DM type 1 (T1DM).6,7

Despite a lack of understanding of the complex stages of AMAG pathogenesis, histological changes have been well studied (Figures 1 and 2). The initial changes include infiltration of oxyntic mucosa by lymphocytes and plasma cells. The uneven destruction of parietal cells with preserved islands of relatively normal oxyntic mucosa leads to the appearance of “islands in the sea”. This phenomenon, also known as gastric pseudopolyposis, is similar to colonic lesions in patients with ulcerative colitis.8,9 Hypochlorhydria, or the decrease/loss of hydrochloric acid secretion, then develops as a result of the combination of two factors: 1) loss of oxyntic mucosa and 2) disruption of maturation of parietal cells.10 Absence of negative feedback from parietal cells induces G-cell hyperplasia and increased gastric secretion in the tantrum, which, in turn, leads to parietal cell pseudo hypertrophy resembling proton pump inhibitor-induced effects on parietal cells.11 It is worth mentioning that this phenomenon cannot develop in atrophic glands, since anti-parietal cell antibodies also bind selectively to H+/K+ ATPase.12 Another important effect of elevated gastric secretion is its direct stimulation and proliferation of enterochromaffin-like (ECL) cells, which depends on severity and can be hyperplastic, dysplastic and neoplastic.13 Progression of ECL cell hyperplasia to neoplastic subtype can result in carcinoid tumor formation, which will be described subsequently. Areas of metaplasia develop within gastric body and fundus: pseudopyloric, intestinal metaplasia (IM) and pancreatic. Pseudopyloric metaplasia (“oxyntic antralization”) develops in oxyntic glands from mucus-secreting cells phenotypically resembling antral mucous cells. Although histologically pseudopyloric metaplasia may be indistinguishable from antral gland cells, pepsinogen (PG) immunostaining can be helpful in differentiating: pepsinogen I (PG1) is characteristic of cells of oxyntic mucosa and is absent in the antrum.14 Recently, a new term to describe pseudopyloric metaplasia has been widely used: spasmolytic polypeptide-expressing metaplasia (SPEM). The etiology of SPEM is not clear. Several theories have been proposed: 1) longstanding inflammation of oxyntic mucosa, 2) acute direct effect of toxic substances on parietal cells (DMP-777)15,16 and 3) transdifferentiation of chief cells.17 Chief cells and SPEM express MAL2. This protein is involved in vesicle trafficking and considered the first trafficking protein, which is upregulated in SPEM.18 It has been shown that SPEM is a preneoplastic gastric lesion19 that can also transform into IM.20 IM is the replacement of glandular, foveolar and surface epithelium of gastric mucosa.
by intestinal epithelium. Depending on the histological features, two subtypes have been described: small intestinal and colonic. They, in turn, can be grouped into three types, type 1, or small intestinal, with brush border, “complete”, which are replaced fully by small intestinal epithelium with all types of cells (goblet, Paneth, etc), expresses syalomucins. Type 3, or colonic type, without brush border, “incomplete”, are metaplastic cells that are formed in the neighborhood of normal gastric cells, expresses sulfomucins. Type 2, or colonic type, without brush border, “incomplete”, where metaplasia is similar to Type 3, expresses both gastric and intestinal mucins. Apart from the abovementioned pathological changes, inflammatory and hyperplastic polyps develop in the later stages of AMAG. Oxynctic mucosa can be totally absent in advanced disease.

Association with H. pylori

It is a well-known fact that H. pylori can cause atrophic gastritis on its own. On the other hand, it is important to remember that in many cases patients with AMAG may have concurrent H. pylori infection. A third possible scenario is the progression of H. pylori-induced gastritis to AMAG. It is thought that etiology of this process is antigenic mimicry or cross-reactivity. Many patients with H. pylori develop a wide spectrum of antibodies, which includes antifoveolar, anticanalicular and the classic APCA. The most frequently detected antibodies are anticanalicular antibodies that, similar to APCA, are directed against H+/K+ ATPase (proton pump). Despite many overlaps in the course of the disease, it is important to differentiate AMAG from H. pylori-induced gastritis. AMAG affects only the body and fundus of the stomach, while H. pylori-induced lesions are known to have a multifocal pattern (Table 1). Other important factors that help differentiate between AMAG and H. pylori-induced gastritis are 1) ECL hyperplasia (more common in AMAG), 2) parietal cell pseudohypertrophy (in AMAG; can be seen in H. pylori infection secondary to proton pump inhibitor use) and 3) oxyntic gland involvement (more common in AMAG).

Additionally, inflammatory changes are quite distinctive in both of these conditions: lymphocytes and plasma cells infiltrating lamina propria with involvement of deep layers (AMAG), superficial band-like lesions with active inflammation (H. pylori-induced atrophic gastritis). Gastrin-17 (high in AMAG, low although may be elevated in H. pylori infection) and PGI levels (low in AMAG, normal in H. pylori infection) may also be utilized in patients at risk for gastric cancer (GC).28

| Table 1 | Comparison of AMAG with H. pylori-induced atrophic gastritis |
|---|---|---|
| Characteristics | Type of atrophic gastritis | |
| | Autoimmune metaplastic | H. pylori induced |
| Pattern of distribution | Corpus and fundus (antrum is spared) | Multifocal including antrum |
| ECL cell hyperplasia | Common | Rare |
| Parietal cell pseudohypertrophy | Common | Usually secondary to PPI use |
| Oxynctic gland involvement | Common | Rare |
| Inflammatory changes | Lymphocytes, plasma cells | Active inflammation, band-like lesions |
| Depth of inflammation | Lamina propria is usually involved | Superficial layers |
| Gastrin-17 level | High | Low but may be elevated |
| Pepsinogen I level | Low | Normal |
| Pepsinogen II level | Normal | Varies |
| Antibodies | Against parietal cells and intrinsic factor | Against H. pylori |
| Clinical manifestations | Asymptomatic or dyspepsia; symptoms of associated autoimmune conditions | Asymptomatic or dyspepsia |
| Risk of gastric neoplasms | Increased risk of gastric cancer and carcinoid | Increased risk of gastric cancer and carcinoid |

Abbreviations: AMAG, autoimmune metaplastic atrophic gastritis; H. pylori, Helicobacter pylori; ECL, enterochromaffin like; PPI, proton pump inhibitor.

Association with other autoimmune conditions

It has been well recognized that AMAG has tendency to occur more often in patients with other autoimmune conditions. Up to one-third of patients with autoimmune thyroid disease (AITD) and 6–10% of patients with T1DM have concurrent AMAG. Patients with polyglandular autoimmune (PGA) syndromes (especially PGA type 3B, which always includes AITD) are known to have a high prevalence of PA.22 The other autoimmune conditions that have been known to co-occur with AMAG (or its advanced form PA) are vitiligo, Addison’s disease, myasthenia gravis and perioral cutaneous autoimmune conditions (especially, erosive oral lichen planus).32–35

Familial cases of pernicious anemia (FPA) have been described including those in twins, suggesting genetic component of the disease. However, more studies need to be conducted to shed more light on how genetic variations predispose to the development of AMAG. Very rare cases...
of coexistence of two inherited disorders (FPA and hereditary hemochromatosis) have also been described in the literature.38

**Diagnosis**

In this section, we discuss the most common diagnostic tests used for screening and confirming a diagnosis of AMAG: serologic tests, endoscopy and histopathology.

**Serological tests**

The detection of target-specific antibodies has been well recognized as an effective method for screening and confirmation purposes. Among antibodies used for the diagnosis of AMAG, the following group is most widely used: APCA, anti-intrinsic factor antibodies (AIFAs) and anti-*H. pylori* antibodies (anti-HP-IgM and anti-HP-IgG). The significance of the measurement of anti-HP-antibodies is due to the frequent coexistence of *H. pylori*-induced gastritis and AMAG. APCA are known to have high sensitivity (~80%) but low specificity for PA.39 In contrast, AIFAs have been shown to be less sensitive (~50%) but more specific for PA.40 In patients with PA and negative AIFA, seroconversion may occur later in the course of the disease.41 Measurement of gastrin level (mainly Gastrin-17) is another diagnostic test that can be abnormal in patients with AMAG due to oxyntic gland atrophy, leading to elevated gastrin production by G-cells in the antrum. The combined assay of APCA, AIFA and anti-HP-antibodies along with the measurement of serum gastrin (Gastrin-17) are also known as “serological gastric biopsy”. It has been recognized to be effective for diagnostic purposes and highly correlates with the histological findings.42

The hypergastrinemia observed may be clinically difficult to differentiate from the other causes of hypergastrinemia. One method to identify the cause of hypergastrinemia is to measure the level of gastric acid output. With atrophic gastritis, the level of gastric acid output is low (<5 mEq/h), whereas with the hypergastrinemia associated with Zollinger-Ellison syndrome, the gastric acid output is >10 mEq/h. Furthermore, the secretin test is negative in >80% of patients.43 Another commonly overlooked cause of hypergastrinemia is gastric outlet obstruction and gastric dysmotility, which may require an upper endoscopy and radiological studies to be evaluated. With gastric dysmotility, the parietal cell complement will be either normal or increased.44 The measurement of PGI and PGII as well as PGI/PGII ratio can also be used to suspect AMAG. Specifically, PGI is secreted by the chief cells of oxyntic mucosa of gastric corpus and fundus, while PGII is produced by the chief cells and mucous neck cells of the entire gastric mucosa. Therefore, oxyntic atrophy is characteristic of AMAG, resulting in a decrease in PGI level along with low PGI/PGII ratio (<3).45 PGII level is mainly unaffected by atrophy of oxyntic mucosa.

Patients with laboratory confirmation of macrocytic anemia require serum vitamin B12 measurement. When high suspicion of PA is present, normal vitamin B12 level should be followed by homocysteine (HCys) and methylmalonic acid (MMA) measurements.46 However, it has also been shown that the serum levels of all three tests (vitamin B12, HCys and MMA) can fluctuate over time and even be normal in cobalamin-responsive disorders.47

The measurement of the plasma chromogranin A (CgA) level has been suggested for the diagnosis of AMAG, ECL hyperplasia and gastric carcinoids. CgA levels have been found to correlate well with the degree of ECL hyperplasia in patients with AMAG. In one study, the elevated CgA is thought to be associated with the development of non-alcoholic fatty liver disease (NAFLD) and is undergoing additional investigation.48 At the same time, the specificity of CgA level is too low (23%) to reveal gastric carcinoids in that group of patients.49

In other conditions, CgA can lead to false-positive results, including in inflammatory bowel diseases, hepatocellular carcinomas50 or other conditions such as with the chronic use of proton pump inhibitors or in renal insufficiency.

**Endoscopy**

In Western countries, endoscopic techniques for the diagnosis of AMAG have been used mainly for biopsy sampling purposes. The limitations related to endoscopy are the following: 1) low sensitivity, 2) low specificity and 3) interobserver variability.51 However, with the advent of novel endoscopic modalities (magnifying endoscopy, narrow-band imaging [NBI] and autofluorescence imaging [AFI]), it has become possible to detect minimal atrophic changes of the gastric mucosa.52 For instance, it has been shown that normal gastric corpus and fundus mucosal microvessels are characterized by the presence of 1) subepithelial capillary network (SECN) resembling honeycomb and 2) collecting venules in regular shape and appearance. In patients with atrophic gastritis, these normal findings are not seen.53 It is worth noting that none of the endoscopic findings should be used alone to make a diagnosis of atrophic gastritis. In fact, the combination of them (for example, vascular pattern and swelling of *areae gastricae*) can significantly improve diagnostic accuracy.54 As previously mentioned, in patients with high suspicion of atrophic gastritis, endoscopy has been used to get biopsy samples. According to the updated Sydney system recommendations.
five biopsy samples should be obtained: two from the corpus, two from the antrum and one from the incisura angularis.55

**Histopathology**

Biopsy with subsequent histology is considered the most reliable method for the diagnosis of metaplastic atrophic gastritis. Changes described in the “Pathogenesis” section may be seen. In some cases, when severe inflammation is present, it is hard to reliably evaluate oxyntic atrophy. Another limitation can happen when interpreting histological results from patients with early stages of AMAG. Several diagnostic hints have been suggested that may be characteristic of AMAG before profound loss of oxyntic mucosa: 1) infiltrates of lymphocytes and plasma cells in lamina propria, 2) focal atrophy of oxyntic mucosa along with SPEM or IM, 3) pseudohyper trophy of parietal cells and 4) ECL hyperplasia (at least, linear level).

Since ECL hyperplasia is the precursor of gastric carcinoid tumors, it is important to stain corpus and fundus samples with CgA and synaptophysin.56 Additionally, staining for gastrin (negative in case of corpus/fundus biopsy) can help in localizing the site of a biopsy sample.57

**Clinical manifestations**

The symptoms related to atrophic gastritis develop slowly and, in fact, may have a long asymptomatic period. In many cases, it is challenging to diagnose AMAG or its advanced form PA based only on clinical manifestations. The affected patients may present with a variety of signs and symptoms ranging from weakness to severe neurological manifestations such as paranoia (megaloblastic madness).58 That is why among medical professionals, PA is also known as a “great pretender”. In this article, we would like to categorize clinical manifestations into three major groups: hematological, neurological and gastrointestinal.

**Hematological manifestations**

Iron-deficiency anemia (IDA) is one of the earliest presentations of AMAG that develops due to achlorhydria from oxyntic atrophy. Several studies have shown that refractory or unexplained IDA should increase clinicians’ suspicion of AMAG not only in adults but also in pediatric population.59–61 PA is the most common cause of cobalamin deficiency.62 Although the underlying mechanisms of how cobalamin deficiency causes megaloblastosis have not been fully elucidated, it is believed that it is due to cobalamin’s essential role in DNA synthesis.63 The asymptomatic increase in mean corpuscular volume and hypersegmented neutrophils are usually the initial laboratory findings in PA. With progression of the disease patients may complain of the weakness, light-headedness and palpitations. In advanced stages, symptoms of angina and congestive heart failure (peripheral edema and shortness of breath) may manifest.64 Other very significant laboratory findings include thrombocytopenia, increased levels of LDH and bilirubin (signs of hemolysis). In rare cases, schistocytes in the peripheral smear may mimic other more serious conditions, such as disseminated intravascular coagulopathy (DIC) or thrombotic thrombocytopenic purpura/hemolytic uremic syndrome (TTP/HUS).65 Cobalamin deficiencies have been associated with increased risk of thrombosis likely as a result of hyperhomocysteinemia. Elevated levels of HCys cause endovascular dysfunction. This, in turn, activates the coagulation system, increases platelet aggregation and constricts vessels. Acute myocardial infarction and pulmonary embolism have been described in young patients with severe hyperhomocysteinemia secondary to PA.66,67

**Neurological manifestations**

Neurological manifestations of cobalamin deficiency have long been associated with demyelination followed by axonal damage and eventually neuronal death.68 The pathophysiological changes are not fully understood, however, MMA accumulation has been recognized to have direct impact on myelin formation and attributes to the myriad of neurological problems in patients with cobalamin deficiency.69 Interestingly, neurological symptoms associated with cobalamin deficiency may be present in the absence of hematological changes.70,71 Subacute combined degeneration (SCD) is one of the most prominent neurological manifestations of PA. Posterior and lateral columns of the cervical and upper thoracic segments of the spinal cord are involved. This results in sensory abnormalities (usually initial symptoms) such as loss of vibratory and position sensations along with distal paresthesias. In advanced stages, corticospinal tract can also be affected.72 Although in many situations, the neurological damage is irreversible, it is crucial to timely treat these patients with parenteral vitamin B12 in order to stop progression and improve neurological deficits.73 Peripheral neuropathy is another common neurological manifestation of PA. The initial symptoms include paresthesia and numbness of the lower extremities. In this regard, it can be very difficult to distinguish clinically between peripheral neuropathy and SCD.74 Both asymptomatic and overt optic neuropathy cases have been described in the medical literature.75

Neuropsychiatric conditions associated with PA include mania, depression, obsessive-compulsive disorder (OCD),...
psychosis and dementia. It is worth mentioning that the use of high dose of vitamins B12, B6 and folic acid has been shown to slow the shrinkage of the whole brain as well as reduce the cerebral atrophy in patients with Alzheimer’s disease (AD).

**Gastrointestinal manifestations**

Counterintuitively, AMAG rarely causes gastrointestinal symptoms. It has been suggested that this is due to the fact that most of the upper gastrointestinal-related complaints are secondary to increased level of hydrochloric acid. Hence, AMAG resulting in hypo- or even achlorhydria usually presents only with vague dyspeptic symptoms such as bloating, early satiety and epigastric discomfort. Atrophic glossitis, which usually presents as burning sensation of the tongue, has also been known as an early clinical manifestation of cobalamin deficiency.

**Neoplastic complications**

The incidence of gastric neoplasms is higher in patients with AMAG compared to the general population. Overall, AMAG has been associated with the development of two types of gastric neoplasms: intestinal type GC and type I gastric carcinoid (T1GC).

**Intestinal-type gastric cancer**

Two main factors that have been known to explain the occurrence of GC in AMAG patients are IM and concurrent *H. pylori* infection, which per se is the most common trigger of IM of the gastric mucosa. It should be pointed out that eradication of *H. pylori* in patients with known precancerous lesions (gastric atrophy, IM or gastric dysplasia) does not significantly lower the incidence of GC. The pathogenesis of the development of GC has been described by Correa and Piazuelo and is better known as “Correa cascade”. A simplified model of the cascade can be divided into following steps: 1) normal gastric mucosa, 2) nonatrophic gastritis, 3) multiple atrophic gastritis without (initially) and with (later) IM, 4) dysplasia progressing from low grade to high grade and 5) GC. It should be noted that AMAG without concurrent *H. pylori* infection is not considered to be part of the abovementioned cascade. Not all patients with *H. pylori*-induced gastritis develop GC. The chances are higher when certain virulence factors are present. For instance, CagA-positive strains of *H. pylori* have been shown to have significantly higher risk of the development of peptic ulcer and GC compared to CagA-negative strains. Another well-known virulence factor known to be associated with GC is VacA gene. Variations in this gene can be explained by the presence of signal (s) and middle (m) regions. Several studies have demonstrated the increased incidence of peptic ulcer and GC in patients infected with s1m1 compared to those infected with s2m2.

**Type I gastric carcinoid**

Although it has been recognized that AMAG is associated with increased risk of the development of T1GC, the exact incidence is not known. There are three known types of gastric carcinoids: type I is associated with AMAG, type II can be present in patients with multiple endocrine neoplasia (MEN) I and Zollinger-Ellison syndrome and type III, the most aggressive variant, usually occurs sporadically. Serum gastrin levels vary depending on the type of gastric carcinoid: types I and II – high, and type III – normal (Table 2). The pathologic changes in T1GC are initiated by the loss of negative feedback by parietal cells on gastrin secretion. Hypo-/achlorhydria subsequently results in hypergastrinemia which, in turn, has trophic effects on ECL cells. ECL hyperplasia followed by ECL dysplasia

| Parameters                  | Gastric carcinoid |
|-----------------------------|-------------------|
| Frequency                   | Type I    | Type II   | Type III  |
| Gender                      | 65–80%    | 5–6%      | 14–25%    |
| Age (years)                 | 40–60     | 45        | 50        |
| Associated conditions       | AMAG      | MEN1; ZES | None      |
| Endoscopic features         | Multiple, small| Similar to type I | Solitary, large, ulcerated |
| Affected areas              | Corpus and fundus | Similar to type I + antrum | Anywhere |
| Gastrin (level) had         | Increased  | Increased | N         |
| Management                  | Yes       | Yes       | No        |
| Risk of metastases to regional lymph nodes and liver | Very low | Low | High |

**Table 2 Comparison of different types of gastric carcinoids**

**Abbreviations:** AMAG, autoimmune metaplastic atrophic gastritis; MEN1, multiple endocrine neoplasia type 1; ZES, Zollinger-Ellison syndrome; ECL, enterochromaffin like; N, normal.
is considered precancerous lesions and over time can progress to T1GC. The detection of body polyps during endoscopy in patients with AMAG is strongly associated with the presence of T1GC. Patients with T1GC are usually asymptomatic, although symptoms of dyspepsia and IDA can be present. That is why the diagnosis is usually made during gastroscopy.

**Treatment**

The management strategies for AMAG and its advanced form PA depend on clinical manifestations, laboratory and imaging results. The therapy with the supplementation of iron, folic acid and cobalamin is commonly recommended in the early stages prior to progression to PA. Oral vitamin B12 supplement is used since it has been shown 1% of free vitamin B12 can be absorbed in the small intestine via passive diffusion. However, in patients with neurological manifestations, parenteral administration of vitamin B12 is currently recommended.

Given the fact that AMAG is highly associated with other autoimmune conditions, appropriate diagnostic investigation should be conducted especially for disorders such as autoimmune thyroiditis and T1DM.

Detection and subsequent treatment for *H. pylori* infection is another very important therapeutic strategy due to associated risks related to *H. pylori* coinfection. Since it has been confirmed by several studies that *H. pylori* infection can induce autoimmune process in the gastric lining including oxyntic mucosa, eradication of *H. pylori* can decrease the levels of antibodies associated with AMAG and has been proven effective to cure early stages of autoimmune gastritis.

T1GC has an excellent prognosis, therefore, different approaches have been suggested: surveillance, polypectomy and antrectomy (removal of gastrin-producing part of the stomach). One of the potential treatments for T1GC has been recently introduced. Netazepide, a gastrin receptor antagonist, has been shown to decrease the plasma level of CgA along with tumor number and size. Another treatment option is to consider using somatostatin analogs. In one prospective study in a population of 107 with chronic atrophic gastritis, the authors showed that the use of somatostatin analogs resulted in a reduction in median gastrin and CgA levels and thus should be considered as effective therapy.

A new and emerging form of therapy for the treatment of neuroendocrine tumors is the use of peptide receptor radiotherapy (PRRT), although these newer therapies have not been prospectively studied to date for autoimmune atrophic gastritis.

Clinical and Experimental Gastroenterology

Publish your work in this journal

Clinical and Experimental Gastroenterology is an international, peer-reviewed, open access, online journal publishing original research, reports, editorials, reviews and commentaries on all aspects of gastroenterology in the clinic and laboratory. This journal is included in PubMed. The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit http://www.dovepress.com/testimonials.php to read real quotes from published authors.
