Certifying 3-Edge-Connectivity

Kurt Mehlhorn  Adrian Neumann  Jens M. Schmidt

May 5, 2014

We present a certifying algorithm that tests graphs for 3-edge-connectivity; the algorithm works in linear time. If the input graph is not 3-edge-connected, the algorithm returns a 2-edge-cut. If it is 3-edge-connected, it returns a construction sequence that constructs the input graph from the graph with two vertices and three parallel edges using only operations that (obviously) preserve 3-edge-connectivity.

Additionally, we show how compute and certify the 3-edge-connected components and a cactus representation of the 2-cuts in linear time. For 3-vertex-connectivity, we show how to compute the 3-vertex-connected components of a 2-connected graph.

1. Introduction

Advanced graph algorithms answer complex yes-no questions such as “Is this graph planar?” or “Is this graph k-vertex-connected?” These algorithms are not only nontrivial to implement, it is also difficult to test their implementations extensively, as usually only small test sets are available. It is hence possible that bugs persist unrecognized for a long time. An example is the implementation of the linear time planarity test of Hopcroft and Tarjan [10] in LEDA [18]. A bug in the implementation was discovered only after two years of intensive use.

Certifying algorithms [16] approach this problem by computing an additional certificate that proves the correctness of the answer. This may, e.g., be either a 2-coloring or an odd cycle for testing bipartiteness, or either a planar embedding or a Kuratowski subgraph for testing planarity. Certifying algorithms are designed such that checking the correctness of the certificate is substantially simpler than solving the original problem. Ideally, checking the correctness is so simple that the implementation of the checking routine allows for a formal verification. In that case, the solution of every instance is correct by a formal proof [1].

Our main result is a linear time certifying algorithm for 3-edge-connectivity based on a result of Mader [15]. He showed that every 3-edge-connected graph can be obtained from $K^2_3$, the graph consisting of two vertices and three parallel edges, by a sequence of three simple operations that each introduce one edge and, trivially, preserve 3-edge-connectivity. We show how to compute such a sequence in linear time for 3-edge-connected graphs. If the input graph is not 3-edge-connected, a 2-edge-cut is computed. The previous algorithms [8,19,27,29] for deciding 3-edge-connectivity are not certifying; they deliver a 2-edge-cut for graphs that are not 3-edge-connected but no certificate in the yes-case.
Our algorithm uses the concept of a chain decomposition of a graph introduced in \cite{24}. A chain decomposition is a special ear decomposition \cite{14}. It is used in \cite{26} as a common and simple framework for certifying 1- and 2-vertex, as well as 2-edge-connectivity. Further, \cite{25} uses them for certifying 3-vertex-connectivity. Chain decompositions are an example of path-based algorithms (see, e.g., Gabow \cite{7}), which use only the simple structure of certain paths in a DFS-tree to compute connectivity information about the graph.

We use chain decompositions to certify 3-edge-connectivity in linear time. Thus, chain decompositions form a common framework for certifying \(k\)-vertex- and \(k\)-edge-connectivity for \(k \leq 3\) in linear time. We use many techniques from \cite{25}, but in a simpler form. Hence our paper may also be used as a gentle introduction to the 3-vertex-connectivity algorithm in \cite{25}.

We state Mader’s result in Section 3 and introduce chain decompositions in Section 4. In Section 5 we show that chain decompositions can be used as a basis for Mader’s construction. This immediately leads to an \(O((m+n)\log(m+n))\) certifying algorithm (Section 6). The linear time algorithm is then presented in Sections 7 and 8. In Section 9 we discuss the verification of Mader construction sequences.

The mincuts in a graph can be represented succinctly by a cactus representation \cite{5,6,20}; see Section 10. The 3-edge-connected components of a graph are the maximal subsets of the vertex set such that any two vertices in the subset are connected by three edge-disjoint paths.

Our algorithm can be used to turn any algorithm for computing 3-edge-connected components into a certifying algorithm for computing 3-edge-connected components and the cactus representation of 2-cuts (Section 10). An extension of our algorithm computes the 3-edge-connected components and the cactus representation directly (Section 11). A similar technique can be used to extend the 3-vertex-connectivity algorithm in \cite{25} to an algorithm for computing 3-vertex-connected components.

2. Related Work

Deciding 3-edge-connectivity is a well researched problem, with applications in diverse fields such as bioinformatics \cite{4} and quantum chemistry \cite{3}. Consequently, there are many different linear time solutions known \cite{8,19,20,27,29}. None of them is certifying. All but the first algorithm also compute the 3-edge-connected components. The cactus representation of a 2-edge-connected, but not 3-edge-connected graph \(G\), can be obtained from \(G\) by repeatedly contracting the 3-edge-connected components to single vertices \cite{20}.

The paper \cite{16} is a recent survey on certifying algorithms. For a linear time certifying algorithm for 3-vertex-connectivity, see \cite{25} (implemented in \cite{21}). For general \(k\), there is a randomized certifying algorithm for \(k\)-vertex connectivity in \cite{13} with expected running time \(O(kn^{2.5} + nk^{3.5})\). There is a non-certifying algorithm \cite{12} for deciding \(k\)-edge-connectivity in time \(O(m\log^3 n)\) with high probability.

In \cite{8}, a linear time algorithm is described that transforms a graph \(G\) into a graph \(G'\) such that \(G\) is 3-edge-connected if and only if \(G'\) is 3-vertex-connected. Combined with this transformation, the certifying 3-vertex-connectivity algorithm from \cite{25} certifies 3-edge-connectivity in linear time. However, that algorithm is much more complex than the algorithm given here. Moreover, we were unable to find an elegant method for transforming the certificate obtained for the
3-vertex-connectivity of $G'$ into a certificate for 3-edge-connectivity of $G$.

3. Preliminaries

We consider finite undirected graphs $G$ with $n = |V(G)|$ vertices, $m = |E(G)|$ edges, no self-loops, and minimum degree three, and use standard graph-theoretic terminology from [2], unless stated otherwise. We use $uv$ to denote an edge with endpoints $u$ and $v$.

A set of edges that leaves a disconnected graph upon deletion is called edge cut. For $k \geq 1$, let a graph $G$ be $k$-edge-connected if $n \geq 2$ and there is no edge cut $X \subseteq E(G)$ with $|X| < k$. Let $v \rightarrow_G w$ denote a path $P$ between two vertices $v$ and $w$ in $G$ and let $s(P) = v$ and $t(P) = w$ be the source and target vertex of $P$, respectively (as $G$ is undirected, the direction of $P$ is given by $s(P)$ and $t(P)$). Every vertex in $P \setminus \{s(P), t(P)\}$ is called an inner vertex of $P$ and every vertex in $P$ is said to lie on $P$.

Let $T$ be an undirected tree rooted at vertex $r$. For two vertices $x$ and $y$ in $T$, let $x$ be an ancestor of $y$ and $y$ be a descendant of $x$ if $x \in V(r \rightarrow_T y)$. If additionally $x \neq y$, $x$ is a proper ancestor and $y$ is a proper descendant. We write $x \leq y$ ($x < y$) if $x$ is an ancestor (proper ancestor) of $y$. The parent $p(v)$ of a vertex $v$ is its immediate proper ancestor. The parent function is undefined for $r$. Let $K_m^2$ be the graph on 2 vertices that contains exactly $m$ parallel edges.

Let subdividing an edge $uv$ of a graph $G$ be the operation that replaces $uv$ with a path $uzv$, where $z$ was not previously in $G$. All 3-edge-connected graphs can be constructed using a small set of operations starting from a $K_3^2$.

![Figure 1: Two ways of constructing the 3-edge-connected graph shown in the rightmost column. The upper row shows the construction according to Theorem 1. The lower row shows the construction according to Corollary 1. Branch (non-branch) vertices are depicted as filled (non-filled) circles. The black edges exist already, while dotted gray vertices and edges do not exist yet.](image)

**Theorem 1 (Mader [15])** Every 3-edge-connected graph (and no other graph) can be constructed from a $K_3^2$ using the following three operations:

- Adding an edge (possibly parallel or a loop).
- Subdividing an edge $xy$ and connecting the new vertex to any existing vertex.
- Subdividing two distinct edges $wx, yz$ and connecting the two new vertices.

A subdivision $G'$ of a graph $G$ is a graph obtained by subdividing edges of $G$ zero or more times. The branch vertices of a subdivision are the vertices with degree at least three (we call
the other vertices non-branch-vertices) and the links of a subdivision are the maximal paths whose inner vertices have degree two. If \( G \) has no vertex of degree two, the links of \( G' \) are in one-to-one correspondence to the edges of \( G \). Theorem 1 readily generalizes to subdivisions of 3-edge-connected graphs.

**Corollary 1** Every subdivision of a 3-edge-connected graph (and no other graph) can be constructed from a subdivision of a \( K_3^2 \) using the following three operations:

- Adding a path connecting two branch vertices.
- Adding a path connecting a branch vertex and a non-branch vertex.
- Adding a path connecting two non-branch vertices lying on distinct links.

In all three cases, the inner vertices of the path added are new vertices.

Each path that is added to a graph \( H \) in the process of Corollary 1 is called a Mader-path (with respect to \( H \)). Note that an ear is always a Mader-path unless both endpoints lie on the same link.

Figure 1 shows two constructions of a 3-edge-connected graph, one according to Theorem 1 and one according to Corollary 1. In this paper, we show how to find the Mader construction sequence according to Corollary 1 for a 3-edge-connected graph in linear time. Such a construction is readily turned into one according to Theorem 1.

4. Chain Decompositions

We use a very simple decomposition of graphs into cycles and paths. The decomposition was previously used for linear-time tests of 2-vertex- and 2-edge-connectivity [26] and 3-vertex-connectivity [25]. In this paper we show that it can also be used to find Mader’s construction for a 3-edge-connected graph. We define the decomposition algorithmically; a similar procedure that serves for the computation of low-points can be found in [23].

Let \( G \) be a connected graph without self-loops and let \( T \) be a depth-first search tree of \( G \). Let \( r \) be the root of \( T \). We orient tree-edges \( uv \) up, i.e., towards the root such that \( v < u \), and back-edges \( xy \) down, that is, such that \( x < y \).

We define the decomposition of \( G \) into a set \( \mathcal{C} = \{C_1, \ldots, C_{|E|}\} \) of cycles and paths, called *chains*, by applying the following procedure for each vertex \( v \) in the order in which they were discovered during the DFS.

First, we declare \( v \) visited. Then, for every back-edge \( vw \) with \( s(vw) = v \), we traverse the path \( w \rightarrow r \) until a vertex \( x \) is encountered that was visited before; \( x \) is a descendant of \( v \). The traversed subgraph \( vw \cup (w \rightarrow r x) \) forms a new chain \( C \) with \( s(C) = v \) and \( t(C) = x \). All inner vertices of \( C \) are declared visited. Observe that \( s(C) \) and \( t(C) \) are already visited when the construction of the chain starts.

Figure 2 illustrates these definitions. Since every back-edge defines one chain, there are precisely \( m - n + 1 \) chains. We number the chains in the order of their construction.

We call \( \mathcal{C} \) a chain decomposition. It can be computed in time \( O(n + m) \). For 2-edge-connected graphs the term decomposition is justified by Lemma 1.

---

1. If \( G \) is not 2-edge-connected, there will be edges and maybe vertices not belonging to any chain.
2. Initially, no vertex is visited.
Figure 2: The left side of the figure shows a DFS tree with a chain decomposition; tree-edges are solid and back-edges are dashed. $C_1$ is (16,65,54,43,32,21), $C_2$ is (17,76), $C_3$ is (24), $C_4$ is (37), and $C_5$ is (45). $C_3$ and $C_5$ are nested children of $C_1$ and $C_4$ is an interlacing child of $C_2$. Also, $s(C_4)$ s-belongs to $C_1$.

In the algorithm of Sect. 8, we start with $G_c = C_1 \cup C_2$. In the first phase, we form three segments, namely $\{C_4\}$, $\{C_3\}$, and $\{C_5\}$. The first segment can be added according to Lemma 4. Then $C_3$ can be added and then $C_5$.

Lemma 1 ([26]) Let $\mathcal{C}$ be a chain decomposition of a graph $G$. Then $G$ is 2-edge-connected if and only if $G$ is connected and the chains in $\mathcal{C}$ partition $E(G)$.

Since the condition of Lemma 1 is easily checked during the chain decomposition, we assume from now on that $G$ is 2-edge-connected. Then $\mathcal{C}$ partitions $E(G)$ and the first chain $C_1$ is a cycle containing $r$ (since there is a back-edge incident to $r$). We say that $r$ strongly belongs ($s$-belongs) to the first chain and any vertex $v \neq r$ $s$-belongs to the chain containing the edge $v p(v)$. We use s-belongs instead of belongs since a vertex can belong to many chains when chains are viewed as sets of vertices.

We can now define a parent-tree on chains. The first chain $C_1$ is the root. For any chain $C_i$, $i \geq 2$, has a parent chain $p(C_i)$. We have $s(p(C_i)) \leq s(C_i)$ and $p(C_i) = C_j$ for some $j < i$.

Lemma 2 Let $\{C_1, \ldots, C_{m-n+1}\}$ be a chain decomposition of a 2-edge-connected graph $G$ and let $r$ be the root of the DFS-tree. Then

1. For every chain $C_i$, $i \geq 2$, has a parent chain $p(C_i)$.
2. We have $s(p(C_i)) \leq s(C_i)$ and $p(C_i) = C_j$ for some $j < i$.
3. If $t(C_i) \neq r$, $t(p(C_i)) < t(C_i)$. If $t(C_i) = r$, $t(p(C_i)) = t(C_i)$.
4. If $u \leq v$, $u$ $s$-belongs to $C$, and $v$ $s$-belongs to $D$ then $C \leq D$.
5. If $u \leq t(D)$ and $u$ $s$-belongs to $C$, then $C \leq D$.
6. For $i \geq 2$, $s(C_i)$ $s$-belongs to a chain $C_j$ with $j < i$.

Proof: (1) to (5) follow from the discussion preceding the Lemma and the construction of the chains. We turn to (6). Consider two vertices $u$ and $v$ with $u \leq v$ and let $u$ $s$-belong to $C$ and let $v$ $s$-belong to $D$. Then $C \leq D$, as the following simple induction on the length of the tree path from $u$ to $v$ shows. If $u = v$, $C = D$ by the definition of $s$-belongs. So assume $u$ is a proper ancestor of...
v. Since v s-belongs to D, by definition v ≠ t(D) and v p(v) is contained in D. Let D' be the chain to which p(v) s-belongs. By induction hypothesis, C ≤ D'. Also, either D = D' (if p(v) s-belongs to D) or D' = p(D) (if p(v) = t(D)) and hence p(v) s-belongs to p(D). In either case C ≤ D.

Claim (5) is an easy consequence of (4). If t(D) = r, C = C_1, and the claim follows. If t(D) ≠ r, t(D) s-belongs to p(D). Thus, C ≤ p(D) by (4).

The final claim is certainly true for each C_i with s(C_i) = r. So assume s(C_i) > r and let y = p(s(C_i)). Since G is 2-edge-connected, there is a back-edge uv with u ≤ y and s(C_i) ≤ v. It induces a chain C_k with k < i and hence s(C_i)y is contained in a chain C_j with j ≤ k.

5. Chains as Mader-paths

We show that, assuming that the input graph is 3-edge-connected, there are two chains that form a subdivision of a $K^3_2$, and that the other chains of the chain decomposition can be added one by one such that each chain is a Mader-path with respect to the union of the previously added chains. We will also show that chains can be added parent-first, i.e., when a chain is added, its parent was already added. In this way the current graph $G_c$ consisting of the already added chains is always parent-closed. We will later show how to compute this ordering efficiently. We will first give an $O((n + m) \log(n + m))$ algorithm and then a linear time algorithm.

We assume that the input graph is 2-edge-connected. This is easily checked using Lemma 1. This guarantees that the chain decomposition is a partition of the edge set of the input graph. We will also use the following necessary condition for 3-edge-connectivity.

**Proposition 1** Let T be a DFS tree with root r for a graph G. If G is 3-edge-connected, then the subtree of every child of r must be connected to r by at least two back-edges.

**Proof:** A subtree connected by at most one back-edge gives rise to a 2-edge-cut consisting of a tree-edge and a back-edge. □

Using the chain decomposition, we can identify a $K^3_2$ subdivision in the graph as follows. We may assume that the first two back-edges explored from r in the DFS have their other endpoint in the same subtree $T'$ rooted at some child of r. The first chain $C_1$ forms a cycle. The vertices in $C_1 \setminus r$ are then contained in $T'$. By assumption, the second chain is constructed by another back-edge that connects r with a vertex in $T'$. If there is no such back-edge, Proposition 1 exhibits a 2-edge-cut, namely the tree-edge and the back-edge connecting r and $T'$. Let $x = t(C_2)$. Then $C_1 \cup C_2$ forms a $K^3_2$ subdivision with branch vertices r and x. The next lemma derives properties of parent-closed unions of chains.

**Lemma 3** Let $G_c$ be a parent-closed union of chains that contains $C_1$ and $C_2$. Then

1. For any vertex v ≠ r of $G_c$, the edge v p(v) is contained in $G_c$, i.e., the set of vertices of $G_c$ is a parent-closed subset of the DFS-tree.

2. s(C) and t(C) are branch vertices of $G_c$ for every chain C contained in $G_c$. □
(3) Let $C$ be a chain that is not in $G_c$ but a child of some chain in $G_c$. Then $C$ is an ear with respect to $G_c$ and the path $t(C) \to_T s(C)$ is contained in $G_c$. $C$ is a Mader-path (i.e., the endpoints of $C$ are not inner vertices of the same link of $G_c$) with respect to $G_c$ if and only if there is a branch vertex on $t(C) \to_T s(C)$.

**Proof:** (1): Let $v \neq r$ be any vertex of $G_c$. Let $C$ be a chain in $G_c$ containing the vertex $v$. If $C$ also contains $v p(v)$ we are done. Otherwise, $v = t(C)$ or $v = s(C)$. In the first case, $v$ s-belongs to $p(C)$, in the second case $v$ s-belongs to some $C' \subseteq C$ by Lemma 2[4]. Hence, by parent-closedness, $v p(v)$ is an edge of $G_c$.

(2): Let $C$ be any chain in $G_c$. Since $C_1$ and $C_2$ form a $K^3_{1,1}$, $r$ and $x = t(C_2)$ are branch vertices. If $s(C) \neq r$, the edge $s(C) p(s(C))$ is in $G_c$ by (1), the back-edge $s(C) v$ inducing $C$ is in $G_c$, and the path $v \to_T s(C)$ is in $G_c$ by (1). Thus $s(C)$ has degree at least three. If $t(C) \neq [r, x]$, let $\hat{C}$ be the chain to which $t(C)$ s-belongs, i.e. $\hat{C}$ is the parent of $C$. As $G_c$ is parent-closed $\hat{C}$ is contained in $G_c$. By the definition of s-belongs, $t(C)$ has degree two on the chain $\hat{C}$. Further, it has degree one on the chain $C$. Since chains are edge-disjoint, it has degree at least three in $G_c$.

(3) We first observe that $t(C)$ and $s(C)$ belong to $G_c$. For $t(C)$, this holds since $t(C)$ s-belongs to $p(C)$ and $p(C)$ is part of $G_c$ by assumption. For $s(C)$, this follows from $s(C) \subseteq t(C)$ and (1). No inner vertex $u$ of $C$ belongs to $G_c$, because otherwise the edge $u p(u)$ would belong to $G_c$ by (1), which implies that $C$ would belong to $G_c$, as $G_c$ is a union of chains. Thus $C$ is an ear with respect to $G_c$, i.e., it is disjoint from $G_c$ except for its endpoints. Moreover, the path $t(C) \to_T s(C)$ belongs to $G_c$ by (1).

If there is no branch vertex on $t(C) \to_T s(C)$, the vertices $t(C)$ and $s(C)$ are inner vertices of the same link of $G_c$ and hence $C$ is not a Mader-path with respect to $G_c$. If there is a branch vertex on $t(C) \to_T s(C)$, the vertices $t(C)$ and $s(C)$ are inner vertices of two distinct links of $G_c$ and hence $C$ is a Mader-path with respect to $G_c$. \hfill \Box

We can now prove that chains can always be added in parent-first order.

**Theorem 2** Let $G$ graph and let $G_c$ be a parent-closed union of chains such that no child of a chain $C \subseteq G_c$ is a Mader-path with respect to $G_c$ and there is at least one such chain. Then the extremal edges of every link of length at least two in $G_c$ are a 2-cut in $G$.

**Proof:** Assume otherwise. Then there is a parent-closed union $G_c$ of chains such that no child of a chain in $G_c$ is a Mader-path with respect to $G_c$ and there is at least one such child outside of $G_c$, but for every link in $G_c$ the extremal edges are not a cut in $G$.

Consider any link $L$ of $G_c$. Since the extremal edges of $L$ do not form a 2-cut, there is a path in $G - G_c$ connecting an inner vertex on $L$ with a vertex that is either a branch vertex of $G_c$ or a vertex on a link of $G_c$ different from $L$. Let $P$ be such a path of minimum length. By minimality, no inner vertex of $P$ belongs to $G_c$. Note that $P$ is a Mader-path with respect to $G_c$. We will show that at least one edge of $P$ belongs to a chain $C$ with $p(C) \in G_c$ and that $C$ can be added, contradicting our choice of $G_c$.

Let $a$ and $b$ be the endpoints of $P$, let $z$ be the lowest common ancestor of all points in $P$. Since a DFS generates only tree- and back-edges, $z$ lies on $P$. Since $z \leq x$ for all $x \in P$, no inner vertex of $P$ belongs to $G_c$, and the vertex set of $G_c$ is a parent-closed subset of the DFS-tree, $z$ is equal to
a or b. Assume w.l.o.g. that $z = a$. All vertices of $P$ are descendants of $a$. We view $P$ as oriented from $a$ to $b$.

Since $b$ is a vertex of $G_c$, the path $b \rightarrow_T a$ is part of $G_c$ by Lemma 2 and hence no inner vertex of $P$ lies on this path. Let $av$ be the first edge on $P$. The vertex $v$ must be a descendant of $b$ as otherwise the path $v \rightarrow_P b$ would contain a cross-edge, i.e. an edge between different subtrees. Hence $av$ is a back-edge. Let $D$ be the chain that starts with the edge $av$. $D$ does not belong to $G_c$, as no edge of $P$ belongs to $G_c$.

We claim that $t(D)$ is a proper descendant of $b$ or $D$ is a Mader-path with respect to $G_c$. Since $v$ is a descendant of $b$ and $t(D)$ is an ancestor of $v$, $t(D)$ is either a proper descendant of $b$, equal to $b$, or a proper ancestor of $b$. We consider each case separately.

If $t(D)$ were a proper ancestor of $b$ the edge $b \rightarrow_T D$ would belong to $D$ and hence $D$ would be part of $G_c$, contradicting our choice of $P$. If $t(D)$ is equal to $b$ as then $D$ is a Mader-path with respect to $G_c$. This leaves the case that $t(D)$ is a proper descendant of $b$.

Let $yb$ be the last edge on the path $t(D) \rightarrow_T b$. We claim that $yb$ is also the last edge of $P$. This holds since the last edge of $P$ must come from a descendant of $b$ (as ancestors of $b$ belong to $G_c$) and since it cannot come from a child different from $y$ as otherwise $P$ would have to contain a cross-edge.

Let $D^*$ be the chain containing $yb$. Then $D^* \leq D$ by Lemma 2 (applied with $C = D^*$ and $u = y$) and hence $s(D^*) \leq s(D) \leq a$ by part (4) of the same lemma. Also $t(D^*) = b$. Since $b = t(D^*) \in G_c$, $p(D^*) \in G_c$.

As $a$ and $b$ are not inner vertices of the same link, the path $t(D^*) \rightarrow_T s(D^*)$ contains a branch vertex. Thus $D^*$ is a Mader-path by Lemma 3.

\[ \square \]

**Corollary 2** If $G$ is 3-edge-connected, chains can be greedily added in parent-first order.

**Proof:** If we reach a point where not all chains are added, but we cannot proceed in a greedy fashion, by Theorem 2 we find a cut in $G$. \[ \square \]

### 6. A First Algorithm

Theorem 2 gives rise to an $O((n + m) \log(n + m))$ algorithm, the Greedy-Chain-Addition Algorithm. In addition to $G$, we maintain the following data structures:

- The current graph $G_c$. Each link is maintained as a doubly linked list of vertices. Observe that all inner vertices of a link lie on the same tree path and hence are numbered in decreasing order. The vertices in $G$ are labeled *inactive*, *branch*, or *non-branch*. The vertices in $G \setminus G_c$ are called *inactive*. Every non-branch vertex stores a pointer to the link on which it lies and a list of all chains incident to it and having the other endpoint as an inner vertex of the same link.
- A list $\mathcal{L}$ of addable chains. A chain is addable if it is a Mader-path with respect to the current graph.
- For each chain its list of children.
We initialize $G_c$ to $C_1 \cup C_2$. It has three links, $t(C_2) \rightarrow r, r \rightarrow C_1, t(C_2)$, and $r \rightarrow C_2, t(C_2)$. We then iterate over the children of $C_1$ and $C_2$. For each child, we check in constant time whether its endpoints are inner vertices of the same link. If so, we associate the chain with the link by inserting it into the lists of both endpoints. If not, we add the chain to the list of addable chains. The initialization process takes time $O(n + m)$.

As long as the list of addable chains is non-empty, we add a chain, say $C$. Let $u$ and $v$ be the endpoints of $C$. We perform the following actions:

- If $u$ is a non-branch vertex, we make it a branch vertex. This splits the link containing it and entails some processing of the chains having both endpoints on this link.
- If $v$ is a non-branch vertex, we make it a branch vertex. This splits the link containing it, and entails some processing of the chains having both endpoints on this link.
- We add $C$ as a new link to $G_c$.
- We process the children of $C$.

We next give the details for each action.

If $u$ is a non-branch vertex, it becomes a branch vertex. Let $L$ be the link of $G_c$ containing $u$; $L$ is split into links $L_1$ and $L_2$ and the set $S$ of chains having both endpoints on $L$ is split into sets $S_1$, $S_2$ and $S_{add}$, where $S_i$ is the set of chains having both endpoints on $L_i$, $i = 1, 2$, and $S_{add}$ is the set of chains that become addable (because they are incident to $u$ or have one endpoint each in $L_1$ and $L_2$).

We show that we can perform the split of $L$ in time $O(1 + |S_{add}| + \min(|L_1| + |S_1|, |L_2| + |S_2|))$.

We walk from both ends of $L$ towards $u$ in lockstep fashion. In each step we either move to the next vertex or consider one chain. Once we reach $u$ we stop. Observe that this strategy guarantees the time bound claimed above.

When we consider a chain, we check whether we can move it to the set of addable chains. If so, we do it and delete the chain from the lists of both endpoints. Once, we have reached $u$, we split the list representing the link into two. The longer part of the list retains its identity, for the shorter part we create a new list header and redirect all pointers of its elements.

Adding $C$ to $G_c$ is easy. We establish a list for the new link and let all inner vertices vertices of $C$ point to it. The inner vertices become active non-branch vertices.

Processing the children of $C$ is also easy. For each child, we check whether both endpoints are inner vertices of $C$. If so, we insert the child into the list of its endpoints. If not, we add the child to the list of addable chains.

If $\mathcal{L}$ becomes empty, we stop. If all chains have been added, we have constructed a Mader sequence. If not all chains have been processed, there must be a link having at least one inner vertex. The first and the last edge of this link form a 2-edge-cut.

It remains to argue that the algorithm runs in time $O((n + m) \log(n + m))$. We only need to argue about the splitting process. We distribute the cost $O(1 + |S_{add}| + \min(|L_1| + |S_1|, |L_2| + |S_2|))$ as follows: $O(1)$ is charged to the vertex that becomes a branch vertex. All such charges add up to $O(n)$. $O(|S_{add}|)$ is charged to the chains that become addable. All such charges add up to $O(m)$. $O(\min(|L_1| + |S_1|, |L_2| + |S_2|))$ is charged to the vertices and chains that define the minimum.

We account for these charges with the following token scheme inspired by the analysis of the corresponding recurrence relation in [17].

Consider a link $L$ with $k$ chains having both endpoints on $L$. We maintain the invariant that each vertex and chain owns at least $\log(|L| + k)$ tokens. When a link is newly created we give $\log(n + m)$ tokens to each vertex of the link and to each chain having both endpoints on the link. In
We distinguish two cases. We now make this distinction explicit by classifying chains into two types, interlacing and nested. When we add a chain in the Greedy-Chain-Addition algorithm, we also process its children.

These cases are exhaustive as the following argument shows. Let \( s \) and hence \( D \) be an interlacing chain contained in \( G \), and that \( s \)-belongs to a chain which is a proper ancestor of \( \hat{C} \) or \( \hat{C} = C_1 \). The next lemma confirms that interlacing chains can be added once their parent belongs to \( G_c \).

**Lemma 4** Let \( G_c \) be a parent-closed union of chains that contains \( C_1 \) and \( C_2 \), let \( C \) be any chain contained in \( G_c \), and let \( D \) be an interlacing child of \( C \) not contained in \( G_c \). Then \( D \) is a Mader-path with respect to \( G_c \).

**Proof:** We have already shown in Lemma 3 that \( D \) is an ear with respect to \( G_c \), that the path \( t(D) \rightarrow_T s(D) \) is part of \( G_c \), and that \( s(C) \) and \( t(C) \) are branching vertices of \( G_c \). Since \( D \) is interlacing, we have \( s(C) \leq s(D) \leq t(C) \leq t(D) \). Thus \( t(D) \rightarrow_T s(D) \) contains a branching vertex and hence \( D \) is a Mader-path by Lemma 3. \( \square \)

In [25], three types of chains are distinguished. What we call nested is called Type 1 there and what we call interlacing is split into Types 2 and 3 there. We do not need this finer distinction.

**Theorem 3** The Greedy-Chain-Addition algorithm runs in time

\[
O((n + m) \log(n + m)).
\]

7. A Classification of Chains

When we add a chain in the Greedy-Chain-Addition algorithm, we also process its children. Children that do not have both endpoints as inner vertices of the chain can be added to the list of addable chains immediately. However, children that have both endpoints as inner vertices of the chain cannot be added immediately and need to be observed further until they become addable. We now make this distinction explicit by classifying chains into two types, interlacing and nested.

We classify the chains \( \{C_3, \ldots, C_{m-n+1}\} \) into two types. Let \( C \) be a chain with parent \( \hat{C} = p(C) \). We distinguish two cases for \( C \):

- If \( s(C) \) is an ancestor of \( t(\hat{C}) \) and a descendant of \( s(\hat{C}) \), \( C \) is interlacing. We have \( s(\hat{C}) \leq s(C) \leq t(\hat{C}) \leq t(C) \).
- If \( s(C) \) is a proper descendant of \( t(\hat{C}) \), \( C \) is nested. We have \( s(\hat{C}) \leq t(\hat{C}) < s(C) \leq t(C) \) and \( t(C) \rightarrow_T s(C) \) is contained in \( \hat{C} \).

These cases are exhaustive as the following argument shows. Let \( s(\hat{C}) \) be the first edge on \( \hat{C} \). By Lemma 2, \( s(C) \leq v \). We split the path \( v \rightarrow_T s(\hat{C}) \) into two parts corresponding to the two cases above, namely \( t(\hat{C}) \rightarrow_T s(\hat{C}) \) and \( (v \rightarrow_T t(\hat{C})) \setminus s(\hat{C}) \). Depending on which of these paths \( s(C) \) lies, it is classified as interlacing or nested.

The following simple observations are useful. For any chain \( C \neq C_1 \), \( t(C) \) \( s \)-belongs to \( \hat{C} \). If \( C \) is nested, \( s(C) \) and \( t(C) \) \( s \)-belong to \( \hat{C} \). If \( C \) is interlacing, \( s(C) \) \( s \)-belongs to a chain which is a proper ancestor of \( \hat{C} \) or \( \hat{C} = C_1 \). The next lemma confirms that interlacing chains can be added once their parent belongs to \( G_c \).
Algorithm 1 Certified linear-time algorithm for 3-edge connectivity.

procedure CONNECTIVITY(G=(V,E))

Let \{C_1, C_2, \ldots, C_{m-n+1}\} be a chain decomposition of G as described in Sect. 4.
Initialize \(G_c\) to \(C_1 \cup C_2\);
for \(i\) from 1 to \(m-n+1\) do
  \(\triangleright\) Phase \(i\): add all chains whose source \(s\)-belongs to \(C_i\)
  Group the chains \(C\) for which \(s(C)\) \(s\)-belongs to \(C_i\) into segments;
  \(\triangleright\) Part I of Phase \(i\): add segments with interlacing root
  Add all segments whose minimal chain is interlacing to \(G_c\);
  \(\triangleright\) Part II of Phase \(i\): add segments with nested root
  Either find an insertion order \(S_1, \ldots, S_k\) on the segments having a nested minimal chain
  or exhibit a 2-edge-cut and stop;
  for \(j\) from 1 to \(k\) do
    Add the chains contained in \(S_j\) parent-first;
  end for
end for
end procedure

8. A Linear Time Algorithm

According to Lemma 4, interlacing chains whose parent already belongs to the current graph are always Mader-paths and can be added. Adding a chain may create new branching vertices which in turn can turn other chains into Mader-paths. This observation suggests adding interlacing chains as early as possible. Only when there is no interlacing chain to add, we need to consider nested chains. In that case and if the graph is 3-edge-connected, some nested chain must be addable (because a previously added chain created a branching vertex on the tree-path from the sink to the source of the chain). The question is how to find this nested chain efficiently.

The following observation paves the way. Once we add a nested chain, its interlacing children and then their interlacing children etc. become addable. This suggests considering nested chains not in isolation, but to consider them together with their interlacing offspring. We formalize this intuition in the concept of segment below.

Nested chains have both endpoints on their parent chain. Consider the chains nested in chain \(C_i\). Which chains can help their addition by creating branching points on \(C_i\)? First, chains nested in \(C_i\) and their interlacing offspring, and second, interlacing chains having their source on some \(C_j\) with \(j < i\). Chains having their source on some \(C_j\) with \(j > i\) cannot help because they have no endpoint on \(C_j\). These observations suggest an algorithm operating in phases. In the \(i\)-th phase, we try to add all chains having their source vertex on \(C_i\).

The overall structure of the linear-time algorithm is given in Algorithm 1. An implementation in Python is available at [https://github.com/adrianN/edge-connectivity](https://github.com/adrianN/edge-connectivity)
are added parent-first and hence $G_c$ is always parent-closed. We maintain the following invariant:

**Invariant:** After phase $i$, $G_c$ consists of all chains for which the source vertex $s$-belongs to one of the chains $C_1$ to $C_i$.

**Lemma 5**  For all $i$, the current chain $C_i$ is part of the current graph $G_c$ at the beginning of phase $i$ or the algorithm has exhibited a 2-edge-cut before phase $i$.

**Proof:** The initial current graph consists of chains $C_1$ and $C_2$ and hence the claim is true for the first and the second phase. Consider $i > 2$. The source vertex $s(C_i)$ s-belongs to a chain $C_j$ with $j < i$ (Lemma 2.6) and hence $C_i$ is added in phase $j$. □

The next lemma gives information about the chains for which the source vertex $s$-belongs to $C_i$. None of them belongs to $G_c$ at the beginning of phase $i$ (except for chain $C_2$ that belongs to $G_c$ at the beginning of phase 1) and they form subtrees of the chain tree. Only the roots of these subtrees can be nested. All other chains are interlacing.

**Lemma 6** Assume that the algorithm reaches phase $i$ without exhibiting a 2-edge-cut. Let $C \neq C_2$ be a chain for which $s(C)$ s-belongs to $C_i$. Then $C$ is not part of $G_c$ at the beginning of phase $i$. Let $D$ be any ancestor of $C$ that is not in $G_c$. Then:

1. $s(D)$ s-belongs to $C_i$.
2. If $D$ is nested, it is a child of $C_i$.
3. If $p(D)$ is not part of the current graph, $D$ is interlacing.

**Proof:** We use induction on $i$. Consider the $i$-th phase and let $C \neq C_2$ be chains whose source vertex $s(C)$ s-belongs to $C_i$. We first prove that $C$ is not in $G_c$. This is obvious, since in the $j$-th phase we add exactly the chains whose source vertex $s$-belongs to $C_j$.

1. Let $D$ be any ancestor of $C$ which is not part of $G_c$. By Lemma 2, we have $s(D) \leq s(C)$ and hence $s(D)$ belongs to $C_j$ for some $j \leq i$. If $j < i$, $D$ would have been added in phase $j$, a contradiction to the assumption that $D$ does not belong to $G_c$ at the beginning of phase $i$.

2. $s(D)$ s-belongs to $C_i$ by (1). If $D$ is nested, $s(D)$ and $t(D)$ s-belong to the same chain. Thus $D$ is a child of $C_i$.

3. If $p(D)$ is not part of the current graph, $p(D) \neq C_i$ by Lemma 5 and hence $D$ is not a child of $C_i$. Hence by (2), $D$ is interlacing. □

We can now define the segments with respect to $C_i$. Consider the set $\mathcal{S}$ of chains whose source vertex $s$-belongs to $C_i$. For a chain $C \in \mathcal{S}$, let $C^*$ be the minimal ancestor of $C$ that does not belong to $G_c$. Two chains $C$ and $D$ in $\mathcal{S}$ belong to the same segment if and only if $C^* = D^*$, see Figure 2 for an illustration.

Consider any $C \in \mathcal{S}$. By part (1) of the preceding lemma either $p(C) \in \mathcal{S}$ or $p(C)$ is part of $G_c$. Moreover, $C$ and $p(C)$ belong to the same segment in the first case. Thus segments correspond to subtrees in the chain tree. In any segment only the minimal chain can be nested by Lemma 6. If it is nested, it is a child of $C_i$ (parts (2) and (3) of the preceding lemma). Since only the root of a segment may be a nested chain, once it is added to the current graph all other chains in the segment can be added in parent-first order by Lemma 4. All that remains is to find
the proper ordering of the segments faster than in the previous section. We do so in Lemma 10. If no proper ordering exists, we exhibit a 2-edge-cut.

**Lemma 7** All chains in a segment \( S \) can be added in parent-first order if its minimal chain can be added.

**Proof:** By Lemma 6, all but the minimal chain in a segment are interlacing. Thus the claim follows from Lemma 4. □

It is easy to determine the segments with respect to \( C_i \). We iterate over all chains \( C \) whose source \( s(C) \) s-belongs to \( C_i \). For each such chain, we traverse the path \( C, p(C), p(p(C)), \ldots \) until we reach a chain that belongs to \( G_e \) or is already marked\(^4\). In the former case, we distinguish cases. If the last chain on the path is nested we mark all chains on the path with the nested chain. If we hit a marked chain we copy the marker to all chains in the path. Otherwise, i.e., all chains are interlacing and unmarked, we add all chains in the path to \( G_c \) in parent-first order, as this segment can be added according to Corollary 7. We have now completed part I of phase \( i \), namely the addition of all segments whose minimal chain is interlacing. We have also determined the segments with nested minimal chain.

It remains to compute a proper ordering of the segments in which the minimal chain is nested or to exhibit a 2-edge-cut. We do so in part II of phase \( i \). For simplicity, we will say ‘segment’ instead of ‘segment containing a nested chain’ from now on.

For a segment \( S \) let the attachment points of \( S \) be all vertices in \( S \) that are in \( G_c \). Note that the attachment points must necessarily be endpoints of chains in \( S \) and hence adding the chains of \( S \) makes the attachment points branch vertices. Nested children \( C \) of \( C_i \) can be added if there are branch vertices on \( t(C) \to_T s(C) \), therefore adding a segment can make it possible to add further segments.

**Lemma 8** Let \( C \) be a nested child of \( C_i \) and let \( S \) be the segment containing \( C \). Then all attachment points of \( S \) lie on the path \( t(C) \to_T s(C) \) and hence on \( C_i \).

**Proof:** Let \( D \) be any chain in \( S \) different from \( C \). By Lemma 6, \( C \) is the minimal chain in \( S \). Since \( S \) is a subtree of the chain tree, we have \( C < D \) and hence by Lemma 2, \( t(C) \leq t(D) \).

Since none of the chains in \( S \) is part of \( G_e \), parent-closedness implies that no vertex on the path \( (t(D) \to_T t(C)) \setminus t(C) \) belongs to \( G_e \). In particular, either \( t(D) = t(C) \) or \( t(D) \) is not a vertex of \( G_e \) and hence not an attachment point of \( S \). It remains to show \( s(C) \leq s(D) \leq t(C) \). Since \( C \leq D \), we have \( s(C) \leq s(D) \) by Lemma 2. Since \( s(D) \leq t(D) \) and \( t(C) \leq t(D) \) we have either \( s(D) \leq t(C) \leq t(D) \) or \( t(C) < t(D) \). In the former case, we are done. In the latter case, \( s(D) \) is not a vertex of \( G_e \) by the preceding paragraph, a contradiction, since \( s(D) \) s-belongs to \( C_i \) by Lemma 6. □

For a set of segments \( S_1, \ldots, S_k \), let the overlap graph be the graph on the segments and a special vertex \( R \) for the branch vertices on \( C_i \). In the overlap graph, there is an edge between \( R \) and a vertex \( S_i \), if there are attachment points \( a_1 \leq a_2 \) of \( S_i \) such that there is a branch vertex

\(^4\) Initially, all chains are unmarked
We say that $S$ with $t$ vertices on $C$ beginning of part II the phase. Hence $R$ is not connected. Let $C$ be any connected component of the overlap graph $H$ and let $S$ be any segment with respect to $C$. whose minimal chain $C$ is nested. Then $S \in C$ if and only if

(i) $R \in C$ and there is a branch vertex on $t(C) \rightarrow_T s(C)$ or

(ii) there are attachments $a_1$ and $a_2$ of $S$ and attachments $b_1$ and $b_2$ of segments in $C$ with $a_1 \leq b_1 \leq a_2 \leq b_2$ or $b_1 \leq a_1 \leq b_2 \leq a_2$.

Proof: We first show $S \in C$ if (i) or (ii) holds. For (i) the claim follows directly from the definition of the overlap graph. For (ii), assume $S \notin C$ for the sake of a contradiction. Then either $R \notin C$ or there is no branch vertex in $t(C) \rightarrow_T s(C)$ by (i). Further, no segment in $C$ overlaps with $S$ and hence any segment in $C$ has its attachments points either strictly between $a_1$ and $a_2$ or outside the path $a_2 \rightarrow_T a_1$. Moreover, both classes of segments are non-empty. However, segments in the two classes do not overlap and $R$ cannot be connected to the segments in the former class. Thus $C$ is not connected, a contradiction.

If neither (i) nor (ii) hold, there can be no segment in $C$ overlapping $S$ and either $S$ is not connected to $R$ or no segment in $C$ is connected to $R$. □

Lemma 10 Assume the algorithm reaches phase $i$. If the overlap graph $H$ induced by the segments with respect to $C_i$ is connected, we can add all segments of $C_i$. If $H$ is not connected, we can exhibit a 2-edge-cut for any component of $H$ that does not contain $R$.

Proof: Assume first that $H$ is connected. Let $R, S_1, \ldots, S_k$ be the vertices of $H$ in a preorder, e.g. the order they are explored by a DFS, starting at $R$, the vertex corresponding to the branch vertices on $C_i$. An easy inductive argument shows that we can add all segments in this order. Namely, let $k \geq 1$ and let $C$ be the minimal chain of $S_k$. All attachment points of $S_k$ lie on the path $t(C) \rightarrow_T s(C)$ by Lemma 8. Moreover, there is an edge between $R$ and $S_k$ or an edge between $S_j$ and $S_k$ for some $j < k$. In the former case, there is a branch vertex on $t(C) \rightarrow_T s(C)$ at the beginning of the phase, in the latter case after adding $S_j$. Thus the minimal chain of $S_k$ can be added and then all other chains by Lemma 7.

On the other hand, suppose $H$ is not connected. Let $C$ be any connected component of $H$ that does not contain $R$, and let $C_R$ be the connected component that contains $R$. Let $x$ and $y$ be the minimal and maximal attachment points of the segments in $C$, and let $G_c$ be the current graph after adding all chains in $C_R$ of $H$. We first show that there is no branch vertex of $G_c$ on the path $y \rightarrow_T x$. Assume otherwise and let $w$ be any such branch vertex. Observe first that there must be a chain $C \in C$ with $s(C) \leq w \leq t(C)$. Otherwise, every chain in $C$ has all its attachment points at proper ancestors of $w$ or at proper descendants of $w$ and $C$ is not connected. Let $S$ be the segment containing $C$. By Lemma 8 we may assume w.l.o.g. that $C$ is the minimal chain of $S$. Since $S \notin C_R$, $R S$ is not an edge of $H$ and hence no branch vertex exists on the path $t(C) \rightarrow_T s(C)$ at the beginning of part $i$ the phase. Hence $w$ is an attachment point of a segment in $C_R$. In particular $C_R$ contains at least one segment. We claim that $C_R$ must also have an attachment point outside
\( t(C) \rightarrow_T s(C) \). This holds since all initial branch vertices are outside the path and since \( \mathcal{C}_R \) is connected. Thus \( S \in \mathcal{C}_R \) by Lemma 9, a contradiction.

We show next that the tree-edge \( xp(x) \) and the edge \( zy \) from \( y \)'s predecessor \( z \) on \( C_i \) to \( y \) form a 2-edge-cut; \( zy \) may be a tree-edge or a back-edge. The following argument is similar to the argument in Theorem 2 but more refined.

Assume otherwise. Then, as in the proof of Theorem 2 there is a path \( P = a \rightarrow b \) such that \( a \leq u \) for all \( u \in P \), and either \( a \) lies on \( y \rightarrow_T x \) and \( b \) does not, or vice versa, and no inner vertex of \( P \) is in \( G_c \). Moreover, the first edge \( av \) of \( P \) is a back-edge and \( v \) is a descendant of \( b \). Note that unlike in the proof of Theorem 2, \( a \) and \( b \) need not lie on different links, as we want to show that \( xp(x) \) and \( zy \) form a cut and these might be different from the last edges on the link containing \( x \) and \( y \).

Let \( D \) be the chain that starts with the edge \( av \). \( D \) does not belong to \( G_c \), as no edge of \( P \) belongs to \( G_c \). In particular, \( a \) does not s-belong to \( C_j \) for \( j < i \) (as otherwise, \( D \) would already be added). Since \( a \leq b \) and one of \( a \) and \( b \) lies on \( y \rightarrow_T x \) (which is a subpath of \( C_i \)), \( a \) s-belongs to \( C_i \).

We show next that \( t(D) \) is a descendant of \( b \). Since \( v \) is a descendant of \( b \) and \( t(D) \) is an ancestor of \( v \), \( t(D) \) is either a descendant of \( b \) or a proper ancestor of \( b \). But \( t(D) \) cannot be a proper ancestor of \( b \) as then the edge \( bp(b) \) would belong to \( D \) and hence \( D \) would be part of \( G_c \).

Let \( D^* \) be the chain that contains the last edge of \( P \). If \( t(D) = b \), \( D = D^* \). Otherwise, \( t(D) \) is a proper descendant of \( b \). Let \( ub \) be the last edge on the path \( t(D) \rightarrow_T b \). We claim that \( ub \) is also the last edge of \( P \). This holds since the last edge of \( P \) must come from a descendant of \( b \) (as ancestors of \( b \) belong to \( G_c \)) and since it cannot come from a child different from \( y \) as otherwise \( P \) would have to contain a cross-edge. Thus \( D^* \leq D \) by Lemma 2 and hence \( s(D^*) \leq s(D) \leq a \) by part (4) of the same lemma.

\( D \) and \( D^* \) belong to the same segment with respect to \( C_i \), say \( S \), and \( a \) and \( b \) are attachment points of \( S \). This can be seen easily. Since \( a \) s-belongs to \( C_i \), \( D \) belongs to some segment with respect to \( C_i \) and since \( D^* \leq D \), \( D^* \) belongs to the same segment. Since \( t(D^*) = b \) and \( b \) is a vertex of \( G_c \), \( D^* \) is the minimal chain in \( S \). Thus \( D^* \) is nested and hence \( b \) s-belongs to \( C_i \). Hence \( a \) and \( b \) are attachment points of \( S \).

Thus \( S \) overlaps with \( \mathcal{C} \) and hence \( S \in \mathcal{C} \) by Lemma 9. Therefore \( x \) and \( y \) are not the extremal attachment points of \( \mathcal{C} \), a contradiction. \( \square \)

It remains to show that we can find an order as required in Lemma 10, or a 2-edge-cut, in linear time. We reduce the problem of finding an order on the segments to a problem on intervals of \( C_i \), numbered consecutively from 1 to \( |C_i| \). Consider any segment \( S \), and let \( a_0 \leq a_1 \leq \ldots \leq a_k \) be the set of attachment points of \( S \), i.e., the set of vertices that \( S \) has in common with \( C_i \). We associate the intervals \( \{[a_0, a_\ell] \mid 1 \leq \ell \leq k \} \cup \{[a_\ell, a_k] \mid 1 \leq \ell < k \} \), with \( S \) and for every branch vertex \( v \) on \( C_i \) we define an interval \([0, v] \). See Figure 3 for an example.

We say two intervals \([a, a'], [b, b'] \) overlap if \( a \leq b \leq a' \leq b' \). Note that overlapping is different from intersecting; an interval does not overlap intervals in which it is properly contained or which
it properly contains. This relation naturally induces a graph $H'$ on the intervals. Contracting all intervals that belong to the same segment makes $H'$ isomorphic to the overlap graph as required for Lemma [10]. Hence we can use $H'$ to find the order on the segments.

A naive approach that constructs $H'$, contracts intervals, and runs a DFS will fail, since the overlap graph can have a quadratic number of edges. However, using a method developed by Olariu and Zomaya [22], we can compute a spanning forest of $H'$ in time linear in the number of intervals. The presentation in [22] is for the PRAM and thus needlessly complicated for our purposes. A simpler explanation can be found in the appendix.

Since the number of intervals created for a chain $C_i$ is bounded by

$$|\text{NestedChildren}(C_i)| + 2|\text{Interlacing}(C_i)| + |\text{Vbranch}(C_i)|,$$

where NestedChildren$(C_i)$ are the nested children of $C_i$, Interlacing$(C_i)$ are the interlacing chains that start on $C_i$, and Vbranch$(C_i)$ is the set of branch vertices on $C_i$, the total time spent on this procedure for all chains is $O(m)$. From the above discussion follows:

**Theorem 4** For a 3-edge-connected graph, a Mader construction sequence can be found in time $O(n + m)$.

9. Verifying the Mader Sequence

The certificate is either a 2-edge-cut, or a sequence of Mader-paths. For a 2-edge-cut, we simply remove the two edges and verify that $G$ is no longer connected.

For checking the Mader sequence, we doubly-link each edge in a Mader-path to the corresponding edge in $G$. Let $G'$ be a copy of $G$. We remove the Mader-paths, in reverse order of the sequence, suppressing vertices of degree two as they occur. This can create multiple edges and loops. Let $G'_i$ be the multi-graph before we remove the $i$-th path $P_i$. We need to verify the following:

- $G$ must have minimum degree three.
- The union of Mader-paths must be isomorphic to $G$ and the Mader-paths must partition the edges of $G$. This is easy to check using the links between the edges of the paths and the edges of $G$.
- The paths we remove must be ears. More precisely, at step $i$, $P_i$ must have been reduced to a single edge in $G'_i$, as inner vertices of $P_i$ must have been suppressed if $P_i$ is an ear for $G'_i$.
- The $P_i$ must not subdivide the same link twice. That is, after deleting the edge corresponding to $P_i$, it must not be the case that both endpoints are still adjacent (or equal, i.e. $P_i$ is a loop) but have degree two.
- When only two paths are left, the graph must be a $K_3^3$. 

![Figure 3: Intervals for the solid segment with attachment points 1,2,4.](image-url)
10. The Cactus Representation of 2-Cuts

We review the cactus representation of 2-cuts in a 2-connected but not 3-connected graph and show how to certify it.

A cactus is a graph in which every edge is contained in exactly one cycle. Dinits, Karzanov, and Lomonsov [5] showed that the set of mincuts of any graph has a cactus representation, i.e., for any graph \(G\) there is a cactus \(C\) and a mapping \(\phi : V(G) \to V(C)\) such that the mincuts of \(G\) are exactly the preimages of the mincuts of \(C\) (i.e., for every mincut \(A \subseteq V(C)\), \(\phi^{-1}(A)\) is a mincut of \(G\) and all mincuts of \(G\) can be obtained in this way. The pair \((C, \phi)\) is called a cactus representation of \(G\). Fleiner and Frank [6] provide a simplified proof for the existence of a cactus representation. We will call the elements of \(V(G)\) vertices, the elements of \(V(C)\) nodes, and the preimages of nodes of \(C\) blobs.

In general, a cactus representation needs to include nodes with empty preimages. This happens for example for the \(K_4\); its cactus is a star with double edges where the leaves correspond to the vertices of the \(K_4\) but the central node has an empty preimage. For graphs whose mincuts have size two, nodes with empty preimages are not needed as Nagamochi and Ibaraki show [20, Section 2.3.5]. A 3-edge-connected component of a graph \(G\) is a maximal subset \(V'\) of its vertices such that between every two vertices in \(V'\) there are at least 3 edge-disjoint paths in \(G\) (note that these paths may leave \(V'\)).

**Lemma 11** Let \(G\) be a 2-edge-connected graph that is not 3-edge-connected. There is a cactus representation \((C, \phi)\) of \(G\) with the following properties:

i) The edges of \(C\) are in one-to-one correspondence to the edges of \(G\) that are contained in a 2-cut.

ii) For every node \(c \in V(c)\), \(\phi^{-1}(c)\) is a 3-edge-connected component of \(G\).

**Proof:** Consider the graph \(C'\) whose nodes correspond to the 3-edge-connected components of \(G\) and there is an edge between two nodes \(u, v\) in \(C'\) if there is an edge between the subgraphs in \(G\) induced by \(u\) and \(v\). Alternatively, \(C'\) is obtained from \(G\) by contracting each 3-edge-connected component of \(G\) into a node. Clearly, the edges of \(C'\) correspond to the edges of \(G\) that are contained in 2-edge-cuts.

We show that \(C'\) is a cactus. Assume first that there is an edge \(uv\) in \(C'\) contained in two distinct cycles \(X\) and \(Y\). Let \(P\) be a maximal path in \(X \sim Y\); note that \(P\) is non-empty. Then the endpoints \(a\) and \(b\) of \(P\) are connected by at least three edge-disjoint paths in \(G\), namely \(P\) and the two \(a\)-\(b\)-paths in \(Y\). This contradicts that \(a\) and \(b\) are in different 3-edge-connected components. Assume next that there is an edge \(uv\) in \(C'\) that is not contained in any cycle. Then this edge is a 1-edge-cut in \(G\), a contradiction. \(\Box\)

10.1. Verifying a Cactus Representation

Let \(G\) be a graph and let \((C, \phi)\) be an alleged cactus-representation of its 2-cuts in the sense of Lemma [11]. We show how to certify an augmented cactus representation in linear time. To

\[\text{For this theorem, a cut is specified by a set of vertices, and the edges in the cut are the edges with exactly one endpoint in the vertex set.}\]
verify the cactus representation, we need to check two things. First, we need to ensure that $C$ in indeed a cactus graph, that is, every edge of $C$ is contained in exactly one cycle, that $\phi$ is a surjective mapping and hence there are no empty blobs, and that every edge of $G$ either connects two vertices in the same blob or is also present in $C$. Second, we need to verify that the blobs of $C$ are 3-edge-connected components of $G$. For this purpose, the cactus representation is augmented as discussed below.

When encountering a back-edge from $u$ to $v$, we mark all edges on the tree path between $u$ and $v$, as well as the back edge $uv$, as belonging to the same cycle. We verify that each edge is marked exactly once by this procedure and number the edges of the $i$-th cycle found with $i$. We have now verified that $C$ is a cactus.

Surjectivity of $\phi$ is easy to check. We then iterate over the edges $uv$ of $G$. If its endpoints belong to the same blob, we associate the edge with the blob. If its endpoints do not belong to the same blob, we add the pair $\phi(u) \phi(v)$ to a list. Having processed all edges, we check whether the constructed list and the edge list of $C$ are identical by first sorting both lists using radix sort and then comparing them for identity.

We finally have to check that the blobs of $C$ correspond to 3-edge-connected components of $G$. Our goal is to use the certifying algorithm for 3-edgeconnectivity on the substructures of $G$ that represent 3-edge-connected components. Let $B$ be any blob. We already collected the edges having both endpoints in $B$. We also have to account for the paths leaving $B$. For each path in $G$ leaving $B$ at vertex $u$ and returning to $B$ at vertex $v$, we have to create an edge $uv$. It is straightforward to compute these edges; we look at all edges having exactly one endpoint in the blob. Each such edge corresponds to an edge in $C$. For each such edge, we know to which cycle it belongs. The outgoing edges must pair up so that the two edges of each pair belong to the same cycle. As an additional input to our verification procedure we require a Mader-construction sequence of $G_B$ for every blob $B$. The verification procedure from Sect.9 can then be applied.

The maximality of each blob $B$ is given by the fact that every edge of $C$ is contained in a 2-edge-cut of $C$ and hence contained in a 2-edge-cut of $G$.

Every algorithm for computing the 3-edge-connected components of a graph, e.g. \cite{19, 20, 27, 29}, can be turned into a certifying algorithm for computing the cactus representation of 2-cuts. We obtain the cactus $C$ and the mapping $\phi$ as in Lemma11. This construction is due to Nagamochi and Ibaraki. Then one applies our certifying algorithm for 3-edge-connectivity to each 3-edge-connected component.

In the next section we will show how to extend our algorithm so that it computes the 3-edge-connected components and the cactus representation of 2-cuts of a graph.

11. Computing a Cactus Representation

We discuss how to extend the algorithm to construct a cactus representation. We begin by examining the structure of the 2-cuts of $G$ more closely to extend our algorithm such that it finds all 2-cuts of the graph and encodes them efficiently.

We will first show that the two edges of every 2-edge-cut of $G$ are contained in a common chain. This restriction allows us to focus on the 2-edge-cuts that are contained in the currently processed chain $C_i$ only. In the subsequent section, we show how to maintain a cactus for every
phase $i$ of the algorithm that represents all 2-edge-cuts of $\text{smooth}(C_1 \cup \ldots \cup C_i)$ in linear space. The final cactus will therefore represent all 2-edge-cuts in $G$.

There is one technical detail regarding the computation of overlap graphs: For the computation of a Mader-sequence in Section 8 we stopped the algorithm when the first 2-edge-cut occurred, as then a Mader-sequence does not exist anymore. Here, we simply continue the algorithm with processing the next chain $C_{i+1}$. This does not harm the search for cuts in subsequent chains, as the fact that 2-edge-cuts are only contained in common chains guarantees that every 2-edge-cut that contains an edge $e$ in $C_i$ has its second edge also in $C_i$.

For simplicity, we assume that $G$ is 2-edge-connected and has minimum degree three from now on.

### 11.1. 2-Edge-Cuts are Contained in Chains

The next two lemmas show that the edges $uv$ and $xy$ of every 2-edge-cut are contained in a common chain. This strengthens [20, Lemma 2.37], which states that these edges are contained in a common cycle. As in the previous sections, all DFS-tree-edges are oriented towards the root, while back-edges are oriented away from the root.

**Lemma 12** Let $T$ be a DFS-tree of a 2-edge-connected graph $G$. Every 2-edge-cut $(uv, xy)$ of $G$ satisfies the following:

1. At least one of $uv$ and $xy$ is a tree-edge, say $xy$.
2. $G - uv - xy$ has exactly two components. Moreover, the edges $uv$ and $xy$ have exactly one endpoint in each component.
3. The vertices $u$, $v$, $x$, and $y$ are contained in the same leaf-to-root path of $T$.
4. If $uv$ and $xy$ are tree-edges and w.l.o.g. $u \leq y$, the vertices in $v \rightarrow_T u$ and $\{x, v\}$ are in different components of $G - uv - xy$.
5. If $uv$ is a back-edge, then $xy \in (v \rightarrow_T u)$ and, additionally, the vertices in $v \rightarrow_T x$ and $y \rightarrow_T u$ are in different components of $G - uv - xy$.

**Proof:**

1. If both $uv$ and $xy$ are back-edges, $G - uv - xy$ would still be connected by the tree-edges of $T$.

2. This holds since $G$ is assumed to be 2-edge-connected and hence $(uv, xy)$ is a minimal cut.

3. We distinguish cases according to (1). If w.l.o.g. $uv$ is a back-edge, we show more generally that $xy \in (v \rightarrow_T u)$. Assume otherwise. Then $u$ and $v$ are not in different components in $G - uv - xy$, as they are connected by $v \rightarrow_T u$, contradicting (2).

If both $uv$ and $xy$ are tree-edges, it suffices to show that $u$ and $x$ are contained on a path in $T$ to its root. Assume otherwise. By (2), $x$ and $y$ are in different components of $G - uv - xy$. Since $xy$ is a tree-edge, $G$ does not contain any back-edges connecting these components of $x$ and $y$. Hence, $G - uv$ is disconnected, which contradicts the 2-edge connectivity of $G$.

4. By (3) we can assume $u \leq y$. Then the path tree $y \rightarrow_T u$ still connects $y$ and $u$ in $G - uv - xy$. Hence, all vertices in $y \rightarrow_T u$ are in one component of $G - uv - xy$ and, by (2), $x$ and $v$ are contained in the other.

5. According to the proof of (3), $xy \in (v \rightarrow_T u)$. The claim follows from (2) applied to $xy$. □
Lemma 13  Let $\mathcal{C}$ be a chain decomposition of a 2-edge-connected graph $G$. For every 2-edge-cut $\{uv,xy\}$ of $G$, $uv$ and $xy$ are contained in a common chain $C \in \mathcal{C}$.

Proof: First assume that $uv$ is a back-edge. By Lemma 12.(5), there is no back-edge besides $uv$ that connects an ancestor of $y$ with a descendant of $x$. Hence, the chain $C$ containing $uv$ must contain $xy$.

If both $uv$ and $xy$ are tree-edges, let w.l.o.g. $u \leq y$. Since $G$ is 2-edge-connected, there must be a back-edge connecting a proper ancestor of $u$ to a descendant of $u$. Let $e = (s,t)$ be such a back-edge with $s$ minimal. By Lemma 12.(4), there can be no back-edge from a proper ancestor of $u$ to a vertex that is in the connected component containing $y \rightarrow_T u$ in $G - uv - xy$. Hence $t$ is a proper descendant of $x$. Since $s$ is chosen to be minimal, the chain starting at $e$ contains both $uv$ and $xy$. □

In phase $i$ of the algorithm, using Lemma 10, we can find a 2-edge-cut for any connected component of the overlap graph $H$ that does not contain $R$ ($R$ is the special vertex in $H$ that represents the branch vertices on $C_i$). The next lemma shows that the set of edges contained in these cuts is equal to the set of edges contained in any cut on $C_i$.

Lemma 14  Let $E$ be the set of edges that are contained in the 2-edge cuts induced by the connected components of the overlap graph $H$ at the beginning of part II of phase $i$. Then any 2-edge-cut $\{xy,uv\}$ on $C_i$ is a subset of $E$.

Proof: Assume for the sake of contradiction that there is an edge $uv$ in the 2-edge-cut that is not in $E$. We distinguish the following cases.

First assume that both $uv$ and $xy$ are tree-edges and w.l.o.g. $v < u \leq y < x$. Since $G$ has minimal degree three, every node on $C_i$ has an incident edge that is not on $C_i$. Hence it is either a branch vertex, or belongs to some segment with respect to $C_i$. Incident back-edges start chains in segments w.r.t. $C_i$, incident tree edges are the last edges of chains in segments w.r.t. $C_i$. As $s(C_i) \leq v$ is a branch vertex, by Lemma 12.(4) the path $y \rightarrow_T u$ cannot contain a branch vertex. In particular, $u$ is not a branch vertex.

Let $S_u$ be any segment having $u$ as attachment vertex. All segments in the connected component of $S_u$ in $H$ must have their attachment vertices on $y \rightarrow_T u$ and the connected component does not contain $R$. Hence this connected component induces a cut containing $uv$.

Now assume that one of $uv$ and $xy$ is a back-edge. If $uv$ is the back-edge, then $u = s(C_i)$ and we have $u < y < x < v$ by Lemma 5. The path $v \rightarrow_T x$ cannot contain a branch vertex. Let $S_v$ be any segment that has $v$ as attachment vertex. All segments in the connected component of $S_v$ must have their attachment vertices on $v \rightarrow_T x$ and the connected component does not contain $R$. Hence $uv$ is contained in a cut induced by this connected component.

If on the other hand $uv$ is the tree-edge we have $y < v < u < x$ basically the same argument applies when we replace $S_v$ by a segment $S_u$ containing $u$. □
11.2. An Efficient Representation of Cuts on a Chain

In this section we show how to compute a space efficient representation of all 2-cuts on the chain $C_i$. Using this technique we can store all 2-cuts in $G$ in linear space. In the next section we will then use this to construct the cactus-representation of all 2-cuts in $G$.

Number the edges in $C_i$ as $e_1, e_2, \ldots, e_k$. Here $e_1$ is a back edge and $e_2$ to $e_k$ are tree edges. We start with a simple observation. Let $h < i < j$. If $(e_h, e_i)$ and $(e_i, e_j)$ are 2-edge-cuts, then $(e_i, e_j)$ is a 2-edge-cut.

Using this observation, we want to group the edges of 2-edge-cuts of $C_i$ such that (i) every two edges in a group form a 2-edge-cut and (ii) no two edges of different groups form a 2-edge-cut.

Consider the overlap graph $H$ in phase $i$ of our algorithm. We need some notation. Let $I$ be the set of intervals on $C_i$ that contains for every component of $H$ (except the component representing the branch vertices on $C_i$) with extremal attachment vertices $a$ and $b$ the interval $[a, b]$. Since the connected components of $H$ are maximal sets of overlapping intervals, $I$ is a laminar family, i.e. every two intervals in $I$ are either disjoint or properly contained in each other. In particular, no two intervals in $I$ share an endpoint. Our construction exploits the fact that the layers of this laminar family encode which edges form pairwise 2-cuts in $G$, see Figure 4. We define an equivalence relation to capture this intuition.

For an interval $[a, b]$, $a < b$, let $\ell([a, b])$ and $r([a, b])$ be the edges of $C_i$ directly before and after $a$ and $b$, respectively. We call $\{\ell([a, b]), r([a, b])\}$ the interval-cut of $[a, b]$. For a subset $S \subseteq I$ of intervals, let $E_S$ be the union of edges that are contained in interval-cuts of intervals in $S$. According to Lemma 14, every 2-edge-cut in $C_i$ consists of edges in $E_I$.

We now group the edges of $E_I$ using the observation above. Let two intervals $I_1 \in I$ and $I_2 \in I$ contact if $r(I_1) = \ell(I_2)$ or $\ell(I_1) = r(I_2)$. It is straightforward to check that the transitive closure $\equiv$ of the contact relation is an equivalence relation. Every block $B$ of $\equiv$ is a set of pairwise disjoint intervals which are contacting consecutively; we say $B$ is linear. This allows us to compute the blocks of $\equiv$ efficiently. We can compute them in time $|I|$ and store them in space $|I|$ by using a greedy algorithm that iteratively extracts the inclusion-wise maximal intervals in $I$ that are contacting consecutively. We now show that the blocks of $\equiv$ group the edges of $E_I$ as desired.

\begin{lemma}
Two edges $e$ and $e'$ in $C_i$ form a 2-edge-cut if and only if $e$ and $e'$ are both contained in $E_B$ for some block $B$ of $\equiv$.
\end{lemma}

\begin{proof}
We prove the if statement. Let $B$ be a block of $\equiv$ such that $E_B$ contains $e$ and $e'$.

\end{proof}
According to Lemma 10, every interval-cut of an interval in $B$ is a 2-edge-cut. Since $B$ is linear, applying the observation to these cuts proves that also $\{e, e'\}$ is a 2-edge-cut.

We prove the only-if statement. Let $\{e, e'\}$ be a 2-edge-cut and assume to the contrary that there is no block $B$ of $E_B$ contains both $e$ and $e'$. According to Lemma 14, $e$ and $e'$ are contained in $E_I$. Thus, there are blocks $B$ and $B'$ of $E$ with $e \in E_B$ and $e' \in E_B$. For a block $B$, let $\text{pred}(B)$ and $\text{succ}(B)$ be the predecessor of the minimal vertex and the successor of the maximal vertex contained in an interval of $B$. W.l.o.g. let $|\{\text{pred}(B), \text{succ}(B)\}| \leq |\{\text{pred}(B'), \text{succ}(B')\}|$.

First assume neither $\text{pred}(B)$ nor $\text{succ}(B)$ are branch vertices. Since no vertex is of degree 2 and intervals do not share endpoints, there is an interval $I_1 \subset I$ that starts at $\text{pred}(B)$. Since $I$ is laminar, $I_1 \notin B$, and intervals do not share endpoints, $I_1$ contains $[\text{pred}(B), \text{succ}(B)]$. Similarly, there is an interval $I_2 \subset I$ (maybe identical to $I_1$) that ends at $\text{succ}(B)$ and contains $[\text{pred}(B), \text{succ}(B)]$.

Since $I_1$ represents a component of $H$, $G - e$ contains a path from $\text{pred}(B)$ to the other endpoint of $I_1$. Thus, $\{e, e'\}$ can only be a 2-edge-cut if $e'$ is contained in $I_1$. The same argument for $I_2$ gives that $e'$ must be contained in $I_2$ and we conclude that $e' \in I_1 \cap I_2 = [\text{pred}(B), \text{succ}(B)]$. This and the fact that $I$ is a laminar family implies that $[\text{pred}(B'), \text{succ}(B')]$ lies strictly inside $[\text{pred}(B), \text{succ}(B)]$, which contradicts $|\{\text{pred}(B), \text{succ}(B)\}| \leq |\{\text{pred}(B'), \text{succ}(B')\}|$.

If either $\text{pred}(B)$ or $\text{succ}(B)$ are branch vertices, the same argument applies if one takes $I_1 = [\text{pred}(B), t(C_i)]$, respectively $I_2 = [s(C_i), \text{succ}(B)]$. $\square$

### 11.3. An Incremental Cactus Construction

In this section we show how to construct a cactus representation incrementally along our algorithm for constructing a Mader sequence. At the beginning of each phase $i$, we will have a cactus for the graph $G'$ whose vertices are the branch vertices that exist at this time and whose edges are the links between these branch vertices.

We assume that $G$ is 2-edge-connected but not 3-edge connected and that $G$ has minimum degree three. This ensures that in phase $i$ every vertex on the current chain $C_i$ belongs to some segment or is a branch vertex.

We will maintain a cactus representation $(C, \phi)$, i.e., for every node $v$ of $C$, the blob $B = \phi^{-1}(v)$ is the vertex-set of a 3-edge-connected component in $G'$. We begin with a single blob that consists of the two branch vertices of the initial $K'_2$, which clearly are connected by three edge-disjoint paths.

Consider phase $i$, in which we add all chains whose source $s$-belongs to $C_i$. At the beginning of the phase, the endpoints of $C_i$ and some branch vertices on $C_i$ already exist in $G'$. We have a cactus representation of the current graph. The endpoints of $C_i$ are branch vertices and belong to the same blob $B$, since 2-edge-cuts are contained in chains.

We add all segments that do not induce cut edges and tentatively assign all vertices of $C_i$ to $B$. If the algorithm determines that $C_i$ does not contain any 2-edge-cut, the assignment becomes permanent, the phase is over and we proceed to phase $i + 1$. Otherwise we calculate the efficient representation of 2-edge-cuts on $C_i$ from Sect. 11.2.

Let $e_1$ be the first edge on $C_i$ in a 2-edge-cut, let $A$ be a block of the contact equivalence relation described in the last section containing $e_1$ and let $E_A = \{e_1, e_2, \ldots, e_\ell\}$ such that $e_j$ comes before
The segments attached to chain $C_i$ and the corresponding part of the cactus. We first tentatively assign vertices 1–7 to the blob containing the endpoints $\{0, 8\}$ of $C_i$. The top level cuts are the pairs in the block $\{a, f, h\}$. So we create a cycle with three edges and attach it to the blob containing 0 and 8. We move vertices 1–5 to the blob between $a$ and $f$, vertices 6–7 to the blob between $f$ and $h$, and keep vertices 0 and 8 in the parent blob. We then recurse into the first blob. The second level cuts are the pairs in the block $\{b, d\}$. So we create a cycle with two edges and move vertices 2 and 3 to the new blob.

For every pair $e_j = (a, b), e_{j+1} = (c, d)$ in $E_A$ we remove the vertices between these edges from $B$. Since the edges in $C_i$ are linearly ordered, removing the vertices in a subpath takes constant time. We place the end vertices $b$ and $c$ of the path between $e_j$ and $e_{j+1}$ in the blob $B_j$, add the segments that induced this cut and recurse on the path between $b$ and $c$. That is, we add all vertices on the path from $b$ to $c$ to $B_j$, check for cut edges on this path, and, should some exist, add more blobs to the cactus. The construction takes constant time per blob. Figure 5 shows an example.

Graphs that contain nodes of degree two can be handled in the same way, if we add a cycle to each degree two node $u$. This cycle creates a segment w.r.t. the chain to which $u$ $s$-belongs and hence the algorithm correctly identifies the two incident edges as cut edges.

**Lemma 16** The above incremental procedure constructs a cactus representation of the 2-edge-cuts in $G$ in linear time.

**Proof:** Each vertex in $G$ $s$-belongs to some chain. In the phase in which that chain is treated, all its vertices are added to a blob. Whenever we move a vertex to different blob, we remove it from its previous blob. Therefore each vertex of $G$ is contained in exactly one blob.

Whenever we add edges to the cactus, we do so by adding a cycle that shares but one node with the existing cactus. Hence every edge in the cactus lies on exactly one cycle.
Let \( \{e_1, e_2\} \) be a 2-edge-cut in \( G \). The two edges must lie on a common cycle in the cactus, since the edges in the cactus are in one-to-one correspondence with edges of \( G \) and cutting a cycle in only one place cannot disconnect a graph. As the cycles of the cactus touch in at most one vertex, \( e_1 \) and \( e_2 \) are a cut in the cactus as well.

Conversely let \( e_1', e_2' \) be a cut in the cactus. They must lie on some common cycle which, upon their removal, is split into two nonempty parts \( H_1 \) and \( H_2 \). Assume that \( G - e_1 - e_2 \) is still connected, then there must a path from a vertex in the preimage of \( H_1 \) to a vertex in the preimage of \( H_2 \) in \( G - e_1 - e_2 \). This path must contain at least one edge \( uv \) that does not participate in any 2-edge-cut, as otherwise it would be a path in the cactus as well. Moreover, \( u \) and \( v \) must lie in different blobs \( B_u \) and \( B_v \) of the cactus.

The one that was created last, say \( B_u \), must be different from the initial blob. Consider the time when \( B_u \) was created in the incremental construction of the cactus. We introduced a cycle to some preexisting blob \( B^* \) on which all edges were cut edges, in particular the two cut edges incident to \( B_u \). However, the edge \( uv \) still connects \( B_u \) to the rest of graph, since \( B_u \) also exists at this time, a contradiction. \( \square \)

12. Computing all 3-Vertex-Connected Components

By applying the idea of the last section, the certifying algorithm for 3-vertex-connectivity [25] (which is also based on chain decompositions) can be used to compute the 3-vertex-connected components of a graph. This has been conjectured in [24, p. 18] and yields a linear-time certifying algorithm to construct a SPQR-tree of a graph; we refer to [9, 11] for details about 3-vertex-connected components and SPQR-trees.

A pair of vertices \( \{x, y\} \) is a separation pair of \( G \) if \( G - x - y \) is disconnected. Similarly to the edge-connectivity case, it suffices to compute all vertices that are contained in separation pairs of \( G \) in order to compute all 3-vertex-connected components of \( G \). We assume that \( G \) is 2-vertex-connected and has minimum degree 3.

For a rooted tree \( T \) of \( G \) and a vertex \( x \in G \), let \( T(x) \) be the subtree of \( T \) rooted at \( x \). The following lemmas show that separation pairs can only occur in chains. Weaker variants of Lemma 18 can be found in [11, 30, 31].

**Lemma 17** Let \( T \) be a DFS-tree of a 2-connected graph \( G \) and \( r \) its root. For every vertex \( x \neq r \) and every \( t \in T(x) - x \), there is a path \( P \) from \( t \) to a vertex \( s \in G - T(x) \) such that \( P \) consists only of vertices in \( T(x) - x \cup s \).

**Proof:** Since \( G \) is 2-connected, \( G - x \) is connected. Hence, if \( T(x) - x \) is non-empty, there is a back-edge from a vertex \( s \in G - T(x) \) to some vertex \( t' \in T(x) - x \), which yields the desired path \( P \) for any choice of the vertex \( t \) in \( T(x) - x \). \( \square \)

**Lemma 18** Let \( T \) be a DFS-tree of a 2-connected graph \( G \) and \( \mathcal{C} \) be a chain decomposition of \( G \). For every separation pair \( \{x, y\} \) of \( G \), \( x \) and \( y \) are contained in a common chain \( C \in \mathcal{C} \).
We presented a certifying linear time algorithm for 3-edge-connectivity based on chain decompositions of graphs. It is simple enough for use in a classroom setting and can serve as a gentle introduction to the certifying 3-vertex-connectivity algorithm of [25]. We also provide an implementation in Python, available at [https://github.com/adrianN/edge-connectivity](https://github.com/adrianN/edge-connectivity).

Similarly to edge-connectivity, the connected components of the overlap graph for $C_i$ represent all vertices in separation pairs that are contained in $C_i$. The connected components of the overlap graph can be computed efficiently [23, Lemma 51]. After finding all these vertices for $C_i$, a simple modification allows the algorithm in [25, p. 508] to continue, ignoring all previously found separation pairs: For every separation pair $\{x, y\}, x < y$, that has been found when processing $C_i$, there is a vertex $s$ strictly between $x$ and $y$ in $C_i$. Furthermore, by doing a preprocessing [25, Property B, p. 508] one can assume that also $t(C_i) \rightarrow_T s(C_i)$ has an inner vertex $w$. We eliminate every separation pair $\{x, y\}$ after processing $C_i$ by simply adding the new back-edge $wv$ to $G$. As the new chain containing $vw$ is just an edge, this does not harm future processing steps.

According to Lemma [18], this gives all vertices in the graph that are contained in separation pairs. The 3-vertex-connected components can then be computed in linear time by iteratively splitting separation pairs and gluing together certain remaining structures, as shown in [9][11].

### 13. Conclusion

We presented a certifying linear time algorithm for 3-edge-connectivity based on chain decompositions of graphs. It is simple enough for use in a classroom setting and can serve as a gentle introduction to the certifying 3-vertex-connectivity algorithm of [25]. We also provide an implementation in Python, available at [https://github.com/adrianN/edge-connectivity](https://github.com/adrianN/edge-connectivity).

We also show how to extend the algorithm to construct and certify a cactus representation of all 2-edge-cuts in the graph. From this representation the 3-edge-connected components can be readily read off. The same techniques are used to find the 3-vertex-connected components using...
the algorithm from [25], and thus present a certifying construction of SPQR-trees.

Mader’s construction sequence is general enough to construct $k$-edge-connected graphs for any $k \geq 3$, and can thus be used in certifying algorithms for larger $k$. So far, though, it is unclear how to compute these more complicated construction sequences. We hope that the chain decomposition framework can be adapted to work in these cases too.

A. Computing a Spanning Subgraph of an Overlap Graph

We first assume that all endpoints are pairwise distinct. We will later show how to remove this assumption by perturbation.

For every interval $I = [a, b]$ define its set of left and right neighbors:

$L(I) = \{I' = [a', b'] : a < a' < b < b'\}$,

$R(I) = \{I' = [a', b'] : a < a' < b < b'\}$.

If the set of left neighbors is nonempty, let the interval $I' \in L(I)$ with the rightmost right endpoint be the immediate left neighbor of $I$. Similarly, if the set of right neighbors is nonempty, the immediate right neighbor of $I$ is the interval in $R(I)$ with the leftmost left endpoint.

**Lemma 19** The graph $G'$ formed by connecting each interval to its immediate left and right neighbor (if any) forms a spanning subgraph of the overlap graph $G$ and has exactly the same connected components.

**Proof:** Clearly, every edge of $G'$ is also an edge of $G$ and hence connected components of $G'$ are subsets of connected components of $G$.

For the other direction, assume $I$ and $I'$ are overlapping intervals that are not connected in $G'$. For which the left endpoint of $I$ is as small as possible. Then $a < a' < b < b'$, where $I = [a, b]$ and $I' = [a', b']$. Since $I' \in R(I)$, but $I$ and $I'$ are not connected, $I$ has an immediate right neighbor $J \neq I'$. The left endpoint of $J$ must thus be smaller than $a'$ and the right endpoint of $J$ must be larger than $b$ (since $I$ overlaps with $J$). If the right endpoint is smaller than $b'$, $J$ and $I'$ overlap. By repeating this argument for $J$ and $I'$, we must reach an interval $U = [c, d]$ containing $I'$. Thus

$a < c < a' < b < b' < d$.

Starting from $I'$ and going to left neighbors, we obtain in the same fashion an interval $U' = [c', d']$ with

$c' < a < a' < b < d' < b'$.

We conclude that $U'$ and $U$ overlap, but are not connected in $G'$. Since the left endpoint of $U'$ is to the left of the left endpoint of $I$, this contradicts the choice of $I$ and $I'$.

It is easy to determine all immediate right neighbors by a linear time sweep over all intervals. We sort the intervals in decreasing order of left endpoint and then sweep over the intervals starting with the interval with rightmost left endpoint. We maintain a stack $S$ of intervals, initially empty. If $I_i = [a_1, b_1], \ldots, I_k = [a_k, b_k]$ are the intervals on the stack with $I_i$ being on the top of the stack,
Algorithm 2 Finding a spanning forest of a overlap graph

procedure SP(I = \{[a_0, a'_0], \ldots, [a_\ell, a'_\ell]\})
