Single Top Production at Next-to-Leading Order in the Standard Model Effective Field Theory

Cen Zhang

Department of Physics, Brookhaven National Laboratory, Upton, New York, 11973, USA

Single top production processes at hadron colliders provide information on the relation between the top quark and the electroweak sector of the standard model. We compute the next-to-leading order QCD corrections to the three main production channels: $t$-channel, $s$-channel and $tW$ associated production, in the standard model including operators up to dimension-six. The calculation can be matched to parton shower programs and can therefore be directly used in experimental analyses.

The QCD corrections are found to significantly impact the extraction of the current limits on the operators, because both of an improved accuracy and a better precision of the theoretical predictions. In addition, the distributions of some of the key discriminating observables are modified in a nontrivial way, which could change the interpretation of measurements in terms of UV complete models.

Introduction. —At high-energy colliders, physics beyond the standard model (SM) is searched for either by looking for evidence of new particles or for deviations in the predicted interactions between the SM particles. In the latter effort the top quark plays a special role: thanks to its large mass it can naturally probe high scales and in particular the electroweak symmetry breaking sector. A general theoretical framework where the experimental information on the interactions and possible deviations can be consistently and systematically interpreted is provided by the SM effective field theory (SMEFT) approach [1, 5]. The SMEFT Lagrangian corresponds to that of the SM augmented by higher-dimensional operators that respect the symmetries of the SM. It provides a powerful approach to identify observables where deviations could be expected in the top sector [4–6]. Besides and more importantly, it allows a global interpretation of measurements coming from different processes and experiments [7–10], which can be consistently evolved up to new physics scales, and provide hints to specific models at high scales.

Given the results of the LHC run I [11], expectations from run II on the attainable precision of the top-quark couplings are very high. Theoretical predictions that are at least as accurate and precise as the experimental projections are thus required. This motivates the calculation of higher-order corrections. In this work, we focus on the single-top production processes. At the LHC, single-top production proceeds through three main channels: $t$-channel, $s$-channel and $tW$ associated production. They are ideal for probing the top-quark couplings to the electroweak sector of the SM, and can provide key and complementary information to that coming from top-quark decay. To this aim we promote the single-top predictions, for the first time, to next-to-leading order (NLO) in QCD in the SMEFT, and study their impact on the interpretation of measurements.

The main results of this work can be summarized as follows. First, we show that QCD corrections not only affect total cross sections and reduce their uncertainties, but also impact the distributions of key observables, in such a way that the interpretation of possible deviations from the SM would lead to quite different UV complete models. Moreover, these corrections cannot be captured by either the $K$-factors or the renormalization group (RG) improvements of the Wilson coefficients. Second, we demonstrate that a new type of scale uncertainty in EFT, coming from the running and mixing of dimension-six terms, needs to be considered and can be reduced by including QCD corrections. Finally, by matching our NLO computation to a parton shower (PS) program, predictions can be obtained through an event generator that can be used directly in experimental simulations, to design optimized analyses that can maximize the sensitivity to new physics.

Effective operators. —In the EFT approach deviations from the SM are captured by effective operators. Up to dimension six, four operators are relevant [4, 5, 12]:

\begin{align}
O_{\varphi Q}^{(3)} &= \frac{1}{2} y_t^2 \left( \varphi^+ \overleftrightarrow{D}_\mu \right) \left( \overline{Q}_i \gamma^\mu \tau^I Q_i \right) \\
O_{tW} &= y_t g_W \left( \overline{Q}_i \sigma^{\mu\nu} \tau^I t \right) \gamma_\mu W_\nu^I \\
O_{tG} &= y_t g_s \left( \overline{Q}_i \sigma^{\mu\nu} T^A t \right) \gamma_\mu G_\mu^A \\
O_{Q^{(3)}_{qQ,rs}} &= (\bar{q}_r \gamma_\mu \tau^I q_s) \left( Q_i \gamma^\mu \tau^I Q_i \right)
\end{align}

Here $q_r$ and $q_s$ are the quark doublet fields in the first two generations, while $Q$ is in the third generation. $r, s$ are flavor indices. $\varphi$ is the Higgs doublet. $g_W, g_Y$ and $g_s$ are the SM gauge coupling constants. $y_t$ is the top-quark Yukawa coupling, defined by its pole mass. The effective Lagrangian is

\begin{equation}
\mathcal{L}_{\text{eff}} = \mathcal{L}_{\text{SM}} + \sum_i \frac{C_i}{\Lambda^2} O_i + H.c.,
\end{equation}

where $\Lambda$ is the expected scale of new physics. $C_i$ is the coefficient to parametrize the deviation from $O_i$. In this work we assume flavor universality in the first two generations, defining $O_{\varphi Q}^{(3)} = O_{Q^{(3)}_{Q,11}} + O_{Q^{(3)}_{Q,22}}$. Dimension-six...
operators affect all three channels. Corresponding diagrams are shown in Fig. 1. The operators $O_{1G}$ and $O_{tW}$ have nonzero anomalous dimensions at $O(\alpha_s)$, given by $13[16]$

$$\frac{dC_i}{d\log \mu} = \frac{\alpha_s}{\pi} \gamma_{ij} C_j, \quad \gamma = \frac{1}{3} \left[ \begin{array}{ccc} 1 & 0 \\ 2 & 2 \end{array} \right]$$

This matrix controls the running and mixing of the operators and can be used to evolve them from scale $\Lambda$ down to the scales of the measurements.

Calculation.—The NLO automation is implemented and validated in the MadGraph5_AMC@NLO framework $17$, with the help of a series of packages, including FeynRules and NLOCT $18[24]$. A model in the Universal FeynRules Output format $20$ is built at NLO, allowing for simulating a variety of processes important for top-coupling measurements. In this work we only focus on single-top processes, but other promising (and more complicated) channels, such as $t\bar{t}Z$/W/γ and $tjZ/\gamma$, are all made available at NLO in EFT with PS. In Ref. $25$ we have discussed the physical results for $t\bar{t}Z$/W/γ processes. More details of this implementation will be presented in a separate work $26$.

We adopt $\overline{MS}$ with five-flavor running in $\alpha_s$ with the top-quark subtracted at zero momentum transfer $27$. Additional contributions to top-quark and gluon-field renormalizations and $\alpha_s$ renormalization from $O_{1G}$ are included $28$. For operator coefficients we use $\overline{MS}$ subtraction, with

$$C_i^0 \to Z_{ij} C_j(\mu')$$

$$= \left[ 1 + \frac{\alpha_s}{2\pi} \Gamma(1 + \varepsilon) \left( \frac{4\pi\mu^2}{\mu'^2} \right)^\varepsilon \frac{1}{\varepsilon} \frac{\mu^2}{\mu'^2} \right] C_j(\mu')$$

where the anomalous dimension matrix $\gamma$ is given in Eq. (6). UV counterterms needed in this work are computed using the above information. Note that with Eq. (7) the operators will run with $\mu'$ separately from the running of $\alpha_s$. This allows for the dynamical renormalization scale to be adopted without having to run the operator coefficients.

Results are presented in terms of operators defined at $\mu' = m_t$, i.e. the log terms from high scale, log($\Lambda/m_t$), are already resummed by evolving operators down to this scale using Eq. (6). Thus the NLO corrections presented here do not include any of such large log terms, and cannot be captured by the RG equations.

Total cross sections.—Cross sections, obtained at LO and NLO, can be parametrized as

$$\sigma = \sigma_{SM} + \sum_i \frac{1}{\Lambda^2} C_i(\mu')^2 + \sum_{i,j} \frac{1}{\Lambda^4} C_i C_j (\mu')^2 + \cdots$$

We work up to order $1/\Lambda^2$, and present results for $\sigma^{(1)}$, the interference between an operator $O_i$ and the SM. We use NNPDF2.3 parton distributions $29$. Input parameters are

$$m_t = 172.5 \text{ GeV} \quad m_Z = 91.1876 \text{ GeV} \quad (8)$$

$$\alpha(m_Z) = 1/127.9 \quad G_F = 1.16637 \times 10^{-5} \text{GeV}^{-2} \quad (9)$$

Central renormalization and factorization scales are fixed at $\mu_R = \mu_F = m_t$. To estimate theoretical uncertainties due to missing higher orders we perform variations with nine combinations of $(\mu_R, \mu_F)$, where $\mu_R, F$ can take values $mt/2, m_t$ and $2mt$.

Total cross sections (including top and antitop) at LHC 13 TeV are presented in Fig. 2. We plot the ratio between the interference cross section, $\sigma^{(1)}$, and SM NLO cross section, $r_i = \sigma^{(1)} / \sigma_{SM}^{NLO}$, for individual operators $O_i$ in all three channels. The ratio $r_i$ illustrates how sensitive a process is to a certain operator, and can be interpreted as the signal over background ratio. In the plot, scale uncertainties from the numerator are given, and in the lower panel we show the $K$-factor of each operator contribution. Improved accuracy is reflected by the $K$-factors, typically ranging from $\sim 10\%$ to $\sim 50\%$, and improved precision is reflected by the significantly reduced scale uncertainties. Furthermore, most NLO results are outside of the uncertainty range of corresponding LO results, indicating that QCD corrections are essential for a correct interpretation of measurements in terms of operators. For comparison, at 8 TeV the $t$-channel has been measured at better than $\sim 10\%$ level $30[34]$, and the $t + W$ channel is at about $20\%$ $32$. At the high-luminosity LHC the $t$-channel can reach $\sim 4\%$ $33$, while the $s$-channel may reach $\sim 15\%$ $34$. NNLO approximate QCD corrections are available for the SM predictions, and corresponding theoretical uncertainties are at the percentage level $35$.

NLO corrections already affect current bounds on the coefficients of the dimension-six operators. For illustration we perform two-operator fits, for $(O_{tQ}^{(3)}, O_{tW})$ and for $(O_{tQ}^{(3)}, O_{tQ}^{(3)})$, using cross sections available at the LHC at 8 TeV $30[32][36]$ with the state-of-the-art SM prediction $34$ and NLO EFT predictions from this work. Limits are improved thanks to better accuracy and precision, and can be clearly seen in Fig. 3. For comparison we also show current limits on $O_{tW}$ from decay measurements.
decayed keeping spin correlations [11]. In Fig. 4 we show the normalized distributions of the top-quark rapidity, \( y_t \), in \( t \)-channel single-top production, which is an efficient discriminating observable, and has been measured already [42, 10]. We can see that its distribution is more forward for \( O_{1W} \) rather central for \( O_{Q}^{(3)} \). The difference arises already at the parton level due to the Lorentz structure of \( O_{1W} \) suppressing the forward scattering amplitude [5], and it is diluted at NLO due to real corrections.

FIG. 4. Normalized rapidity distributions of the top quark in \( t \)-channel single-top production, from \( O_{1W} \) and \( O_{Q}^{(3)} \). Only the interference with the SM is included. Lower panel shows the K-factors of individual operators, with scale uncertainties.

Fig. 4 also explains why NLO corrections are important when shape information is used. It makes both distributions more central, and missing this correction would lead to an underestimate of the size of the \( O_{1W} \) contribution on one hand and a corresponding overestimate of \( O_{Q}^{(3)} \) on the other. We find that other variables, including \( p_T \) and rapidity of the first non-\( b \)-jet and of the first \( b \)-jet, are affected in a similar way. Moreover, the theory uncertainty in shapes due to missing QCD is not captured by varying \( \mu_R \) and \( \mu_F \). We thus conclude that NLO QCD corrections can lead to bias in an EFT analysis, by shifting the theoretical predictions for the shapes of discriminating observables.

To quantify this effect, we consider two benchmark points, (1): \( C_{Q}^{(3)} = 0.8, C_{1W} = 2 \), and (2): \( C_{Q}^{(3)} = -1.1, C_{1W} = -1.4 \), each corresponding to about a 15% deviation in the total cross section. We compute at NLO the distributions of two observables, \( y_t \) and \( p_T \) of the first non-\( b \)-jet, and use the results as pseudodata, which we consider in 5 bins for \( p_T \) from 20 to 180 GeV and 6 bins for \( |y_t| \) from 0 to 3. We then perform \( \chi^2 \) fits with LO

---

**FIG. 3.** 95% limit from single-top measurements, with LO or NLO predictions for EFT. Left: \( (O_{Q}^{(3)}, O_{1W}); \) right: \( (O_{Q}^{(3)}, O_{Q}^{(3)}) \). Limits from top decay measurements are compared.

**Distributions.**—The QCD corrections have more crucial effects on the shapes of observables that can be used to identify deviations. Some key observables have very distinct distributions that depend on the relative contribution from different operators. If any deviation in total cross section is observed, these observables will determine which operator is the source of the deviation. Even without any deviation, including these observables in a global analysis can help to constrain flat directions.

In our approach, distributions can be obtained at NLO in QCD with PS simulation [23, 30], and with top quarks
and NLO predictions respectively and compare. Results depend on the combined uncertainty of experiment and theory. Current data at LHC 8 TeV correspond to ~10% uncertainty in each bin. Foreseeing future improvements in the analyses, we assume ~5% uncertainty in each bin and we find that the operator coefficients extracted from the fit are shifted by NLO effects. This is shown in Fig. 5.

The dotted contours in Fig. 5 represent a constant deviation in the cross section. Cross section measurements constrain the direction orthogonal to these contours. On the other hand, including shape information constrains the direction along these lines. The bias induced by QCD corrections is reflected by the dashed and the solid arrows, which represent the resulting deviations from the fit, at LO and NLO respectively. For example, in the second scenario the central values of coefficients extracted at LO are (−1.5, −0.18), and become (−1.1, −1.4) at NLO, and the one-sigma regions have almost no overlap. This shift is not in the radial direction corresponding to an overall rescale by the NLO K-factor. Rather, it leads to a different direction of deviation in the $C_{tW} − C_{tW}$ plane, as clearly indicated by the angle between the dashed and the solid arrows.

At this point it is important to note that the two operators, $O_{tW}$ and $O_{tG}$, correspond to different types of new physics. The first operator is likely to be generated by mixing SM particles with heavy objects such as $W’$ and heavy quarks; the second one is loop induced, and typical scenarios include two-Higgs-doublet models and supersymmetric models.

It follows that a missing QCD correction will lead us to an incorrect conclusion about the type of UV physics.

To sum up, there are two kinds of QCD NLO effects for single-top processes. The first is on total cross sections. It can be captured by applying a $K$-factor to LO results, and only affects the magnitude of deviation from the SM. The second is on the shapes of discriminator observables. It cannot be captured by a simple $K$-factor, and it affects the direction in which new physics deviates from the SM. Hence it is important because if deviations are observed in the single-top channel, missing such corrections would lead us to misinterpret measurements of possible deviations and misconclude the nature of UV physics.

**EFT scale uncertainties.**—Perturbative calculations performed in SMEFT suffer from a new source of scale uncertainty: the running and mixing of operator coefficients. In our calculation operators are defined at a scale $\mu'$, separately from $\mu_R$ and $\Lambda$. This allows us to study this uncertainty alone, independent of the usual renormalization and factorization scale uncertainties.

This uncertainty can be estimated with $\sigma^{(1)}(\mu', \mu_0) \equiv \Gamma(\mu', \mu_0) \sigma^{(3)}(\mu');$ i.e., the operator contributions at $\mu'$ evolved back to central scale $\mu_0$. Here $\Gamma_{ij}$ is the solution to the RG equations:

$$\Gamma_{ij}(\mu', \mu_0) = \exp\left(-\frac{2}{\beta_0} \log \frac{\alpha_s(\mu')}{\alpha_s(\mu_0)} \gamma_{ij}\right),$$

with $\beta_0 = 11 - 2/3n_f$, and $n_f = 5$ is the number of running flavors.

For illustration, we present the scale variation in the $tW$ associated channel. This process involves both $O_{tW}$ and $O_{tG}$ already at the tree level, so both the running and the mixing effects are observable. In Fig. 6 we show the $\mu'$ dependence of the dimension-six contribution from $O_{tW}$ and $O_{tG}$, where we choose $\mu'_0 = m_t$ as the central scale, and vary $\mu'$ from $m_t/10$ to 2 TeV, fixing $\mu_R$ and $\mu_F$. It is clear from the plot that this kind of scale dependence can be reduced at NLO, indicating that the leading QCD log terms from the running and mixing of operator coefficients are cancelled by NLO corrections. We should point out that there are cases where mixing effects are much more important than the presented example in Fig. 6, but the latter is a proof of principle that the related EFT scale uncertainties can be taken under control by including the full NLO corrections.

Finally, it is worth pointing out that the RG equations for operators cannot capture the dominant NLO corrections. From the plot we can see that the RG correction to $O_{tW}$ from high scale $\Lambda$ down is negative, while the complete NLO correction gives a sizeable increase. A reliable result can only be obtained by carrying out the complete NLO computation. A similar observation in the context of Higgs physics has been pointed out by the authors of Ref. 61, 62.
Summary.—We have presented predictions for single-top processes at NLO with PS in SMEFT. Bounds on higher-dimensional operators are improved thanks to better accuracy and precision. More importantly, QCD corrections lead to nontrivial modifications to the shapes of the most powerful discriminating observables. If new physics shows up in single-top processes, missing such corrections would change the interpretation of the measurements and lead us to bias our interpretations in terms of new physics models. We have also demonstrated that the scale uncertainties associated with the running and mixing of operator coefficients should be considered, and can be reduced by including NLO corrections.

Our results should be used in experimental simulations, as they are important for interpreting measurements, and are available as an NLO+PS event generator. With more accurate and precise EFT simulation and uncertainties under control, SM deviations can now be analyzed in a top-down way, designing new analyses to maximize sensitivity and allowing for a more efficient approach to the study of the top-quark interactions.

I would like to thank F. Maltoni for constantly supporting projects on EFT at NLO in QCD. I am grateful for valuable discussions with S. Dawson and M. Selvaggi. I would like to thank E. Vryonidou for pointing out typos. This work is supported by U.S. Department of Energy under Grant No. [de-sc0012704].
