Introduction

Unileaflet mitral valve is the rarest of congenital mitral valve anomalies and is usually life threatening in infancy due to severe mitral regurgitation (MR). In most asymptomatic individuals, it is mostly due to hypoplastic posterior mitral leaflet. We present a 22-year-old male with palpitations, who was found to have an echocardiogram revealing an elongated anterior mitral valve leaflet with severely hypoplastic posterior mitral valve leaflet appearing as a unileaflet mitral valve without MR. Our case is one of the 11 reported cases in the literature so far. We hereby review those cases and conclude that these patients are likely to be at risk of developing worsening MR later in their lives.

Discussion

Congenital malformations of the mitral valve are extremely rare and include congenital mitral stenosis, parachute mitral valve, double orifice of the mitral valve, cleft mitral valve, atresia, and unileaflet mitral valve. Unileaflet mitral valve is the rarest of these congenital anomalies. Aplasia of the posterior mitral valve leaflet is responsible for unileaflet mitral valve in the neonatal period and associated with severe MR that is usually incompatible with life without surgical intervention. Existing literature in the field documents cases of unileaflet mitral valve in asymptomatic patients of all age groups and mostly result from a severely hypoplastic posterior mitral valve. The prevalence of this anomaly is estimated to be 1:8800 in the German population; however, the true prevalence is expected to be much lower in the general population.

To the best of our knowledge, there have only been 11 reported cases of post-neonatal unileaflet mitral valve in the literature, of which 70% of cases were found to be in asymptomatic patients. The majority of cases were found after detection of a systolic murmur during routine physical examination. In the aforementioned cases, transthoracic echocardiography (TTE) revealed a thickened and elongated anterior mitral valve with significant prolapse into the left atrium. In two of the cases,
patients developed severe MR and underwent surgical correction and were found to have hypoplasia of the posterior mitral valve with absence of the chordae tendinae.\textsuperscript{4,6} It was also suggested that 3D echocardiography with transesophageal echocardiography (TEE) outlines the congenital abnormalities of mitral valve better than TTE or only TEE.\textsuperscript{11}

The prognosis in asymptomatic individuals is unclear; however, there is a potential for worsening MR with age due to annular dilation. There are no guidelines or recommendations currently for screening or follow-up monitoring of these patients. In our opinion, it may be appropriate to follow-up such patients with annual physical examinations and perform echocardiography if symptoms develop or MR murmur develops/worsens.

In conclusion, hereby we present a rare case of unileaflet mitral valve and review not only the importance of echocardiography in accurate diagnosis, but also highlight the importance of periodic surveillance with echocardiography in early detection of MR in such cases.
