One-dimensional models are not only prime toys for theoretical physicists but also allow for deep physical insights. For instance, in solid state physics lattice models describe the behavior of metals quite accurately [1, 2]. Over the years these models have been refined and augmented to address different phenomena, such as the dynamics of atoms in optical lattices and the Anderson localization in systems with energetic disorder [3]. Classical one-dimensional models allow to address various aspects of normal and anomalous diffusion [4].

The simplest model describing a particle moving on a regular structure assumes only jumps from one position $j$ to its nearest neighbors (NN) $j \pm 1$. The tight-binding approximation for such systems is equivalent to the so-called continuous-time quantum walks (CTQW), which model quantum dynamics of excitations on networks [5, 6, 7]. Recently, there have been several experimental proposals addressing CTQW in various types of systems, ranging from microwave cavities [8], waveguide arrays [9], atoms in optical lattices [10, 11], or structured clouds of Rydberg atoms [12]. A large class of these systems do not show NN steps. Consider, for instance, a chain of clouds of Rydberg atoms where each cloud can contain only one excitable atom due to the dipole blockade [12, 13]. The excited atoms of different clouds interact via long-range couplings decaying as $R^{-3}$, where $R$ is the distance between different clouds.

The dynamics of excitations can be efficiently described by continuous-time random walks [14]. Here, is has been shown that CTRW in one dimension with step lengths decaying as $R^{-\gamma}$ belong only to the same universality class if $\gamma > 3$. Those CTRW show normal diffusion, whereas CTRW with $\gamma < 3$ show anomalous diffusion as, e.g., Lévy flights. The reason is that the for $\gamma < 3$ the second moment of the step-length distribution $\langle R^2 \rangle$ diverges [12, 15].

In the following we will consider in one dimension the dependence of the dynamics of excitations on the range of the step length. We restrict ourselves to the extensive cases, i.e., we explicitly exclude ultra-long range interactions, where the exponent $\gamma$ of the decay of the step length is smaller than the dimension ($\gamma < d$, $\gamma = d$ is the marginal case); thus we take here $\gamma \geq 2$. The effect of ultra-long range interactions on the thermodynamics and dynamics of regular one-dimensional lattices has been studied numerically before [16].

Our analysis is based on the density of states (DOS) of the corresponding Hamiltonian. The DOS contains the essential information about the system and allows to calculate various dynamical quantities, such as the probability to be at time $t$ at the initially excited site.

The coherent dynamics of excitons on a graph of connected nodes is modeled by CTQW, which follows by identifying the Hamiltonian $H$ of the system with the CTRW transfer matrix $T$, i.e., $H = -T$; see e.g. [3, 8] (we will set $\hbar = 1$ in the following). For NN step lengths and identical transfer rates, $T$ is related to the connectivity matrix $A$ of the graph by $T = -A$. In the following, we will consider one-dimensional networks with periodic boundary conditions (i.e., a discrete ring). Here, when the interactions go as $R^{-\gamma}$, with $R = |k - j|$ being the (on the ring minimal) distance between two nodes $j$ and $k$, the Hamiltonian has the following structure:

$$H_\gamma = \sum_{n=1}^{N} \sum_{R=1}^{R_{\text{max}}} R^{-\gamma} \left( 2|n\rangle\langle n| - |n - R\rangle\langle n| - |n + R\rangle\langle n| \right),$$

where $R_{\text{max}}$ is a cut-off for finite systems. Note, that in the infinite system limit we first take $N \to \infty$ before taking also $R_{\text{max}} \to \infty$. For the cases considered here, namely $\gamma \geq 2$ and $N$ of the order of a few hundred nodes, a resolvable cut-off is $R_{\text{max}} = N/2$, which is also the largest distance between two nodes on the discrete ring. In this way, to each pair of sites a single (minimal) distance and a unique interaction is assigned.

The states $|j\rangle$ associated with excitons localized at the nodes $j = 1, \ldots, N$ form a complete, orthonormal basis set (COBS) of the whole accessible Hilbert space, i.e., $\langle k|j\rangle = \delta_{kj}$ and $\sum_k |k\rangle\langle k| = 1$. In general, the transition amplitudes from state $|j\rangle$ to state $|k\rangle$ during $t$ and the corresponding probabilities read $\alpha_{kj}^{(\gamma)}(t) \equiv \langle k| \exp(-iH_\gamma t)|j\rangle$ and $\eta_{kj}^{(\gamma)}(t) \equiv \left| \alpha_{kj}^{(\gamma)}(t) \right|^2$, respectively. In the classical CTRW case the transition probabilities obey a master equation and can be expressed as $p_{kj}^{(\gamma)}(t) = (k| \exp(T_\gamma t)|j\rangle$ [5, 6].

For all $\gamma$, the time independent Schrödinger equation $H_\gamma |\Phi_\theta\rangle = E_\gamma(\theta)|\Phi_\theta\rangle$ is diagonalized by Bloch states $|\Phi_\theta\rangle = N^{-1/2} \sum_{j=1}^{N} \exp(i\theta j)|j\rangle$. One obtains the eigenvalues

$$E_\gamma(\theta) = \sum_{R=1}^{R_{\text{max}}} R^{-\gamma} \left[ 2 - 2 \cos(\theta R) \right].$$

Universal Behavior of Quantum Walks with Long-Range Steps

Oliver Müllken, Volker Pernice, and Alexander Blumen

Theoretische Polymerphysik, Universität Freiburg, Hermann-Herder-Straße 3, 79104 Freiburg, Germany

(Dated: February 2, 2008)

Quantum walks with long-range steps $R^{-\gamma}$ ($R$ being the distance between sites) on a discrete line behave in similar ways for all $\gamma \geq 2$. This is in contrast to classical random walks, which for $\gamma > 3$ belong to a different universality class than for $\gamma \leq 3$. We show that the average probabilities to be at the initial site after time $t$ as well as the mean square displacements are of the same functional form for quantum walks with $\gamma = 2, 4$, and with nearest neighbor steps. We interpolate this result to arbitrary $\gamma \geq 2$. PACS numbers: 05.60.Gg, 05.60.Cd, 03.67.-a, 71.35.-y
In the limit $N \rightarrow \infty$ the $\theta$-values are quasi-continuous. \nThen, the density of states (DOS) $\rho_\gamma(E)$ is obtained by inverting Eq. (3) \nand taking the derivative with respect to $E_\gamma$. \nIn the NN-case ($\gamma = \infty$) only the first term in Eq. (2), \n$R = 1$, contributes. From this we get the known DOS \n$\rho_\infty(E) = (\pi \sqrt{4E - E^2})^{-1}$. \nFor $\gamma = 2$ we can approximate the sum by letting $R_{\rm max} \rightarrow \infty$, \nwhich yields $E_2(\theta) = \pi \theta - \theta^2/2$ (see Eq. 1.443.3 of \n[17]). By inverting this and assuming $\theta$ to be \ninfinite one obtains $\rho_2(E) = (\pi \sqrt{2})^{-1}$. \nIn the intermediate range we have a \nanalytic solution for $\gamma = 4$, namely we have $E_4(\theta) = \theta^4/24 - \pi \theta^3/6 + \pi^2 \theta^2/6$ (see Eq. 1.443.6 of \n[17]), which yields \n$\rho_4(E) = [2 \pi (2/3)^{1/4} \sqrt{E(\pi^2/24) - E^3/2}]^{-1}$. \n
In order to interpolate between $\rho_2(E)$ and $\rho_\infty(E)$ to \narbitrary values of $\gamma \in [2, \infty]$ we assume the following general \nform for the DOS: \n
$$\rho_\gamma(E) \sim \left\{ \begin{array}{ll} \sqrt{c_\gamma \alpha - E} \quad & \alpha \in [0, 1] \quad \beta \in [1, 2] \quad \gamma > 3 \\
E^{-\alpha/2} \quad & \alpha < 1 \quad \left( 2 \leq \gamma \leq 3 \right) \end{array} \right. \quad (4)$$

from which we observe the distinction between $\gamma$-values \nlarger and smaller than three. For the band edge $\theta = \pi$, i.e., \n$E \approx E_{\rm max}$, it is straightforward to show that $\rho(E) \sim \left( E_{\rm max} - E \right)^{-1/2}$ for all $\gamma \geq 2$. The behavior of Eq. (4) \nfor small $E$ is in line with previous studies [19], in which the \nDOS goes as $\rho(E) \sim E^n$, where $n = -1/2$ for $\gamma > 3$ \nand $n = -(\gamma - 2)/(\gamma - 1)$ for $2 \leq \gamma < 3$. \nStarting from the two limiting cases $\gamma = 2$ and $\gamma = \infty$ and supported by \nthe $\gamma = 4$ case, Eq. (3) appears as a natural candidate for a generalized \nDOS.

Figure 1 shows a comparison of the DOS obtained from \nthe numerical diagonalization of $H_1$ for $N = 10000$ with $\gamma = 2, \n3, 4,$ and $\infty$ (solid black curves) with the exact expressions \nfor $\rho_2(E)$, $\rho_4(E)$, and $\rho_\infty(E)$, see above, as well as a fit for \n$\rho_3(E)$. The values of $\alpha$ and $\beta$, extracted from fits to the \nnumerical DOS for various values of $\gamma$, are given in the inset of \nFig. 1. Clearly, for $\gamma \geq 4$ we have $\alpha = 1$, while $\beta \in [1, 2]$. \nFor $\gamma = 2$, the values of $\alpha$ and $\beta$ drop to $\alpha = 0$ and $\beta = 1$, \nrespectively.

CTRW with step widths distributed according to $R_\gamma$ belong to \nthe same universality class for $\gamma > 3$, the mean square \ndisplacement (MSD) going as $\left\langle R^2_\gamma \right\rangle \sim t$, i.e., showing \nnormal diffusion, see e.g. [14]. For $\gamma \leq 3$ the second moment of \nthe distribution diverges, which leads to a MSD showing anomalous diffusion.

Another way to see this is using the average probability to be \nthe initial site at time $t$, $p_\gamma(t)$. Classically one has a simple \nexpression for $p_\gamma(t)$ [20, 21],

$$p_\gamma(t) \equiv \frac{1}{N} \sum_{j=1}^{N} p_{\gamma,j}(t) = \frac{1}{N} \sum_{\theta} \exp[-E_\gamma(\theta)t], \quad (5)$$

which depends only on the eigenvalues but not on the eigenvectors. \nIn the quantum case, the corresponding expression is \n$p_\gamma(t) \equiv \frac{1}{N} \sum_{j=1}^{N} p_{\gamma,j}(t)$. For the discrete ring, we get \n
$$p_\gamma(t) = |\pi_\gamma(t)|^2 = \frac{1}{N} \sum_{\theta} \exp[-iE_\gamma(\theta)t] = \pi_\gamma(t)$$

which also depends only on the eigenvalues. Note that for \nmore complex networks the right-hand-side of Eq. (6) is only \nlower bound to $p_\gamma(t)$ [22]. In the continuum limit, Eqs. (5) \nand (6) can be written as \n
$$p_\gamma(t) = \int dE \rho_\gamma(E) \exp(-Et), \quad (7)$$

$$\pi_\gamma(t) = \left| \int dE \rho_\gamma(E) \exp(-iEt) \right|^2. \quad (8)$$

Having the DOS at hand the integrals in Eqs. (7) and (8) \ncan be calculated - at least asymptotically - for large $t$. In the \nclassical case Eq. (7) will be dominated by small values of $E$ \nwhen $t$ becomes large, see Eq. (4). From the DOS we obtain \n
$$p_\gamma(t) \sim \left\{ \begin{array}{ll} t^{-1/2} \quad & \alpha = 1 \\
\nu^3/2 - 1 \quad & \alpha < 1. \end{array} \right. \quad (9)$$

Quantum mechanically, some care is in order. Here, the \nassumption that $\pi_\infty(t)$ will be dominated by small values of $E$ \nfor large $t$ is not applicable, due to the oscillating exponential \nin Eq. (5). For the NN-case we know that $\pi_\infty(t) \sim t^{-1}$, see \nfor instance [22]. Considering now the other limiting case
\[ \gamma = 2 \text{ we have} \]
\[
\mathcal{P}_2(t) = \left| \int_0^{\pi^2/2} dE \exp(-iEt) \sqrt{\pi^2/2 - E} \right|^2 
= \left| \int_0^{\pi^2/2} dE \exp(-iEt) \sqrt{2\pi} \right|^2 t^{-1}, \tag{10}
\]
where we substituted \( \epsilon \equiv \pi^2/2 - E \). Note that for \( t \gg 1 \), Eq. (10) approaches \( \mathcal{P}_2(t) \approx (2\pi t)^{-1} \). Thus, the dependence of \( \mathcal{P}_2(t) \) on \( t \) is the same as for \( \mathcal{P}_\infty(t) \). This suggests that for all one-dimensional lattices with extensive (\( \gamma \geq 2 \)) interactions the long time dynamics of the excitations is similar, no matter how long- or short-range the step lengths are. This is in contrast to the classical case, where only CTRW with \( \gamma > 3 \) belong to the same universality class.

![FIG. 2: (Color online) (a) Classical \( \mathcal{P}_\gamma(t) \) and (b) corresponding MSD; (c) quantum mechanical \( \mathcal{P}_\gamma(t) \) and (d) corresponding MSD (right) for a discrete ring with \( N = 10000 \) nodes with \( \gamma = 2, 3, 4, \) and \( \infty \).]

To test this we calculated numerically for a discrete ring of \( N = 10000 \) nodes \( \mathcal{P}_\gamma(t) \) and \( \mathcal{P}_\gamma(t) \) for different \( \gamma \); the results are shown in Fig. 2. Clearly, \( \mathcal{P}_\gamma(t) \) changes when increasing the step width from NN steps (\( \gamma = \infty \)) to long-range steps distributed as \( R^{-2} (\gamma = 2) \), see Fig. 2(a). While \( \mathcal{P}_\gamma(t) \) for \( \gamma > 3 \) decays as \( t^{-1/2} \), the power law changes to \( t^{-1} \) for \( \gamma = 2 \). In contrast, the decay of the maxima of the quantum return probability \( \mathcal{P}_\gamma(t) \) follows \( t^{-1} \) for all \( \gamma \), Fig. 2(c). Long-range steps lead only to a damping of the oscillations and to an earlier interference once the excitation has propagated halfway around the ring.

The classical and quantum MSD corroborate these findings, see Figs. 2(b) and 2(d). Now, the MSD for CTRW/CTQW on the discrete ring with initial site \( j \) are given by
\[
\langle R^2(t) \rangle_{\text{cl}, \text{qm}} = \frac{1}{N} \sum_{k=1}^{N} |k-j|^2 \mathcal{P}_{k,j}(t), \tag{11}
\]
where \( \mathcal{P}_{k,j}(t) = p_{k,j}(t) \) for CTRW and \( \mathcal{P}_{k,j}(t) = \mathcal{P}_{k,j}(t) \) for CTQW. Now, decreasing \( \gamma \) has huge effects on the classical MSD. For \( 2 \leq \gamma < 3 \) the MSD starts to diverge, which in the case of finite networks is reflected in the fact that the MSD is of the order of \( N \) already for very short times. Increasing \( \gamma \) to values larger than 3 leads to the expected diffusive behavior \( \langle R^2(t) \rangle_{\text{cl}} \sim t \) for \( \gamma > 3 \). The quantum MSD, on the other hand, do not diverge for all \( \gamma \)-values considered here. All step lengths lead to the same qualitative behavior, \( \langle R^2(t) \rangle_{\text{qm}} \sim t^2 \).

Figure 2 also shows that the MSD can be related to \( \mathcal{P}_{\gamma}(t) \) and \( \mathcal{P}_{\gamma}(t) \), through:
\[
\langle R^2(t) \rangle_{\text{cl}, \text{qm}} \sim \left\{ \frac{\mathcal{P}_{\gamma}(t)}{\mathcal{P}_{\gamma}(t)} \right\}^{-2} \tag{12}
\]
for \( \gamma > 3 \) in the classical and \( \gamma \geq 2 \) in the quantal case. This generalizes previous (classical) results, obtained for regular networks with NN-steps [20], to the quantum case and to long-range steps.

We can now underline our results by analytically evaluating \( \langle R^2(t) \rangle [\text{Eq. (5)}] \) using the stationary phase approximation (SPA) [23]. We expect in general \( E_\gamma(\theta) \) to be a smooth real-valued function on the interval \( \theta = [0,2\pi] \). For large \( N \), we write \( \mathcal{P}_{\gamma}(t) [\text{Eq. (6)}] \) in the integral form
\[
\mathcal{P}_{\gamma}(t) = \frac{1}{2\pi} \int_0^{2\pi} d\theta \exp(iE_\gamma(\theta)t) \tag{13}
\]

The SPA asserts now that the main contribution to this integral comes from those points where \( E_\gamma(\theta) \) is stationary \( dE_\gamma(\theta)/d\theta \equiv E_\gamma''(\theta) = 0 \). If there is only one point \( \theta_0 \) for which \( E_\gamma'(\theta_0) = 0 \) and \( d^2E_\gamma(\theta)/d\theta^2 |_{\theta=\theta_0} = E_\gamma''(\theta_0) \neq 0 \) one gets, see [23],
\[
\mathcal{P}_{\gamma}(t) \approx \frac{1}{\sqrt{2\pi|E_\gamma''(\theta_0)|}} \exp \left( i \left( tE_\gamma(\theta_0) + \pi/4 \text{sgn}[E_\gamma'(\theta_0)] \right) \right)
\]

such that
\[ \mathcal{P}_{\gamma}(t) = |\mathcal{P}_{\gamma}(t)|^2 \approx \frac{1}{2\pi t|E_\gamma''(\theta_0)|} \sim t^{-1}. \tag{14} \]

For the infinite one-dimensional regular network [see Eq. (2), where \( N \to \infty \) and \( R_{\text{max}} \to \infty \)] and for \( \gamma = 2 \), \( E_2(\theta) \) (see above) has only one stationary point in \( \theta \in [0,2\pi] \), namely \( \theta_0 = \pi \). Then \( E_2(\pi) = \pi^2/2 \) and \( E_2''(\pi) = -1 \), leading to \( \mathcal{P}_{\gamma}(t) \approx (2\pi t)^{-1} \), which does not show any oscillations and coincides with the long time limit of Eq. (10).

For \( \gamma > 2 \), \( E_\gamma(\theta) \) [see Eq. (2)] has two stationary points in the interval \( \theta \in [0,2\pi] \), namely \( \theta_0 = 0 \) and \( \theta_0 = \pi \). Then \( \mathcal{P}_{\gamma}(t) \) is approximately given by the sum of the contributions [each being of the form given in Eq. (13)] of the two stationary points. One easily verifies from \( E_\gamma''(0) = 2 \sum_{R} \cos(\theta R)/R^2 \) that \( \text{sgn}[E_\gamma''(0)] = 1 \) and \( \text{sgn}[E_\gamma''(\pi)] = -1 \). Consequently, we obtain
\[
\mathcal{P}_{\gamma}(t) = |\mathcal{P}_{\gamma}(t)|^2 \approx \frac{1}{2\pi t} \left( \frac{1}{|E_\gamma''(0)|} + \frac{1}{|E_\gamma''(\pi)|} \right) + \frac{2 \cos \left[ t\left( E_\gamma(0) - E_\gamma(\pi) \right) + \pi/2 \right]}{\sqrt{|E_\gamma''(0)E_\gamma''(\pi)|}} \sim t^{-1}. \tag{15}
\]
The results for the infinite system and arbitrary $\gamma > 2$ are readily obtained: for $\theta_0 = 0$ we have $E_\gamma(0) = 0$ for all $\gamma$ and $E_\gamma''(0) = 2\zeta(\gamma - 2)$, where $\zeta(\gamma) \equiv \sum_{\gamma=1}^{\infty} R^{-\gamma}$ is the Riemann zeta function, Eq. 23.2.1 of [18]. For $\theta_0 = \pi$ we get $E_\gamma(\pi) = E_{\gamma,\text{max}}$ and $E_\gamma''(\pi) = 2\eta(\gamma - 2) = (2 - 2^{\gamma - 1})\zeta(\gamma - 2)$, where $\eta(\gamma) \equiv \sum_{\gamma=1}^{\infty} (-1)^{\gamma - 1} R^{-\gamma}$, Eq. 23.2.19 of [18]. Hence

$$
\pi_\gamma(t) \approx \frac{1}{4\pi t} \left\{ \frac{1}{|\zeta(\gamma - 2)|} + \frac{1}{|\eta(\gamma - 2)|} - \frac{2 \cos[t E_\gamma(\pi) + \eta/2]}{\sqrt{|\zeta(\gamma - 2)|}} \right\}. \tag{16}
$$

For $\gamma = 3$, this yields $\pi_3(t) \approx [2\pi \ln(2)t]^{-1}$, which also does not show any oscillations. Comparing Eq. (16) for $\gamma = \infty$ to the long-time of the exact solution [22], we have $\pi_\infty(t) \approx [2 - 2\cos(4t + \pi/2)]/(2\pi t) = \sin^2(2t + \pi/4)/\pi t$, which is exactly the asymptotic expansion of $\pi_\infty(t) = |J_0(2t)|^2 \approx \sin^2(2t + \pi/4)/\pi t$, where $J_m(2t)$ is the Bessel function of the first kind [18,22].

For $\gamma = 2$ and large $t$, the oscillations of the exact $\pi_2(t)$ have practically vanished and $\pi_2(t) \approx (2\pi t)^{-1}$. The SPA for $\gamma = 3$ still shows oscillations because $E_3''(0) < \infty$. Increasing $\gamma$ further leads to an even better agreement of the SPA with the numerically evaluated decay.

In conclusion, we have analyzed the quantum dynamics of excitations on discrete rings under long-range step lengths, distributed according to $R^{-\gamma}$. For specific cases, we calculated the DOS analytically and interpolated to arbitrary step length ranges. The analytically obtained DOS enabled us to analytically calculate the average probability to be at the initial site at $t$, which we related to the mean square displacement at time $t$. The classical MSD show that only CTRW with $\gamma > 3$ belong to the same universality class, displaying normal diffusion. In contrast, the quantal MSD increase as $t^2$ for all extensive cases, $\gamma \geq 2$. Analytic calculations of the probability to be at the initial node within the stationary phase approximations confirm these findings.

Support from the Deutsche Forschungsgemeinschaft (DFG) and the Fonds der Chemischen Industrie is gratefully acknowledged.
