DIMENSIONAL SPLITTING OF HYPERBOLIC PARTIAL DIFFERENTIAL EQUATIONS USING THE RADON TRANSFORM

DONSUB RIM*

Abstract. We introduce a dimensional splitting method based on the intertwining property of the Radon transform, with a particular focus on its applications related to hyperbolic partial differential equations (PDEs). This dimensional splitting has remarkable properties that make it useful in a variety of contexts, including multi-dimensional extension of large time-step (LTS) methods, absorbing boundary conditions, displacement interpolation, and multi-dimensional generalization of transport reversal [31].

1. Introduction. Dimensional splitting provides the simplest approach to obtaining a multi-dimensional method from a one-dimensional method [26, 34, 23]. Although extremely powerful, existing splitting methods do not preserve a special feature that is easily obtained for 1D methods. For 1D hyperbolic partial differential equations (PDEs) of the type

\[ q_t + A q_x = 0 \]  

where \( A \) is a constant diagonalizable matrix with real and distinct eigenvalues, one can devise large time-step (LTS) methods that allow the solution to be solved up to any time without incurring excessive numerical diffusion [19, 21, 20]. Previous splitting methods do not lead to such LTS methods in multi-dimensions.

In this paper, we introduce a dimensional splitting method that allows multi-dimensional linear constant coefficient hyperbolic problems to be solved up to desired time. The method relies on the intertwining property of Radon transforms [17, 27], thereby transforming a multi-dimensional problem into a family of one-dimensional ones. Simply by applying an 1D LTS method on each of these one-dimensional problems, one obtains a multi-dimensional LTS method. While this intertwining property is well-known and appears in standard references, it has not been used for constructing multi-dimensional numerical methods, to the best of our knowledge.

The method also has implications for the problem of imposing absorbing boundary conditions, a problem that has received sustained interest over many decades [14, 3, 11, 4]. By using the Radon transform, the splitting decomposes multi-dimensional waves into planar ones, thereby allowing a separate treatment of each incident planar wave near the boundary. This yields the desired absorbing boundary conditions in odd dimensions, and in even dimensions one obtains an approximation up to \( O(1/t) \) that does not cause spurious reflections.

Another useful application of this dimensional splitting is in displacement interpolation, a concept that arises naturally in optimal transport [37]. Our interest in displacement interpolation is motivated by model reduction. To construct reduced order models for typical hyperbolic problems, one cannot rely solely on linear subspaces [1, 10], and it is necessary to interpolate over the Lagrangian action [33, 32, 30, 31]. In a single spatial dimension this can be done in a relatively straightforward manner, owing to the LTS methods available for 1D [31]. The multi-dimensional LTS method is useful also for the multi-dimensional extension of displacement interpolation, and this in turn will yield a straightforward way for low-dimensional information to be extracted for multi-dimensional hyperbolic problems.

arXiv:1705.03609v1  [math.NA]  10 May 2017
For the dimensional splitting to be computationally successful, one requires an algorithm for computing the Radon transform and its inverse efficiently. Throughout this paper we use the approximate discrete Radon transform (ADRT), also called simply the discrete Radon transform (DRT), devised in [8, 16]. Throughout this paper we will refer to ADRT as DRT. It is a fast algorithm with the computational cost of $O(N^2 \log N)$ for an $N \times N$ image or grid, and the efficiency is obtained through a geometric recursion of so-called digital lines. The inversion algorithm using the full multi-grid method appeared in [28], but here we adopt a simpler approach by making use of the conjugate gradient algorithm [15] for the inversion. We conjecture the worst-case cost of the inversion to be $O(N^{5/2} \log N)$.

This paper is organized as follows. In Section 2, we give a review of the intertwining property of the Radon transform and introduce the dimensional splitting method. In Section 3, discuss its applications in absorbing boundary and in displacement interpolation. In Section 4, we give a brief introduction to the DRT algorithm and discuss its inversion. In this paper we will fully implement only constant coefficient linear problems in spatial dimension two, although we will also discuss how the splitting can be extended to fully nonlinear problems and to higher spatial dimensions. Further investigations into these and other related topics will be mentioned in Section 5.

The Radon transform was introduced by Johann Radon [29] and has been a major subject of study, perhaps primarily due to its use in medical imaging but also as a general mathematical and computational tool.

2. Dimensional splitting using the Radon transform. In this section, we briefly review the intertwining property of the Radon transform [17, 27] then show that it can be used as a dimensional splitting tool that extends the large time-step (LTS) operator to multiple spatial dimensions. It preserves the ability to take large time-steps without loss of accuracy in the constant coefficient case. Moreover, this splitting can be used for fully nonlinear problems as well, in a similar manner to the other splitting methods, with the usual CFL condition for the time-step.

2.1. Intertwining property of Radon transforms. The Radon transform $\hat{\varphi} : S^{n-1} \times \mathbb{R} \to \mathbb{R}$ of the function $\varphi : \mathbb{R}^n \to \mathbb{R}$ is defined as

$$\hat{\varphi}(\omega, s) = \mathcal{R}\varphi(\omega, s) = \int_{\langle x, \omega \rangle = s} \varphi(x) \, dm(x),$$

in which $dm$ is the Euclidean measure over the hyperplane. For any fixed pair $(\omega, s) \in S^{n-1} \times \mathbb{R}$, the set $\{x \in \mathbb{R}^n : \langle x, \omega \rangle = s\}$ defines a hyperplane, so the transform is simply an integration of the function over this hyperplane. In effect, $\hat{\varphi}$ decomposes $\varphi$ into planar waves in the direction of $\omega$.

The back-projection is defined as the dual of $\mathcal{R}$ with respect to the obvious inner product over $S^{n-1} \times \mathbb{R}$. For $\psi : S^{n-1} \times \mathbb{R} \to \mathbb{R}$ the back-projection $\check{\psi}$ is

$$\check{\psi}(x) = \mathcal{R}^\# \psi(x) = \int_{S^{n-1}} \psi(\omega, \langle \omega, x \rangle) \, dS(\omega),$$

where $dS$ is the measure on $S^{n-1}$ and $\langle \cdot, \cdot \rangle$ denotes the usual inner product in $\mathbb{R}^n$.

The Radon transform has a remarkable property, that it intertwines a partial derivative with a univariate derivative. The $i$-th partial derivative $\partial / \partial x_i$ of $\varphi$ is now

The term grid (cell) is a more appropriate term for our PDE applications, but DRT originally comes from imaging literature so we will sometimes also use the term image (pixel), interchangeably.
transformed to the derivative of $\hat{\varphi}$ with respect to $s$ multiplied by $\omega_i$,

$$(2.3) \quad \left( \frac{\partial}{\partial x_i} \varphi(\mathbf{x}) \right)^\wedge = \omega_i \frac{\partial}{\partial s} \hat{\varphi}(\omega, s).$$

This is the key property that allows us to transform a multi-dimensional hyperbolic problem into a collection of one-dimensional problems. For example, let us apply the Radon transform to the transport equation in $\mathbb{R}^2$, in which the scalar state variable $q : \mathbb{R}^+ \times \mathbb{R}^2 \to \mathbb{R}$ satisfies,

$$(2.4) \quad q_t + \mathbf{\theta} \cdot \nabla q = 0 \quad \text{where} \quad \mathbf{\theta} \in S^1.$$

The transformation produces a family of 1D advection equations

$$(2.5) \quad \hat{q}_t + (\theta \cdot \omega) \hat{q}_s = 0,$$

whose coefficient varies for each $\omega$. Similarly, consider the acoustic equations for $p, u, v : \mathbb{R}^+ \times \mathbb{R}^2 \to \mathbb{R}$, where the state variable $p$ denotes pressure, $u$ the velocity in $x$-direction, $v$ the velocity in $y$ direction,

$$(2.6) \quad \begin{bmatrix} p \\ u \\ v \end{bmatrix}_t + \begin{bmatrix} 0 & K_0 & 0 \\ 1/\rho_0 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix} \begin{bmatrix} p \\ u \\ v \end{bmatrix}_x + \begin{bmatrix} 0 & 0 & K_0 \\ 0 & 0 & 0 \\ 1/\rho_0 & 0 & 0 \end{bmatrix} \begin{bmatrix} p \\ u \\ v \end{bmatrix}_y = 0.$$

After the transform, we obtain

$$(2.7) \quad \begin{bmatrix} \hat{p} \\ \hat{u} \\ \hat{v} \end{bmatrix}_t + \begin{bmatrix} 0 & \omega_1 K_0 & \omega_2 K_0 \\ \omega_1/\rho_0 & 0 & 0 \\ \omega_2/\rho_0 & 0 & 0 \end{bmatrix} \begin{bmatrix} \hat{p} \\ \hat{u} \\ \hat{v} \end{bmatrix}_s = 0.$$

This PDE has one spatial dimension in variable $s$. Letting $\mu = \omega_1 u + \omega_2 v$ and $\nu = -\omega_2 u + \omega_1 v$, (2.7) can be rewritten as three equations for new states $\hat{p}, \hat{\mu}$ and $\hat{\nu}$. If one omits the trivial equation $\nu_t = 0$, the equation (2.7) is reduced to the 1D acoustic equations,

$$(2.8) \quad \begin{bmatrix} \hat{p} \\ \hat{\mu} \end{bmatrix}_t + \begin{bmatrix} 0 & K_0 \\ 1/\rho_0 & 0 \end{bmatrix} \begin{bmatrix} \hat{p} \\ \hat{\mu} \end{bmatrix}_s = 0.$$

In this case, the equation depends on $\omega$ through the variable $\mu$. However, the equation itself is invariant over all $\omega$, owing to the fact that the problem (2.7) is isotropic. Moreover, note that this is exactly the same equation obtained in the physical space if you consider the case of a plane wave where the data varies only in the direction $\omega$ so that derivatives in the orthogonal direction vanish.

The Radon transform therefore transforms $n$-dimensional hyperbolic problems such as (2.4) and (2.7) into their 1-dimensional counterparts (2.5) and (2.8), respectively.

### 2.2. Multi-dimensional extension of large time-step (LTS) methods.

Previous dimensional splitting methods [34, 26, 23] such as Strang splitting do not allow a natural extension of large time-step (LTS) methods [19, 21, 20] to multiple spatial dimensions. In order to take large time-steps for constant coefficient multi-dimensional hyperbolic problems, one can use the Fourier transform, for example. Upon taking the Fourier transform, one is left with a set of ordinary differential equations (ODEs) different from the original problem [35, 7]. On the other hand, using
the Radon transform, one obtains a dimensional splitting that reduces the multi-
dimensional problem into a family of one-dimensional counterparts of similar (if not
equivalent) form. This allows 1D LTS methods to be applied for each of these problems,
and the multi-dimensional solution is obtained by computing the inverse of the Radon
transform. Moreover, the Radon transform provides an intuitive geometrical inter-
pretation as a decomposition into planar waves and thus yields other useful applications.
These applications will be illustrated in Section 3.

This multi-dimensional extension of the LTS method for the constant coefficient
case is very straightforward. Taking the Radon transform of the problem as above,
one obtains a set of 1D problems such as (2.5) or (2.8). Then one applies the 1D
LTS solution operator $K$ to evolve the initial data $\hat{u}_0(\omega, s)$ for each $\omega$
up to desired final time $T$. The operator $K$ may depend on the direction $\omega$, so we denote the
dependence as a parameter by writing $K = K(T; \omega)$. This yields the Radon transform
of the solution at time $T$,

$$(2.9) \quad \hat{q}(T, \omega, s) = K(T; \omega)\hat{q}_0(\omega, s).$$

Then, to compute the solution $q$ we can apply the inversion formula

$$(2.10) \quad c_n q(T, x) = \begin{cases} 
\mathcal{R}^s \frac{d^{n-1}}{ds^{n-1}} \hat{q}(T, \omega, s) & \text{if } n \text{ is odd}, \\
\mathcal{R}^s H \frac{d^{n-1}}{ds^{n-1}} \hat{q}(T, \omega, s) & \text{if } n \text{ even}, 
\end{cases}$$

where the constant $c_n = (4\pi)^{(n-1)/2} \Gamma(n/2)/\Gamma(1/2)$ and $H$ denotes the Hilbert trans-
form. Much is known about the inversion; see standard texts such as [17, 27] for more
details.

This splitting can also be related to the Strang splitting, if one views it as a decom-
position of the multi-dimensional problem into planar wave propagation. In Strang
splitting one constructs the planar waves emanating in varying directions by divid-
ing a single time-step into multiple successive planar wave propagations. The Radon
transform decomposes the multi-dimensional directions by explicitly discretizing the
sphere $S^{n-1}$.

Let us consider a concrete example, the 2D acoustic equation (2.7). Let us set
$K_0 = \rho_0 = 1$, so that we have the sound speed $c = 1$, and impose the initial conditions

$$(2.11) \quad q_0(x, y) = \begin{bmatrix} p_0(x, y) \\ 0 \\ 0 \end{bmatrix}, \quad p_0(x, y) = \begin{cases} 
\cos(\pi(x^2 + y^2)/2) & \text{if } x^2 + y^2 < 1, \\
0 & \text{otherwise}.
\end{cases}$$

The initial pressure profile is a cosine hump supported in a disk of radius 1 centered at
the origin, and the initial velocity profile is identically zero. We will also set absorbing
boundary conditions in the manner to be described in Section 3.1.

On the transformed side (2.8), the evolution for any fixed direction $\omega \in S^1$ is
given by the d’Alembert solution (2.12),

$$(2.12) \quad \hat{q}(t, \omega, s) = \frac{1}{2} (r_1 \hat{q}_0(\omega, s - t) + r_2 \hat{q}_0(\omega, s + t)) \quad \text{where } r_1 = \begin{bmatrix} 1 \\ 1 \end{bmatrix} \text{ and } r_2 = \begin{bmatrix} 1 \\ -1 \end{bmatrix}.$$
Fig. 1: The solution to the acoustic equation using the Radon transform in the square domain $[-4,4] \times [-4,4]$. The pressure $p$ is shown on the left column and its Radon transform $\hat{p}$ is shown on the right column, at times $t = 0$ (first row), $t = 1$ (second row), and $t = 3$ (third row).

The solution to the acoustic equation computed on the domain $[-4,4] \times [-4,4]$ is shown in the left column of Figure 1. The Radon transform of the pressure term $\hat{p}$ is plotted in the right column of the same figure. Note that this problem is radially symmetric about the origin. A consequence of this is that the Radon transform is invariant with respect to the variable $\omega$, hence the Radon transform of the solutions at different times all appear as horizontal stripes. (There is a small amount of shift, following from the fact that for an image of even size $N$, the origin is chosen as the $(N/2, N/2)$-pixel, slightly off center.)

A key observation is that the evolution of the solution in the transformed variables is a sum of two shifting horizontal stripes, although the wave profile in the spatial domain propagates radially. For each fixed angle $\omega$, one only need solve the
d’Alembert solution (2.12), which is easy to solve to any time \( t \) by shifting the initial profile twice each according to two opposite speeds, and summing them. Intuitively, the shifts correspond to the propagation of decomposed planar waves for any fixed normal directions in \( S^1 \).

The actual computational did not make use of the continuous Radon transform (2.1), but rather a completely discrete approximation called the discrete Radon transform (DRT), which is plotted in Figure 2. The DRT will be introduced and discussed in further detail in Section 4. Here it will suffice to mention that the continuous transform can be obtained by an easy change of variables (4.5) which scale the domain and amplitude of the DRT, and that the change of variables do not affect the intertwining property. The 1D LTS method can still be used on the DRT, just as in the case of
the continuous transform.

A grid of size 128 × 128 was used and prologation of $p = 2$ (see Section 4.3) was used for the inversion of DRT. This solution is compared with a reference finite volume solution computed on a larger domain $[-8, 8] × [-8, 8]$, using the wave propagation algorithm [22] with Lax-Wendroff flux and Van Leer limiter [36, 23], implemented in the CLAWPACK software package [12]. The reference solution was computed on a 1024 × 1024 finer grid-cells of uniform size, then corresponding cells have been summed and compared with coarser cells of the DRT solution. The $L^2$-norm of the difference over time is displayed below in Figure 3, where the error is in the order of $10^{-3}$ up to time $t = 2.5$, before the profile starts approaching the boundary. The subsequent increase in the error is expected from the particular absorbing boundary set up here, as will be discussed in Section 3.1.

While this problem was radially symmetric, the splitting is by no means restricted to problems with radial symmetry. Let us modify the initial conditions above so that it is the sum of two cosine humps of different radii and heights,

\[
q_0(x, y) = \begin{bmatrix} p_1(x, y) \\ 0 \\ 0 \end{bmatrix},
\]

\[
p_1(x, y) = p_0(x + 1, y + 1.5) + 1.5 p_0(1.25(x - 0.75), 1.25(x - 1.1)).
\]

The splitting solution and its continuous Radon transform is plotted in Figure 4. In the first row of the figure, the initial condition and its Radon transform are shown. The two cosine humps in the initial condition each correspond to a sinusoidal signal on the transformed side. Recall the horizontal line centered at $s = 0$ from the previous example (Figure 1). The sinusoidal shift away from $s = 0$ is due to the fact that translation is an anisotropic operation. This can also be deduced from the transformed transport equation (2.5) in which the transport speed is $\theta \cdot \omega$, that is, $\cos \phi$ where $\phi
Fig. 4: The solution to the acoustic equation using the Radon transform in the square domain $[-4, 4] \times [-4, 4]$. The pressure $p$ is shown on the left column and its Radon transform $\hat{p}$ is shown on the right column, at times $t = 0$ (first row), $t = 0.5$ (second row), $t = 1$ (third row), and $t = 1.5$ (fourth row).
is the angle between transport direction $\theta$ and the direction of the transform $\omega$. For example, when the cosine hump at the origin $p_0$ (2.11) is transported away from the origin by $r\theta$, $\hat{p}_0$ is shifted by $\hat{p}_0(\omega, s - r \cos(\phi))$.

In any case, the solution is still given by the d’Alembert solution (2.12) and the acoustics equation can be solved exactly the same way as before. The DRT used in the actual computations are plotted in Figure 5. Each corresponds to a continuous transform in Figure 4.

2.3. Splitting for the nonlinear case. Here we will discuss how the splitting above can be applied to a fully nonlinear system of hyperbolic equations. For a state vector $q$, such a PDE is given in the form

$$ q_t + f(q)_x + g(q)_y = 0, \tag{2.14} $$

where $f$ and $g$ are flux functions that can be nonlinear. Taking the Radon transform as before, we obtain

$$ \hat{q}_t + (\omega_1 f(q) + \omega_2 g(q)) \wedge = 0. \tag{2.15} $$

Let us define the directional flux function as

$$ h(q) = \omega_1 f(q) + \omega_2 g(q). \tag{2.16} $$

Then one obtains the nonlinear 1D equations,

$$ \hat{q}_t + h(q) \wedge = 0. \tag{2.17} $$

As in the acoustics equation (2.8), the dependence on $\omega$ enters through the flux function $h(q)$, while the form of the equation is invariant with respect to $\omega$.

As an example, consider the shallow water equations in 2D, in which $\rho, u, v : \mathbb{R}^+ \times \mathbb{R}^2 \to \mathbb{R}$ denote water height, velocity in the $x$-direction and velocity in the $y$-direction, respectively,

$$ \begin{bmatrix} \rho \\ \rho u \\ \rho v \end{bmatrix}_t + \begin{bmatrix} \rho u^2 + \frac{1}{2} \bar{g} \rho v^2 \\ \rho u^2 \\ \rho uv \\ \rho uv \\ \rho v^2 + \frac{1}{2} \bar{g} \rho^2 \end{bmatrix}_x + \begin{bmatrix} \rho v \\ \rho u v \\ \rho u \end{bmatrix}_y = 0. \tag{2.18} $$

Here $\bar{g}$ denotes the gravitational constant. The Radon transform as above yields 1D equation in the form (2.17), in the transformed velocity variables $\mu = \omega_1 u + \omega_2 v$ and $\nu = -\omega_2 u + \omega_1 v$,

$$ \begin{bmatrix} \rho \\ \rho \mu \\ \rho \nu \end{bmatrix}^\wedge_t + \begin{bmatrix} \rho \mu^2 + \frac{1}{2} \bar{g} \rho \nu^2 \\ \rho \mu^2 \\ \rho \mu \nu \end{bmatrix}_s = 0. \tag{2.19} $$

Note that the first two equations of (2.19) are just the shallow water equation in a single dimension in the normal direction of the hyperplane, whereas the third equation is the conservation of momentum in the transverse direction.

We observe that the transformed equations resemble a finite volume discretization. Let us say that $\xi_{i,j}$ is a discretization of the hyperplane $\{x \in \mathbb{R}^n : \langle x, \omega_j \rangle = s_j \}$. The specific discretization for the hyperplanes can take on many different forms, but here
Fig. 5: The discrete Radon transform (DRT) of the solution to the acoustic equation (2.7) with initial conditions (2.13), for times $t = 0, 0.5, 1$ and 1.5. The parameters $h$ and $s$ which appear on the axes designate $d$-lines (see Figure 11) and indices $\{a, b, c, d\}$ denote quadrants (see Figure 12). Details appear in Section 4.
we will leave it in a general form. We denote the approximation to \( \hat{q}(t_n, \omega_i, s_j) \) at time-step \( t_n \) by \( \hat{Q}_{i,j}^n \).

\[
\hat{Q}_{i,j}^n \approx \int_{\xi_{i,j}} q(t_n, x) \, dm(x).
\]

For each fixed direction \( i = i_0 \), the collection of hyperplanes \( \{\xi_{i_0,j}\} \) form a partition of the domain. We consider these hyperplanes to be finite volume cells. In the equation (2.17) the flux function \( h(q) \) assigns the flux between \( \xi_{i_0,j} \) and \( \xi_{i_0,j+1} \). If the cell boundary between \( \xi_{i_0,j} \) and \( \xi_{i_0,j+1} \) is denoted by \( \xi_{i_0,j+\frac{1}{2}} \), we define the numerical flux \( F_{i_0,j+\frac{1}{2}}^n \) to be an approximation to the flux at \( \xi_{i_0,j+\frac{1}{2}} \), valid from time-step \( t_n \) to \( t_{n+1} \). Then we have the finite volume update

\[
\hat{Q}_{i_0,j}^{n+1} = \hat{Q}_{i_0,j}^n - \Delta t(F_{i_0,j+\frac{1}{2}}^n - F_{i_0,j-\frac{1}{2}}^n).
\]

Once these updates are made for all \( i \), the updated \( \hat{Q}_{i_0,j}^{n+1} \) are combined through the inversion formula (2.10) to yield the numerical solution at time \( t_{n+1} \).

The dimensional splitting strategy would be to compute the numerical flux \( F_{i_0,j+\frac{1}{2}}^n \) by solving only the 1D Riemann problems in the \( x \) and \( y \) directions. Since the flux function \( h(q) \) is a linear combination of normal fluxes \( f(q) \) and \( g(q) \) (2.16), we can compute \( h \) once we have the approximation for these normal fluxes. In other words, we can solve the 1D Riemann problems for piecewise constant jumps locally in \( x \) and \( y \) directions, then sum these fluxes across the cell boundary \( \xi_{i,j+\frac{1}{2}} \) to obtain the flux between hyperplanes. One thereby decomposes the multi-dimensional Riemann problem into a set of single-dimensional ones, to be combined together by the inversion formula (2.10).

Unlike in the constant coefficient case, the flux function \( h(q) \) must be updated at every time step, as is usually done for finite volume methods, although one may apply the nonlinear LTS method on the transformed problem regardless. This would be based on the 1D analogues studied in [19, 21, 20]. The fully nonlinear splitting will not be implemented here, but will be investigated in future work.

3. Applications of the dimensional splitting. The dimensional splitting described in Section 2 above is a decomposition of hyperbolic solutions into evolution of planar waves. This decomposition can be useful in diverse settings. Here we discuss two applications: the absorbing boundary conditions and the displacement interpolation.

3.1. Absorbing boundary conditions. It is well-known that imposing absorbing boundary conditions to emulate infinite domains in multi-dimensional wave propagation is a challenging problem [14, 3, 11, 4]. On the other hand, the 1D extrapolation boundary condition is much more tractible [23]. A major advantage of this splitting method is that the 1D extrapolation boundary conditions can be used on the transformed side at the computational boundary to avoid any reflections. This yields exactly the desired absorbing boundary conditions in the odd-dimensional case. Therefore, the dimensional splitting introduced in the previous section can be used directly to impose absorbing boundary conditions in 3D. On the contrary, there is an error caused by such an extrapolation in the even-dimensional case. This is due to the Huygens’ principle, evident in the presence of the Hilbert transform in the inversion formula (2.10). In this section, we discuss the type of error caused by imposing such extrapolation boundary conditions via the Radon transform in even dimensions.
Fig. 6: The splitting solution to the acoustic equation (2.7) in the square domain $[-4,4] \times [-4,4]$. The pressure $p$ and its DRT $R_N p$ at time $t = 3$.

In the true infinite domain, the non-zero values in transformed variables beyond the computational boundary of $S_n^{-1} \times \mathbb{R}$ affect the solution within the computational domain in the original variables $\mathbb{R}^n$. For example, the vertical translation of horizontal strips in Figure 1 should continue beyond the finite computational boundary, and by imposing a 1D extrapolation boundary condition we would be neglecting this infinite propagation. To make this more precise, denote the computational (finite) transformed domain by $\Omega = \{(\omega, s) \in S_n^{-1} \times (-b,b)\}$ for some $b > 0$. Let $\chi_\Omega$ be the characteristic function of the finite and $\chi_{\mathbb{R}^n \setminus \Omega} = 1 - \chi_\Omega$. For $n$ even, the exact solution $q$ can be written as,

$$q(T, x) = \frac{1}{c_n} R^# H_s \frac{d^{n-1}}{ds^{n-1}} \hat{q}(T, \omega, s)$$

(3.1)

$$= \frac{1}{c_n} R^# H_s \chi_\Omega \frac{d^{n-1}}{ds^{n-1}} \hat{q}(T, \omega, s) + \frac{1}{c_n} R^# H_s \chi_{\mathbb{R}^n \setminus \Omega} \frac{d^{n-1}}{ds^{n-1}} \hat{q}(T, \omega, s).$$

(3.2)

Recall that $R^#$ is the back-projection (2.2). The first term in (3.2) is the approximate solution one would obtain if extrapolation boundary is set up at the boundaries $s = \pm b$. Let us call this approximate solution $q_h(x)$. Then the error is

$$q(T, x) - q_h(T, x) = \frac{1}{c_n} R^# \left( \text{p.v} \int_{(\infty,-b) \cup [b,\infty)} \frac{1}{r^s} \frac{\partial^{n-1}}{\partial r^{n-1}} \hat{q}(T, \omega, r) dr \right),$$

(3.3)

where p.v denotes the principal value integral. Note that in hyperbolic problems in free space, wave profiles will radiate outwards, that is, the support of $\hat{q}$ will be transported towards $r = \pm \infty$. This causes the RHS above to decay with time. Furthermore, the principal integral is a smooth function of $s$ as long as $\partial^{n-1}\hat{q}/\partial r^{n-1}$ is integrable. Since $R^#$ is an integral, we expect the error to be smoother than $q(x)$.

Let us revisit the acoustic equations example (2.7) from Section 2.2, with initial conditions (2.11). Since $q_0(x, y)$ is supported in $\{(\omega, s) \in S_n^{-1} \times \mathbb{R} : |s| \leq 1\}$, we have
a simple estimate for the case when $t$ is sufficiently large so that $(-1+t, 1+t) \subset (b, \infty)$,

$$
|q(x) - q_h(x)| = \frac{1}{2c_n} \left| \int_{-\infty}^{-b} \frac{r_1}{r-s} \frac{d}{dr} \hat{q}_0(r+t) \, dr + \int_{b}^{\infty} \frac{r_2}{r-s} \frac{d}{dr} \hat{q}_0(r-t) \, dr \right| 
\leq \frac{2 \, |S^{n-1}| \sup \|p'_0\|_1}{c_n |t+1|},
$$

(3.4)

where $|S^{n-1}|$ is the surface area of an $n$-sphere. Therefore we see that the effect of the extrapolation boundary decays relatively slowly, at the rate of $O(1/t)$.

These observations help us understand the $L_2$ error plot in Figure 3. Recall that the reference solution was computed in a larger domain of size $[-8, 8] \times [-8, 8]$ instead of imposing absorbing boundary conditions (see description in Section 2.2). The error from the truncation (3.4) begins to appear around time $t = 2.5$ and peaks around time $t = 5$, then decays to zero with time. The solution at time $t = 3$, as it has begun to interact with the boundary, is shown in Figure 6. Note that there are no reflections from this boundary condition. On the other hand, a thin layer appears at the computational boundary. The layer is clearly non-physical, but is localized and has limited effect on the solution further in the interior. The DRT of the solution is also shown to its right, and we can see that the two pulses from the d’Alembert solution are hitting the 1D extrapolation boundaries (the top and bottom boundaries of the polygonal region in dark blue). The pulses first arrive at the DRT boundary at the angles $0, \pi/2$ and $\pi$, and this agrees with the solution plot to the left.

Comparing this solution to the reference solution, one discovers that the bulk of this error is concentrated near the thin layer which appears near the boundary. In Figure 7, we have plotted the difference between our solution and the reference solution on the computational domain $[-4, 4] \times [-4, 4]$ to the left. When we restrict the contour plot to the interior portion of the domain $[-3, 3] \times [-3, 3]$ as is shown to the right, we see that the error is significantly smaller as we move away from the boundary. This is to be expected from the decay of the principal value integral in (3.3): the further away the interior point is from the boundary, the smaller the effect of the truncation by $\chi_{\Omega}$. If we denote the the distance by $d$, then the decay will be $O(1/(d+t))$. As $t$ increases and the waves leave the domain, the error also decays,

at a slightly faster rate than the rate $O(1/t)$ estimated by (3.4).

3.2. Displacement interpolation. In projection-based model reduction, the solution to a parametrized PDE is projected into a low-dimensional subspace, yielding a fast solver with significantly lower computational cost without compromising accuracy. To discover this low-dimensional subspace, the popular approach is to use proper orthogonal decomposition (POD) [5]. For hyperbolic PDEs, however, the solutions do not lie in a low-rank linear subspace, even for the simplest problems [33, 1, 10, 30, 31]. For instance, the d’Alembert solution (2.12) is a linearly independent function of $s$ for each $t > 0$. It is easy to see that a linear projection of this solution to a low-dimensional basis would not yield a good approximation of the solution. Naturally, methods to remove translational symmetry [33, 30, 31] are being actively explored. This is also intimately related to the concept of displacement interpolation, a term we borrow from the optimal transport literature [37], in which one aims to minimize the Wasserstein distance, although we will not make the connection more explicit here.
Fig. 7: Difference to the reference solution at time $t = 5$. The difference for all cells in log-scale (left) and the difference for the interior cells in $[-3, 3] \times [-3, 3]$ (right).

Let us first illustrate how displacement interpolation arises naturally, with a simple 1D example. Suppose $\phi_0$ is a hat function, given by

$$
\phi_0(x) = \begin{cases} 
\frac{x}{h} + 1 & \text{if } -h < x < 0, \\
\frac{-x}{h} + 1 & \text{if } 0 \leq x < h, \\
0 & \text{otherwise},
\end{cases}
$$

for some $h > 0$. Let $\phi_1$ and $\phi_2$ be translation and scaling of $\phi_0$,

$$
\phi_1(x) = \phi_0(x) \quad \text{and} \quad \phi_2(x) = \frac{1}{4}\phi_0(x - 2).
$$

For $h = 0.1$, the two functions are shown in the first row of Figure 8. The linear interpolation $\psi$ of the two functions with weights $(1 - \tau)$ and $\tau$ is given by

$$
\psi(x) = (1 - \tau)\phi_1(x) + \tau\phi_2(x) = (1 - \tau)\phi_0(x) + \frac{\tau}{4}\phi_0(x - 2)
$$

whereas a displacement interpolation between the two functions under a simple transport map (1D translation) would be given by

$$
\psi_D(x) = (1 - \tau)\phi_1(x - 2\tau) + \frac{\tau}{4}\phi_2(x + 2(1 - \tau)) = \left(1 - \frac{3}{4}\tau\right)\phi_0(x - 2\tau)
$$

The two interpolants for $\tau = 0.25$ are plotted in the bottom row in Figure 8. Since $\phi_1$ and $\phi_2$ are both translates of a scalar multiple of $\phi_0$, the displacement interpolation reveals the low-rank nature of the two functions, whereas the linear interpolant remains rank two for $\tau \in (0, 1)$.

In practice, one must be able to deduce that $\phi_1$ and $\phi_2$ above lie in the translates of $\text{span}\{\phi_0\}$ without a priori knowledge. To achieve this, one may apply the template-fitting procedure [33] which solves the minimization problem

$$
\tau_\ast = \arg\min_{\tau \in \mathbb{R}} \|\phi_2(x) - \mathcal{K}(\tau)[\phi_1(x)]\|_2,
$$
Fig. 8: Two hat functions \( \phi_1 \) and \( \phi_2 \) (top row) and linear interpolation \( \psi \) and displacement interpolation \( \psi_D \) between the two functions with respective weights 0.75 and 0.25 (bottom row).

where \( K \) is the translation operator, \( K(\tau)[\phi_1(x)] = \phi_1(x - \tau) \), then perform a singular value decomposition (SVD) on \( \{\phi_2, K(\tau_*)\phi_1\} \) [33, 30]. However, this simple formulation does not take into account multiple traveling speeds or heavily deforming profiles, which limits its applicability. Transport reversal was introduced in [31] to overcome these limitations. The algorithm is a greedy iteration over a generalized form of (3.9), which decomposes the 1D function \( \phi_2(x) \) into multiple traveling structures. To be more precise, given two functions \( \phi_1 \) and \( \phi_2 \) as in (3.9), transport reversal yields the decomposition

\[
\psi_D(x; \tau) = \sum_{k=1}^{K} \eta_j(\tau)K(\nu_j \tau)[\rho_j(x)\phi_1(x)].
\]

where \( \eta_j \) is a scaling function and \( \rho_j \) a cut-off function. For more detailed treatment of this decomposition in 1D, we refer the reader to [31]. Let us suppose we have computed this decomposition. The displacement interpolant \( \psi_D \) resulting from this decomposition is set to satisfy,

\[
\psi_D(x, 0) = \phi_1(x) \quad \text{and} \quad \psi_D(x, 1) = \phi_2(x).
\]

As an example, let us assume we are given two functions \( \phi_1 \) and \( \phi_2 \) as shown in Figure 9(a) and 9(b). These are taken from the 1D slice located at \( s = \tan\left(\frac{5}{8} \pi\right) (N - 1) \) of the DRT from Figure 5. The transport reversal would decomposes \( \phi_2(x) \) into a superposition of two traveling profiles,

\[
\eta_1(\tau)K(\tau)[\rho_1(x)\phi_1(x)] \quad \text{and} \quad \eta_2(\tau)K(-\tau)[\rho_2(x)\phi_1(x)],
\]
Fig. 9: Two 1D functions $\phi_1$, $\phi_2$ and the displacement interpolation $\psi_D$ are shown in the first column. These are exactly the $s = \tan\left(\frac{5}{8}\pi\right)(N - 1)$ slice of the DRT of the acoustic equation example in Figure 5. The slice is indicated by the dashed red vertical line in the plots in the right column.

each plotted in Figure 10. In exact arithmetic, the two iterations of transport reversal would pick-up exactly the d’Alembert solution (although in practice numerical error would require further iterations to pick off the residuals). That is, we would obtain $h_1 = h_2 = 1/2$ and $\rho_1 = \rho_2 = 1$ with $\nu_1 = -\nu_2 = 1$ and $K = 2$ in (3.10). Now, the displacement interpolation for $\tau = 1/2$ can be computed, yielding $\psi_D$ shown in Figure 9(c). The exact evolution of the two iterates (3.12) are shown in Figure 10.

Now, this displacement interpolation was done for a single slice of the fixed $\omega$ in the transformed variables. Suppose we are given a function $\varphi$ in 2D. Then by performing the same transport reversal on its Radon transform $\hat{\varphi}$ for all $\omega$ as functions of the variable $s$, we obtain an extension of the 1D displacement interpolant (3.8) to higher spatial dimensions. For each fixed angle $\omega_0 \in S^1$ we obtain the transport reversal that decomposes the traveling structures,

$$
\hat{\psi}_D(\omega_0, s; \tau) = \sum_{k=1}^{K} \eta_{t,k}(\tau)K(\nu_{t,k}\tau)[\rho_{t,k}(s)\hat{\varphi}(\omega_0, s)].
$$

These can be used for displacement interpolation as above for each $\omega$. The inverse transform can be taken to obtain the displacement interpolant $\psi_D$. For given a given
Fig. 10: The first two contributions (3.12) of the transport reversal for $\phi_1$ and $\phi_2$ shown in Figure 9 (left) and the displacement interpolation resulting in $\psi_D(x; 0.5)$ (3.10) (right). $\psi_D$ shown in dotted line is also displayed in the bottom of Figure 9.

value $\tau$, we have

$$
(3.14) \quad \psi_D(x, y; \tau) = R^{-1} \left( \sum_{k=1}^{K} \eta_{i,k}(\tau) K(\nu_{i,k}(\tau)) \rho_{i,k}(s) \hat{\phi}(\omega_i, s) \right).
$$

Let us clarify the implication. For the acoustic equation example with the initial condition (2.13), we were given a snapshot of the solution $q$ at time $t_1 = 0.5$ and $t_2 = 1.5$. From the two snapshots, we were be able to accurately approximate the solution for all time, without additional information about the dynamics, without even knowing the PDE. Thus this interpolant can be more useful than linear interpolation: the linear subspace spanned by $\{q(t_1, x), q(t_2, x)\}$ does not contain a good approximation for representing the evolving solution.

This ability to compute the displacement interpolation by exploiting the simple dynamic on the transformed side will be useful in the future development of transport reversal as a model reduction tool in multi-dimensional settings.

4. Discrete Radon transform (DRT). There are many different discretizations of the Radon transform and its inverse [25, 6, 9, 18, 2], arguably the most well-known being the filtered backprojection (FBP) algorithm [27]. However, its reliance on Fourier transforms and spherical harmonics lead to some filtering of high-frequency content, causing Gibbs phenomenon near the sharp edges in the solution. This is not suitable for use in hyperbolic PDEs, which are known to develop shocks and discontinuities.

Instead, we consider the use of a completely discrete analogue, namely the approximate discrete Radon transform (ADRT), which we refer to simply as the discrete Radon transform (DRT), introduced in [16, 8]. Rather than interpolating pixel values onto straight lines passing near it, DRT sums one entry for each row or column, along so-called digital lines or d-lines. The d-lines are defined recursively, allowing for a fast computation in $O(N^2 \log N)$ for an image of size $N \times N$. The back-projection is given by reversing the recursion, and is also fast with the same computational cost of $O(N^2 \log N)$. The precise definitions are given below.

4.1. Recursive definition of DRT. The d-lines of length $N$ are denoted by $D_N(h, s)$ with two parameters $h$ and $s$ (see Figure 11). $h$ denotes the height ($x$-intercept) and $s$ the slope ($x$-displacement), and the pair corresponds to $s$ and $\omega$ for the continuous transform (2.3), respectively. Although the same notation $s$ is used here again after having been used in the continuous setting (2.1) we will keep the
notation in order to follow the intuitive notation of [28], and mark the continuous variable with a subscript \( s \) whenever the two are used simultaneously. The definition uses the recursion in which d-lines of length \( 2n \) are split into left and right d-lines of half its length.

\[
D_{2n}(h, 2s) = D^L_n(h, s) \cup D^R_n(h + s, s),
\]

\[
D_{2n}(h, 2s + 1) = D^L_n(h, s) \cup D^R_n(h + s + 1, s).
\]

The recursion (4.1) defines only a quarter of the possible d-lines, as the slope \( s \) will range from 0 to \( N \), corresponding to angles 0 to \( \pi/4 \) starting from the x-axis in the counter-clockwise direction. This is referred to by saying that the d-lines cover one quadrant, for the full transform one needs to cover the angles from 0 to \( \pi \). The other d-lines can be computed by transposing and flipping the indices \( h \) and \( s \). We will denote the d-lines and DRT corresponding to the angular intervals \([0, \pi/4], [\pi/4, \pi/2], [\pi/2, 3\pi/4], \) and \([3\pi/4, \pi]\) by \( a, b, c, \) and \( d \).

The DRT of an array \( A \in \mathbb{R}^2 \) for the quadrants \( a, b, c \) and \( d \) are given by the summation of entries of \( A \) over the d-lines,

\[
(R^a_N A)_{h,s} = \sum_{(i,j) \in D^L_N(h,s)} A_{i,j},
\]

\[
(R^b_N A)_{h,s} = \sum_{(i,j) \in D^R_N(h,s)} A_{j,i},
\]

\[
(R^c_N A)_{h,s} = \sum_{(i,j) \in D^L_N(h,s)} A_{j,N-i+1},
\]

\[
(R^d_N A)_{h,s} = \sum_{(i,j) \in D^R_N(h,s)} A_{N-i+1,j}.
\]

The full DRT is simply the ordered tuple of all quadrants, and we write

\[
R_N A = (R^a_N A, R^b_N A, R^c_N A, R^d_N A).
\]

Due to the recursive form of (4.1), the transform can be computed in \( \mathcal{O}(N^2 \log N) \). The parameters \( h \) and \( s \) belong to the range \([-s + 1, N]\) and \([0, N]\) so \( R^*_N A \in \mathbb{R}^{(N + \frac{1}{2} \times N)} \). Therefore, \( R_N : \mathbb{R}^{N \times N} \rightarrow \mathbb{R}^{(6N + 2) \times N} \).

There is a simple relationship between the DRT and the continuous Radon transform. First let us say that \( s_c \in [-1, 1] \) (perhaps through proper scaling) and parameterize \( \omega \) by \( \omega = (\cos \theta, \sin \theta) \) where \( \theta \in [0, \pi] \). The relation to continuous variables
\[(s_c, \omega)\) is given by
\[
s_c = \cos \theta \left(\frac{2h}{N} - 1 + \frac{s}{N-1}\right), \quad \theta = \arctan \left(\frac{s}{N-1}\right).
\]

Then the explicit relation between the DRT \(R_N\) and the continuous transform \(R\) are
given after the density of the lines are also transformed depending on the angle by \(\cos \theta\),
\[
R^a_N f(h, s) = \cos \theta R(s_c, \theta), \\
R^b_N f(h, s) = \cos \theta R(s_c, \pi - \theta), \\
R^c_N f(h, s) = \cos \theta R(s_c, 3\pi/2 - \theta), \\
R^d_N f(h, s) = \cos \theta R(s_c, 3\pi/2 + \theta).
\]

The back-projection is the dual of this transform with respect to the usual dot product in \(\mathbb{R}^{N^2}\). We will denote the back-projection by \(B_N\) or \(R^T_N\). If one explicitly forms the matrix for the linear transforms \(R_N\) and \(R^T_N\) they are indeed transposes of each other. \(R^T_N\) is the discrete analogue of \(R^\#\) in (2.2), a summation of all values assigned to d-lines passing through a point.

\(R^T_N\) is computed by reversing the sweep (4.1) above and computing a sequence of back-projections of decreasing size. Given a matrix \(\hat{A} \in \mathbb{R}^\left(\frac{1}{2}N+\frac{1}{2}\right) \times N\), the reverse sweep for one quadrant is given by
\[
B^L_n(h, s) = B_{2n}(h, 2s) + B_{2n}(h, 2s + 1), \\
B^R_n(h + s, s) = B_{2n}(h, 2s) + B_{2n}(h - 1, 2s),
\]
where the initial array \(B_N(h, s) = \hat{A}_{h,s}\), and \(n\) is set to \(N/2\). This summation is repeated for the two half-images \(B^L_n\) and \(B^R_n\) on the LHS, until \(n\) reaches 1. Again, this summation is only for one quadrant, and we denote the end result as \(\left(B^T_N \hat{A}\right)_{i,j}\).

The full back-projection is given by
\[
\left(B_N \hat{A}\right)_{i,j} = \frac{1}{4N^2} \left(B^a_N \hat{A} + B^b_N \hat{A} + B^c_N \hat{A} + B^d_N \hat{A}\right)
\]

Its inversion algorithm using a full multi-grid method was demonstrated in [28] along with convergence analysis. In this paper, we use the conjugate gradient (CG) algorithm as will be discussed below in Section 4.3.

We end this section with the remark that the recursion (4.1) need not be in two and can be in any prime number, much like the fast Fourier transform [13].

\[4.2.\ DRT\ in\ dimension\ three.\] Just as the continuous Radon transform was defined in (2.1) for arbitrary number of dimensions \(n\), the DRT can also be generalized to higher dimensions [24]. Here we treat the 3D case as an example. The recursive definitions (4.1) for the \(d\)-planes parametrized by three parameters \((h, s_1, s_2)\) can be
Fig. 12: The range of a quadrant of a discrete Radon transform (left) and a diagram showing how the boundary of the quadrants \{a, b, c, d\} can be identified (right). Here \( \theta = \arctan(s/(N - 1)) \).

derived for each hexadecant in a straightforward manner, as follows

\[
D_{2n}(h, 2s_1, 2s_2) = D_{n}^{LL}(h, s_1, s_2) \cup D_{n}^{RL}(h + s_1, s_1, s_2)
\]
\[
\quad \cup D_{n}^{LR}(h + s_2, s_1, s_2) \cup D_{n}^{RR}(h + s_1 + s_2, s_1, s_2),
\]
\[
D_{2n}(h, 2s_1 + 1, 2s_2) = D_{n}^{LL}(h, s_1, s_2) \cup D_{n}^{RL}(h + s_1 + 1, s_1, s_2)
\]
\[
\quad \cup D_{n}^{LR}(h + s_2, s_1, s_2) \cup D_{n}^{RR}(h + s_1 + s_2 + 1, s_1, s_2),
\]
\[
D_{2n}(h, 2s_1, 2s_2 + 1) = D_{n}^{LL}(h, s_1, s_2) \cup D_{n}^{RL}(h + s_1, s_1, s_2)
\]
\[
\quad \cup D_{n}^{LR}(h + s_2 + 1, s_1, s_2) \cup D_{n}^{RR}(h + s_1 + s_2, s_1, s_2),
\]
\[
D_{2n}(h, 2s_1 + 1, 2s_2 + 1) = D_{n}^{LL}(h, s_1, s_2) \cup D_{n}^{RL}(h + s_1 + 1, s_1, s_2)
\]
\[
\quad \cup D_{n}^{LR}(h + s_2 + 1, s_1, s_2) \cup D_{n}^{RR}(h + s_1 + s_2 + 1, s_1, s_2).
\]

The DRT over one hexadecant (a quarter of a quadrant) is defined as the sum over these d-planes as in (4.2), and now the full transform in 3D is given by applying these to each of the hexadecant

\[
H = \begin{cases} 
aa, \ ab, \ ac, \ ad, \\
ba, \ bb, \ bc, \ bd, \\
ca, \ cb, \ cc, \ cd, \\
da, \ db, \ dc, \ dd 
\end{cases}
\]

Hence, via transposing and flipping the indices as necessary, the full DRT is the ordered tuple

\[
R_{NA} = \begin{pmatrix} 
R_{NA}^{aa}, & R_{NA}^{ab}, & R_{NA}^{ac}, & R_{NA}^{ad}, \\
R_{NA}^{ba}, & R_{NA}^{bb}, & R_{NA}^{bc}, & R_{NA}^{bd}, \\
R_{NA}^{ca}, & R_{NA}^{cb}, & R_{NA}^{cc}, & R_{NA}^{cd}, \\
R_{NA}^{da}, & R_{NA}^{db}, & R_{NA}^{dc}, & R_{NA}^{dd} 
\end{pmatrix}
\]
The corresponding back-projection operation for a hexadecant is given by

\[
B_n^{LL}(h, s_1, s_2) = B_{2n}(h, 2s_1, 2s_2) + B_{2n}(h, 2s_1 + 1, 2s_2)
+ B_{2n}(h, 2s_1, 2s_2 + 1) + B_{2n}(h, 2s_1 + 1, 2s_2 + 1),
\]

\[
B_n^{RL}(h + s_1, s_1, s_2) = B_{2n}(h, 2s_1, 2s_2) + B_{2n}(h - 1, 2s_1 + 1, 2s_2)
+ B_{2n}(h, 2s_1, 2s_2 + 1) + B_{2n}(h - 1, 2s_1 + 1, 2s_2 + 1),
\]

\[
B_n^{LR}(h + s_2, s_1, s_2) = B_{2n}(h, 2s_1, 2s_2) + B_{2n}(h, 2s_1 + 1, 2s_2)
+ B_{2n}(h - 1, 2s_1, 2s_2 + 1) + B_{2n}(h - 1, 2s_1 + 1, 2s_2 + 1),
\]

\[
B_n^{RR}(h + s_1 + s_2, s_1, s_2) = B_{2n}(h, 2s_1, 2s_2) + B_{2n}(h - 1, 2s_1 + 1, 2s_2)
+ B_{2n}(h - 1, 2s_1, 2s_2 + 1) + B_{2n}(h - 1, 2s_1 + 1, 2s_2 + 1).
\]

The full back-projection is then the average of back-projections \(B_N\) over all hexadecants in \(\mathcal{H}\),

\[
\left( B_N \hat{A} \right)(i, j) = \frac{1}{16N^3} \sum_{k \in \mathcal{H}} B_n^k \hat{A}.
\]

The computational cost of both operations would be \(O(N^3 \log N)\).

4.3. Inversion of DRT with Conjugate Gradient Method. In order to use the dimensional splitting method to solve PDEs, a method for computing the inverse of a DRT (2.10) is needed. An inversion algorithm using a full multi-grid method appeared in [28]. Here we explore the application of the conjugate gradient method [15] to the least-squares problem

\[
\mathcal{R}_N^T \mathcal{R}_N X = \mathcal{R}_N^T B.
\]

The matrices for the transforms \(\mathcal{R}_N^T\) and \(\mathcal{R}_N\) are never explicitly formed, as we can use the fast algorithm. We conjecture that the computational cost of a DRT inversion is \(O(N^{5/2} \log N)\) for an \(N \times N\) image. Note that this is slightly more costly than \(O(N^2 (\log N)^3)\) that was conjectured for the full multi-grid method [28]. A more careful study of this inversion is of interest on its own right, and will appear elsewhere.

The inversion (4.13) is exact only when \(B\) lies in the range of \(\mathcal{R}_N\). This assumption cannot be satisfied in general once \(B\) is evolved with respect to the dynamics of the transformed variables, as in (2.9). The changes the transformed side and causes the approximation to \(\hat{q}\) to move away from the range of \(\mathcal{R}_N\), and becomes a source of error.

A brute force way to avoid this is to simply prolong the original image \(q\) before the manipulation, and restrict after the back-projection. This enlarges the range of the transform, and allows one to control the inversion error. Fortunately, oversampling is a feasible option, unlike in the tomography context. Therefore \(\mathcal{R}_N\) will be replaced by \(\mathcal{R}_{2pN} \mathcal{P}_{2p}\) where \(\mathcal{P}_p\) is the 0-th order prologation (where the value of each cell in the original grid is assigned to a \(2p \times 2p\) cells in the enlarged grid) and \(\mathcal{R}_N^{2p}\) by \(\mathcal{S}_{2p} \mathcal{R}_N^{2p}\) where \(\mathcal{S}\) is the restriction operator.

5. Conclusion and future work. We have introduced a dimensional splitting method using the intertwining property of the Radon transform. Its applications in solving hyperbolic PDEs, imposing absorbing boundary conditions, and computing displacement interpolations were discussed. For the inversion of DRT the conjugate gradient method was used.
As noted in Section 3.1, the dimensional splitting proposed here used with DRT in 3D (Section 4.2) allows one to impose absorbing boundary conditions for 3D problems without incurring any error of the type (3.3) that appears in 2D. This will be verified in future work. The application of this splitting to fully nonlinear hyperbolic PDEs as discussed in Section 2.3 will be studied as well. The utility of the Radon transform for displacement interpolation (Section 3.2) will be much more compelling when used in conjunction with the fully multi-dimensional transport reversal [31] as a model reduction tool for general hyperbolic PDEs, and work is underway for such an extension.

The number of CG iterations for the inversion (4.13) can be estimated to justify the conjectured $O(N^{5/2} \log N)$ cost for inversion: this and other inversion results will appear elsewhere. While the prologation used in the inversion (Section 4.3) causes expense only of a constant factor, it can be of significant computational cost. Other approaches to reduce the amount of computational effort will be explored. The DRT is essentially a sparse matrix multiplication and is amenable to parallelization, and its performance on graphical processing units (GPUs) will be a future topic of research.

Acknowledgements. The author expresses gratitude to Randall J. LeVeque for carefully reviewing this manuscript. He also thanks Gunther Uhlmann for helpful discussions.
