COVID-19 and human spermatozoa—Potential risks for infertility and sexual transmission?

Robert John Aitken

Abstract

As COVID-19 infections wreak havoc across the globe, attention has rightly been focused on the vital organ systems (lung, kidney and heart) that are vulnerable to viral attack and contribute to the acute pathology associated with this disease. However, we should not lose sight of the fact that COVID-19 will attack any cell type in the body expressing ACE2 - including human spermatozoa. These cells possess the entire repertoire of receptors (AT1R, AT2R, MAS) and ligand processing enzymes (ACE1 and ACE2) needed to support the angiotensin signalling cascade. The latter not only provides COVID-19 with a foothold on the sperm surface but may also promote integration, given the additional presence of a range of proteases (TMPRSS2, TMPRSS11B, TMPRSS12, furin) capable of promoting viral fusion. This article reviews the roles played by these various cellular constituents in maintaining the vitality of human spermatozoa and their competence for fertilization. The reproductive consequences of a viral attack on these systems, in terms of fertility and the risk of sexual transmission, are currently unknown. However, we should be alive to the possibility that there may be reproductive consequences of COVID-19 infection in young males that go beyond their capacity to survive a viral attack.

KEYWORDS

ACE2, COVID-19, male infertility, spermatozoa, TMPRSS2, viral fusion

The COVID-19 (SARS-CoV-2) virus has created a global pandemic responsible for over 500,000 deaths and untold human and economic suffering. Attention has rightly focused on the respiratory system, because this is where a life-and-death battle is waged between the viral horde and the host’s immune system. However, other tissues are also susceptible to viral attack including the kidney, heart, and brain. The purpose of this communication is to highlight the evidence that the male reproductive system, particularly spermatozoa, constitutes another vulnerable target, raising the possibility that COVID-19 might ultimately induce male infertility and/or facilitate the sexual transmission of this virus, depending on the level of infection.

A recent report published in JAMA Network Open revealed that in an analysis of 38 semen samples from COVID-19 patients, 6 (four at the acute stage of infection and, alarmingly, two who were recovering) tested positive for the virus by RT-PCR. Importantly, at this point, we have no idea whether the actual virus was viable and infectious. Nevertheless, the possibility that this coronavirus could have a pathophysiological impact on the testes was suggested by additional data indicating that active COVID-19 infection dramatically reduced the testosterone-to-LH ratio, suggesting a significant impact on the responsiveness of Leydig cells to LH stimulation. In many ways, we should not be surprised by these observations because the blood-testes barrier is known to offer little defense against viral invasion, given the wide range of pathogenic viruses (HIV, hepatitis, mumps, papilloma) that are known to be capable of damaging the testes and rendering the host infertile. Furthermore,
the spike protein that gives the COVID-19 virus its corona is known to target ACE2 (angiotensin-converting enzyme 2), which is highly expressed by several cell types in the testes including Leydig cells, Sertoli cells, and the germ line. As a result of these factors, several opinion pieces have been published already, raising the possibility of testicular damage and infertility consequent to COVID-19 infection. However, if the PI3/AKT pathway becomes compromised, BAD dephosphorylates, is released from its association with 14-3-3, and moves to the mitochondria where it inactivates anti-apoptotic factors and promotes the intrinsic apoptotic cascade. The spike protein on COVID-19 specifically targets ACE2 and in so doing removes an important stimulus for PI3K/AKT, thereby compromising sperm viability. Subsequent to COVID-19 binding, the ectodomain of ACE2 may be removed by ADAM proteases and shed from the sperm surface. Alternatively proteases from the TMPRSS-family, either as intrinsic components of the sperm plasma membrane or delivered by seminal prostasomes, can facilitate fusion between the virus and the sperm surface by cleaving ACE2 and the viral spike proteins (S1 and S2) at the sites indicated by dashed lines, thereby completing the transformation of this cell from procreating gamete to viral vector.

ACE1 is a very ancient protein the appearance of which precedes the evolution of the angiotensin system. As a consequence, functions other than angiotensin processing are likely. Indeed, spermatozoa also express ACE2, which converts angiotensin II to angiotensin (1-7). Reference to the human sperm proteome also indicates that these cells possess the two known receptors for angiotensin II: angiotensin II type-1 receptor (AT1R) and (angiotensin II type-2 receptor) (AT2R). Furthermore, a recent publication has revealed that human spermatozoa also express the angiotensin (1-7) MAS receptor. These cells therefore possess the complete repertoire of ligand-processing enzymes and receptors needed to support angiotensin signaling pathways, raising questions about the physiological roles these pathways play and how they might intersect with COVID-19 (Figure 1).

ACE1 is a very ancient protein the appearance of which precedes the evolution of the angiotensin system. As a consequence, functions other than angiotensin processing are likely. Indeed, spermatozoa are a good example of the multiple roles of ACE1. This enzyme is quite independent of ACE2 (the gene is located on chromosome 17, while ACE2 is transcribed from the X chromosome); however, there is considerable sequence homology (~41%) between these peptidases in terms of their primary amino acid sequences. Notwithstanding such similarities, COVID-19 does not interfere with the functions of ACE1 and, as a result, one of the consequences of infection with this
The importance of ACE2 has recently been highlighted by discovery of the MAS receptor on human spermatozoa.9 This receptor is localized in the principal piece of the sperm tail and the acrosomal domain of the sperm head, in exactly the same place as phosphoinositide 3-kinase (PI3K).23 Activation of the MAS receptor by angiotensin (1-7) leads to PI3K phosphorylation, which in turn leads to the phosphorylation of AKT.25 While AKT is phosphorylated, downstream phosphorylation targets such as the apoptosis regulator, BCL2-associated agonist of cell death (BAD), are also phosphorylated. Phospho-BAD forms a heterodimer with its 14-3-3 keeper protein, leaving Bcl-2 free to inhibit Bax-triggered apoptosis, thereby maintaining spermatozoa a viable motile state (Figure 1). However, if PI3K activity is disrupted, AKT and its downstream targets become dephosphorylated, thereby initiating a truncated apoptotic cascade characterized by rapid motility loss, mitochondrial ROS generation, caspase activation in the cytosol, annexin V binding to the cell surface, cytoplasmic vacuolization and oxidative DNA damage.25 Thus, ACE2 plays an essential role in sperm biology; by stimulating PI3K/AKT phosphorylation, it actively prevents spermatozoa from engaging the intrinsic apoptotic pathway (Figure 1).

The fate of ACE2 following interaction with COVID-19 binding is complex and dependent on cell type. If the cells are capable of endocytosis, then ACE may become internalized within the endocytic vesicle. However, as spermatozoa are generally regarded as non-endocytic, the more likely fate of ACE2 is cleavage (shedding) of its ectodomain through the action of surface proteases such as ADAM17.26,27 This may be a protective strategy because shed ACE2 ectodomain should bind the virus and prevent it gaining access to the cell surface. On the other hand, proteases recruited by the virus to facilitate membrane fusion, notably TMPRSS2 (a type II transmembrane serine protease), can also cleave ACE2 at amino acids 697 to 716, resulting in the shedding of 13 kD ACE2 fragment from the cell surface and facilitating viral entry.28 Cleavage of ACE2 following exposure to COVID-19 would be expected to induce a decrease in sperm viability and function, leading to a loss of fertility. Furthermore, the processing of ACE2 on the surface of human spermatozoa may effectively turn these cells into viral vectors, capable of sexually transmitting COVID-19 to other individuals in the community.

Actual fusion between the virus and human spermatozoa requires the presence of the above-mentioned protease, TMPRSS2, to cleave the viral spike proteins (S) at the S1/S2 boundary or within S2 subunit, thereby removing the structural constraint of S1 on S2 and releasing the internal membrane fusion peptide (Figure 1). This protease is known to be present in prostasomes that are released into seminal fluid from the prostate gland at ejaculation.29 As one of the major functions of these exosome-like structures is to transfer their contents, including proteins, to the spermatozoa following ejaculation, the incorporation of TMPRSS2 from this source seems probable.30 Furthermore, a close examination of the human sperm proteomic databases reveals the presence of related proteases...
TMPRSS11B and TMPRSS12\textsuperscript{7} as well as furin,\textsuperscript{6} in these cells, all of which are thought to serve as activating proteases for viral infection including coronaviruses.\textsuperscript{31-33} The presence of these activating proteases as well as ACE2 in the sperm plasma membrane would be expected to allow the COVID-19 virus to bind to the cell surface and ultimately fuse, either in the testes or during the prolonged sojourn of these cells in the epididymis. In contrast, oocytes appear to be completely devoid of TMPRSS2,\textsuperscript{33} making infection of the female gonad of these cells in the epididymis. In this context, it should be emphasized that spermatozoa have a demonstrable capacity to carry viral infections from the male to the female reproductive tract, as happens during the sexual transmission of the Zika virus, for example.\textsuperscript{34} They also have a proven capacity to fuse with enveloped viruses\textsuperscript{35} and possess reverse transcriptase activity capable of generating proviral DNA,\textsuperscript{36} as is apparently the case for human immunodeficiency virus 1.\textsuperscript{37}

1 | SUMMARY AND FUTURE DIRECTIONS

At present, there have been few opportunities to study the reproductive competence of patients who have recovered from COVID-19 infection. In order to prepare for the moment that we do, there are pieces of information that we should acquire and studies that we should contemplate. At the moment, we do not know the conditions regulating the relative activation of AT1R vs AT2R by angiotensin II in spermatozoa, nor do we fully understand the biological consequences of activating these specific receptors. Given the current availability of AT1R vs AT2R receptor antagonists exhibiting high levels of target specificity, it may be timely to exploit these compounds to gain a deeper understanding of the possible consequences of angiotensin II upregulation consequent to COVID-19 infection at different stages of the spermatozoan’s journey from the seminiferous epithelium to the ejaculate.\textsuperscript{38} We shall also need to assess the extent to which COVID-19 triggers the anticipated release of ACE2 from the sperm surface and whether the loss of this enzyme leads to an increased rate of sperm senescence and cell death. Most importantly, we shall need to investigate the competence of spermatozoa at different stages of epididymal maturation and post-ejaculatory activation, to fuse with this coronavirus and reverse transcribe its genome to create the corresponding DNA. What subsequently happens, when viral RNA and proviral DNA are released into the oocyte at fertilization is a crucial question that will have to be addressed particularly if, as projected, post-COVID-19 patients end up requesting assisted reproductive technology to resolve their infertility problems.

We clearly still have much to learn about COVID-19. Its arrival has been relatively recent and there are still no definitive data to indicate its impact on male fertility or the potential of spermatozoa to serve as vectors for the sexual transmission of this disease. Nevertheless, the evident importance of the renin-angiotensin and TMPRSS-family proteases in sperm cell biology, as well as the clear capacity of these cells to fuse with viruses, suggests that we should at least be open to the possibility.
