Restoration of Albany Subtropical Thicket in South Africa using the plant Portulacaria afra (an ecosystem engineer) has been hampered by selecting sites that are frost prone — this species is rather intolerant of frost. Identifying parts of the landscape that are exposed to frost may be challenging. Our aim is to calibrate an existing cold-air pooling (CAP) model to predict where frost is likely to occur in the valleys along the sub-escarpment lowlands where thicket is dominant. We calibrate this model using two valleys that have been monitored and during frost events. The calibrated model was then used to generate predictions of CAP for a further six valleys across the sub-escarpment lowlands. These predictions were then assessed using a qualitative visual comparison of existing treelines in six valleys — we observe a strong visual match between the predicted frost and frost-free zones with the subtropical thicket (frost-intolerant) and Nama-Karoo shrubland (frost-tolerant) treelines. In addition, we tested the model output using previously established transplant experiments; 300 experimental plots were established across the landscape without consideration of frost events. Here we use a filtered subset of these plots (n=70), and find that net primary production of P. afra was significantly lower in plots that the model predicted to be within the frost zone. We suggest using this calibrated model as part of the site selection process when restoring subtropical thicket in sites that lie within valleys, as it will greatly improve chances of restoration success in these environments.

Abstract

Restoration of Albany Subtropical Thicket in South Africa using the plant *Portulacaria afra* (an ecosystem engineer) has been hampered by selecting sites that are frost prone — this species is rather intolerant of frost. Identifying parts of the landscape that are exposed to frost may be challenging. Our aim is to calibrate an existing cold-air pooling (CAP) model to predict where frost is likely to occur in the valleys along the sub-escarpment lowlands where thicket is dominant. We calibrate this model using two valleys that have been monitored and during frost events. The calibrated model was then used to generate predictions of CAP for a further six valleys across the sub-escarpment lowlands. These predictions were then assessed using a qualitative visual comparison of existing treelines in six valleys — we observe a strong visual match between the predicted frost and frost-free zones with the subtropical thicket (frost-intolerant) and Nama-Karoo shrubland (frost-tolerant) treelines. In addition, we tested the model output using previously established transplant experiments; 300 experimental plots were established across the landscape without consideration of frost events. Here we use a filtered subset of these plots (n=70), and find that net primary production of *P. afra* was significantly lower in plots that the model predicted to be within the frost zone. We suggest using this calibrated model as part of the site selection process when restoring subtropical thicket in sites that lie within valleys, as it will greatly improve chances of restoration success in these environments.

Introduction

Frost can hamper the restoration of plant communities (e.g. Snowcroft and Jeffrey 1999, Snowcroft et al. 2000, Curran et al. 2010; Rorato et al. 2018). In this study, we calibrate a cold-
air pooling (CAP) model to predict where frost may occur in the complex terrain of the sub-
escarpment lowlands of South Africa where Albany Subtropical Thicket is the dominant
vegetation. We argue that mapping frost occurrence is crucial for thicket restoration, which
primarily uses the frost-intolerant succulent shrub, Portulacaria afra (commonly known as
“spekboom”; Fig. 1a).

Exposure to sub-zero temperatures can damage photosynthetic and metabolic activities in plants,
and thereby reduce growth, reproduction, and/or survival (Osmond et al. 1987; Thomashow
1999; Holdo et al. 2006; Körner 2012a; Gusta and Wisniewski 2013). Thus, the distribution of
plant species is commonly influenced by the occurrence of sub-zero temperatures at a variety of
scales, ranging from broad regions to the local landscapes (Rouse 1984; Osmond et al. 1987;
Körner 2012b; Wakeling et al. 2012; Duker et al. 2015a; 2015b; Muller et al. 2016). For
example, alpine treelines — where tall woody vegetation is replaced by shorter shrubland — are
vegetation boundaries driven by decreasing minimum temperatures associated with increasing
elevation.(Körner 2012a). Frost has been suggested to be a driving determinant of treelines
between the Albany Subtropical Thicket and Nama-Karoo biomes (hereafter referred to as
“thicket” and “Karoo shrubland”, respectively) (Duker et al. 2015a; 2015b). The frost-prone,
continentally dry, and high-elevation interior plateau of South Africa is dominated by frost-
tolerant Karoo shrubland vegetation with small patches of thicket vegetation found in frost-free
refugia such as steep slopes and rocky outcrops (Hoare et al. 2006; Mucina et al. 2006. Fig. 1b).

However, this pattern is reversed in the sub-escarpment lowlands, which are lower and warmer
but are prone to cold-air pooling (hereafter CAP; Fig. 1c). These lowlands are topographically
complex due to the Cape Fold Mountains trending from west to east, intersected by rivers
running, roughly, from north to south. In the valleys, the Karoo shrubland only occurs in frost-
exposed valley floor, surrounded by dense thicket in the neighbouring frost-free valley slopes (Duker et al. 2015a; 2015b). Frost occurs on the valley floor due to cold-air pooling (Schulze 2007; Duker et al. 2015a,b). When wind speeds are low or wind is absent, atmospheric buoyancy forces can drive the formation of steep temperature gradients — this is caused by denser cooler air decoupling from the free atmosphere and sinking below relatively more buoyant and warmer air (Goulden et al. 2006; Lundquist et al. 2008; Dobrowski et al. 2009; Smith et al. 2010; Dobrowski 2011). Such CAP in flat and low-lying areas is especially common in regions with complex terrain, where changes in elevation and catchments result in intense frost on valley floors while slopes remain frost-free (Barr and Orgill 1989; Neff and King 1989; Lindkvist et al. 2000; Chung et al. 2006; Bigg et al. 2014). This has led to the exclusion of taller, dense thicket vegetation from valley floors where one would expect it to be dominant on the deeper bottomland soils (Becker et al. 2015); this includes *Portulacaria afra*.

*Portulacaria afra* is an important species in the arid subtypes of the thicket biome, and is considered an ecosystem engineer in this vegetation (van der Vyver et al. 2013). Here, its dense growth form and high levels of litter production enriches the soil and provides shaded, relatively moist microsites for the germination and establishment of woody thicket canopy species (Sigwela et al. 2009; Wilman et al. 2014). This makes arid thicket particularly sensitive to disturbances such as livestock browsing, which selectively removes the highly palatable spekboom from the plant community — i.e. changing the microclimate that is critical for persistence of other plant species. Historically high levels of livestock browsing — primarily by goats or sheep — have removed much of the spekboom in arid thicket. This has resulted in loss of ecosystem functioning and thicket biodiversity (Vlok et al. 2003; Lechmere-Oertel et al. 2005; Lechmere-Oertel et al. 2008b; Sigwela et al. 2009). Subsequent colonization of species from the
neighbouring Karoo shrubland is common (Hoffman and Cowling 1990; Rutherford et al. 2012).

Recently, large-scale initiatives have begun using clonal propagation of spekboom in areas of livestock-degraded thicket, with the aim that this drought-hardy species will facilitate the restoration of thicket ecosystems. A problem is that many areas of degraded thicket are now physiognomically very similar to the Karoo shrubland, and this has meant that some restoration efforts have mistakenly focused on frost-exposed parts of the landscape, specifically valley floors. This significantly reduces survival and growth rates of spekboom (van der Vyver 2018).

Thus, a means to select frost-free sites is required where thicket restoration efforts are being conducted in topographically complex landscapes.

To predict where frost events may occur in the landscape, we calibrated a cold-air pooling model developed by Lundquist et al. (2008) for the subescarpment lowlands of South Africa; this model was developed for high elevations (>1000 m) and latitudes (>37°) in the northern hemisphere. Here we calibrate the model to terrain at lower elevations (generally <1000 m) at lower latitudes (~32-34°) in the southern hemisphere. The CAP model uses a digital elevation model to generate terrain characteristics (slope, relative elevation and curvature), and then threshold values are applied to each of these to classify whether a part of the landscape is prone to CAP. This model has been used to model CAP in other parts of the world (Curtis et al. 2014; Patsiou et al. 2017).

An alternative means to model CAP is to use physics-based modelling that simulates mesoscale and finescale atmosphere flows. However, such high resolution simulations are computationally expensive and need to be adjusted to each location they are applied (Pages et al. 2017).

Furthermore, such modelling is not necessarily superior in CAP prediction as they may not always predict the extent and severity of cold-air drainage (Pages et al. 2017).
We used two adjacent valleys in the southern sub-escarpment lowlands of South Africa that have been well-studied in terms of CAP to calibrate the Lundquist et al. (2008) CAP model. We then tested the calibrated CAP model using two approaches: 1) by visually comparing the model predictions to the thicket–shrubland boundary in six valleys — as stated above, this boundary is similar to an alpine treeline, but inverted with trees above the CAP frost zone; and 2) data from the Thicket-Wide Plot experiment (an extensive transplant experiment conducted across the thicket biome; further details provided in Materials and Methods) to determine if model successfully predicts the decline in *P. afra* growth rates that would be associated with CAP in mountainous areas and related frost occurrence, specifically in valley environments. Note that this model predicts the CAP that occurs in complex terrain only (i.e. it cannot be used to predict CAP in flat terrain).

**Materials & Methods**

**Region**

The terrain of the coastal lowlands is particularly suited for producing CAP due to the characteristic valley morphologies. The west-east trending Cape Folded Belt consists of erosion resistant sandstones that form long parallel ranges with shales and small patches of Dwyka tillite persisting on the lower slopes and valley floors; this gives rise to steep convex slopes with wide flat valley bottoms (similar to the glacially carved U-shaped valleys in the Lundquist et al. 2008 study). The long parallel ranges are each fairly narrow (rarely more than 10 km wide), separated by valleys that range in width (but usually not wider than 30 km). The ranges are cut through by very narrow defiles by rivers flowing from the Great Escarpment to the sea (i.e., roughly from
north to south). The rugged ranges, open valley floors, with valley constrictions through mountains increase the potential for CAP in this landscape.

Our approach, in brief, was to calibrate the CAP model (Lundquist et al. 2008) using two adjacent valleys in the sub-escarpment lowlands where a range of CAP-related data have been collected (e.g. during and after frost events, including temperature, transplant experiments and survival, and field observations; Duker et al. 2015a,b). Next, we tested the model predictions at six different localities — selected from satellite imagery (via Google Earth Pro) — using the visually distinctive treeline between the thicket and Karoo shrubland. Finally, we tested our CAP model by using productivity data of spekboom planted in the biome-wide thicket restoration experiment. We describe each of these steps in detail below.

Cold air pooling model calibration

Two valleys (S33°15’25.00” E25°25’20.10” and S33°15’10.34” E25°24’13.34”; Fig. 2, 3) were used for model calibration and frost-risk mapping. These sites were used because of the availability of five years of temperature data (from July 2012 to October 2017), and many hours of field observations during and after frost events (over 100 days spent on site spread across four consecutive winters from 2013 to 2016). These “calibration valleys” are located in the Zuurberg mountain range in the north-eastern portion of the Cape Fold Mountains. Temperature loggers and field observations have confirmed that radiative frost (0°C at ground level) occurred on valley floors up to fifteen times each winter as a result of CAP on still and clear nights (detailed in Duker et al. 2015a,b).

The first valley (Klipfontein) is ~7.5 km long, ~3 km wide and ~300 m deep, whereas the second valley (Buffels Nek) is ~12 km long, ~2.5 km wide, and ~500 m deep (Fig. 3b,c). The vegetation
patterns in these valleys consist of grassland and fynbos occupying the higher elevation sandstone ridges, and thicket dominating the shale-derived soils on the lower valley slopes, and Karoo shrubland occupying valley floors (which is a combination of shale- and alluvially-derived soils). In these valleys, soil conditions (i.e. particle size, depth, infiltration rate, sodium and electrical conductivity) are consistent across the valley floors and shale-derived sections of the valley slopes (Becker et al. 2015). Nonetheless, Karoo shrubland replaces thicket on the valley floor — this is largely driven by frost (Duker et al. 2015a,b). In these valleys, some of the thicket-shrubland treelines are intact and clearly defined due to historically low levels of livestock pressure (Ian Ritchie, farm manager, pers. comm., 2016); this boundary has become blurred in places as livestock has removed thicket and Karoo shrubland species have invaded. In such cases, frost-intolerant, but browser-tolerant, indicator species (e.g. *Pappea capensis*) were used to identify the position of the treeline.

As outlined in the introduction, radiative frost on the southern African sub-escarpment lowlands predominantly occurs on valley floors and in depressions, and is driven by cold-air pooling. Following the Lundquist et al. (2008) model, and using the ALOS 30 m (Takaku et al. 2014) digital elevation model (DEM), we generated the range of topographic characteristics — slope, height relative to surrounding cells, and curvature — required to identify areas prone to CAP and radiative frost (Fig. 4). Specifically, the Lundquist et al. (2008) model applies thresholds to maps of slope, rank elevation, and curvature and combines these to generate a summary map predicting where CAP should occur. Slope was calculated using the Horn (1981) algorithm in the *raster* package (Hijmans & van Etten 2012; Fig. 4). Rank elevation for each DEM grid cell (i.e., percentile elevation relative to surrounding terrain) was determined by calculating it’s
topographic position within a given radius in the valley landscape — the radius was manually calculated for each valley and is defined as half the distance between the two ridges that define the valley in which the DEM grid cell is situated (Fig. 4). Specifically, we calculated the “rank elevation of each DEM grid cell relative to the elevation of surrounding DEM grid cells within the square with the specified radius in each cardinal direction from the DEM grid cell” (Lundquist et al. 2008, p. 6). Calculating rank elevation in this way places each DEM grid cell within the context of the broader landscape, i.e. valley, rather than the conventional approach that only uses the immediate neighbouring cells for rank calculations.

The broad scale curvature was calculated using the Liston and Elder (2006) snow model formula:

\[
cv = \frac{1}{4r} \left( \frac{Zw + Ze}{2} + Z - \frac{Zn + Zs}{2} \right) + \frac{1}{2\sqrt{2}r} \left( Z - \frac{Zsw + Zne}{2} + Z - \frac{Znw + Zse}{2} \right)
\]

where \( cv \) is the curvature at any particular DEM grid cell, \( Z \) is the elevation of that DEM grid cell, \( r \) is the relevant radius for the landscape under investigation, \( Z_{w/e/n/s} \) is the elevation a distance \( r \) to the west/east/north/south of the DEM grid cell, and \( Z_{sw/ne/nw/se} \) is the elevation a distance \( r \) to the south-west/north-east/north-west/south-east away from the DEM grid cell.

Again, the curvature calculated here does not use the cells immediately surrounding each DEM grid cell, but is a derivative of the specific radius set by the user for the particular valley. Thus, this determines whether a DEM grid cell is on a ridge or within a valley within the broader surrounding landscape (Fig. 4). The curvature and rank elevation calculations used the same user-defined valley radius.

The Lundquist et al. (2008) CAP model was developed in the northern hemisphere (beyond 37°N) — here we are applying this same approach in the southern hemisphere, where continental temperatures are ameliorated by the larger ocean area and in a region that is at least 3° closer to the equator. The model thresholds used by Lundquist et al. (2008) had poor results when applied
to the sub-escarpment coastal plains. Specifically, the model had a high degree of false positives — i.e. it predicted cold-air pooling far upslope beyond the thicket-shrubland tree-line. This is likely because the temperature gradients that form along these southern coastal lowlands are not as steep as those experienced at the high elevation (1000-3000 m) and latitude (37-40° N) study areas of Lundquist et al. (2008). Therefore, we modified the threshold criteria based on observations and data of known frost events in the calibration valleys. Thus, our calibrated thresholds are to predict CAP are i) slope less than 10° (originally: <30° in Lundquist et al. (2008), ii) height relative to surrounding cells less than 30% (i.e. approximately the lower 1/3 of valleys; originally: <50%), and iii) cells with curvature values less than 0 (unchanged). These modifications improved predictions, qualitatively assessed (i.e. a visual match up), of the thicket–shrubland treeline at the two calibration valleys. Most importantly, it was observed that frost only occurred in areas on the bottom of valleys, and in particular those with slope values less than 10° (the uppermost extent of the most extreme frosts). Visual matchups were conducted by generating surface maps of frost risk (a binary no risk or high risk), exporting these as a .kml file (kml package in R; Genolini et al. 2015) to Google Earth Pro, and comparing the CAP predictions with existing vegetation boundaries evident in the imagery (Fig. 5.).

Testing the calibrated CAP model

We used two approaches to test the regionally-adjusted CAP model. First, we assessed its accuracy in predicting the location of frost exposed areas in relation to thicket–shrubland treeline in other valleys. Second, we tested the model predictions for a wide range of valleys against the productivity of the frost-sensitive spekboom cuttings planted in the Thicket-Wide Plot experiment (described below).
Model prediction and treeline comparison

We assessed the model accuracy by visually by comparing the observed thicket-shrubland treeline and predicted CAP boundary in six additional valleys located in sub-escarpment lowlands of the Eastern Cape (Figs. S1-6). In two of these valleys, the treeline was readily apparent (Figs. S1, S2), whilst in the other four valleys the treeline had been disturbed by overbrowsing by domestic-livestock (Fig. S3, S4, S5, S6). In these valleys the historical treeline was identified lay based on the visual persistence of clumps of thicket tree species (usually *Pappea capensis*, *Searsia cf. longispina*). Visual assessment followed the same process as described above (i.e. CAP predictions were exported to Google Earth Pro).

Model prediction and Thicket-Wide Plots

Data from the Thicket-Wide Plot (TWP) experiment were used to test the calibrated CAP model. The TWP experiment was established in 2005 through collaboration amongst numerous stakeholders including: the Subtropical Thicket Restoration Project (STRP), a community of scientists, government departments, and thicket restoration practitioners. The primary aim of the experiment was to inform best-practice restoration protocols. Different planting techniques were tested to determine those that would maximise spekboom cutting survival and growth. Three hundred 50×50 m plots — fenced to exclude indigenous and domestic herbivores — were established in the degraded state of spekboom-rich thicket, mapped as Spekboom Thicket and Spekboomveld by Vlok et al. (2003). These plots spanned a wide variety of climatic and topographic environments (Fig. 2). During the establishment phase of this experiment, the potential of frost as a dominant driver of spekboom growth was not yet fully appreciated, and thus the areas in which plots were established included valley floors— which may be frost-prone.
due to CAP. Thus, plots were positioned in landscapes in a climatically unbiased manner, and
thus offer an opportunity to investigate the effects of frost on thicket restoration success.
In each of the 50×50 m plots, spekboom cuttings of various sizes were planted in different
treatments to identify the most effective methods for maximising survival and net primary
productivity (NPP) and ultimately stimulate thicket restoration (van der Vyver 2018). Here we
use the NPP rates calculated from only one of the treatments (to avoid treatment-related biases)
— specifically, cuttings of 50 cm in length and planted 15 cm deep — as this had the greatest
success rate. In brief, yearly rates of NPP for each plot was calculated through the use of
allometric sampling, where whole spekboom were harvested and their carbon content measured
with conventional methods. Specific details on the calculation of NPP rate are provided in the
Supplementary Information. Of the original 300 plots, only a subset were appropriate for testing
the CAP model. A plot was excluded if: 1) it occurred outside of a valley (where mapping CAP
would be inappropriate), 2) there was evidence of excessive herbivore browsing (by goats, sheep
or Greater kudu) due to a lack of fence maintenance, and 3) it occurred at an elevation >1200 m.
A plot was considered to be outside of a valley if peaks or ridges could not be identified within 8
km of one another. We excluded plots above 1200 m as our CAP model was calibrated for the
sub-escarpment lowlands as we had existing data to conduct the calibration. At higher elevations,
there are steeper temperature gradients and thus another calibration exercise would be required
(with further data collection and field observations required).

Results and Discussion

To the authors’ knowledge, this is the first application of a cold-air pooling (CAP) model in the
southern hemisphere. The predictions of calibrated CAP model successfully matched the thicket-
shrubland treeline in additional testing valleys and the net primary productivity (NPP) was significantly lower for Thicket-Wide Plots found in the predicted CAP zone.

Vegetation boundaries in other valleys in the Eastern Cape

This regionally calibrated model correctly identified the thicket-shrubland treeline at five of the six test valleys (Fig. S1-6). Where valleys were deeper relative to their width, and had a steeper change in gradient from the valley floors to valley slopes (i.e. Fig. S1, S2, S4, S5, S6), the CAP (and thus frost presence) prediction aligned closely with the thicket–shrubland treeline. However, where the valley was shallower (relative to its width, i.e. Fig. S3), the model predicted a larger area covered by the CAP, and thus frost prone area, which extended ~50 m further upslope than the observed treeline between livestock degraded thicket and Karoo shrubland. Nonetheless, in such cases this minor overprediction (false positives) will still assist in landscape restoration planning to avoid planting in frost exposed areas. This predictive mapping of frost-risk (via cold-air pool mapping) may be considered somewhat simplistic as it is based on topographic features alone. Nonetheless, this approach does capture the areas in the landscape that would likely be prone to frost, especially in more mountainous or valley areas such as the Zuurberg mountain range. In addition, physics-based weather modelling has not been shown to have greater accuracy at predicting frost events (e.g. Pages et al. 2017).

In geomorphologically simpler terrain, such as the wide flatland areas found between the Great Escarpment and the Cape Fold Mountains, the CAP model as it is used here (in terms of the thresholds for slope and broad landscape position) would not be suitable for predicting the occurrence of frost. In these areas, where spekboom is locally dominant, weather station data and
field observations would need to be collected to establish the areas within the landscape that frost occurs, and its intensity under different weather conditions.

The Thicket-Wide Plot (TWP) experiment

Of the 70 TWPs selected for the analysis, 30 plots occurred in frost-prone areas and 40 were in frost-free areas. Within this subset, spekboom planted in frost-free areas had significantly higher levels (72.2%) of mean aboveground net primary productivity relative to those situated in the frost-prone areas ($U = 720, p = 0.046$; Fig. 6).

The Great Escarpment versus sub-escarpment coastal plains

The high elevation plateau of Southern Africa is a very different environment to the sub-escarpment coastal plains. The climate in the interior is more continental than that of the coastal plains, with corresponding lower mean and minimum temperatures, and lower rainfall. We have observed that the topographic characteristics associated with frost on the high elevation plateau of South Africa are different to those of the sub-escarpment plains. For example, frost occurs higher up, and on steeper slopes, in the Mountain Zebra National Park of the Eastern Cape than at the calibration valleys in the Zuurberg mountains and in more coastal areas, where it only occurs on very flat ground (RD, pers. obs.). This Park is situated in the Sneeuberg Mountains on the Great Escarpment of South Africa, at much higher elevations (approximately 1100-2000m) and with greater topographic heterogeneity (deeper and wider valleys) and structures (flatter mountaintops) than the calibration valleys in the Zuurberg mountains (400-900m).

Frost in the interior thus seems to have greater intensity on valley floors where minimum temperatures can drop extremely low (< -10°C), occurs much higher up valley slopes, and even occurs on the high elevation plateaux on mountain tops. In this area, the size of frost-free refugia where freezing-intolerant thicket species can survive are thus far smaller and isolated here than
they along the sub-escarpment, where the majority of the landscape is frost-free. Thus, frost characteristics differ substantially between the interior plateau and sub-escarpment lowlands. Thus, the CAP-model thresholds reported here model we used to predict frost occurrence in the sub-escarpment needs region-specific calibration (specifically slope and landscape-level topographic position)

311 Cold-air pooling and climate change

312 CAP is decoupled from regional climate change (Curtis et al. 2014), so it is challenging to predict how CAP-determined treelines will be influenced by warming average temperatures. Thus, the effects of sub-zero temperatures may still affect the distribution of thicket at a regional and elevational scale as fewer frost events occur, but treelines in CAP topography may or may not be affected. This requires monitoring, both in simple and complex terrain. We suspect that thicket treelines will be slow to respond to increasing suitable areas to grow as thicket dynamics are exceptionally slow processes (Cowling et al. 2005, Wilman et al. 2014).

319 Conclusions

320 A basic recalibration of Lundquist et al. (2008) cold-air pooling (CAP) model demonstrates that we can predict which areas are likely to be frost-prone. The reduced rates of aboveground net primary productivity (NPP) in the TWP plots that were situated in frost-prone areas compared to those in frost-free areas is a cause for major concern to restoration practitioners. Thus, we urge that this model should be used to identify no-go areas during the site-selection process for spekboom restoration.

Figure 1

*Portulacaria afra* (spekboom), and the local- and regional treeline of thicket and Karoo shrubland

Fig.1. (A) *Portulacaria afra* (spekboom), (B) the local treeline of thicket and Nama-Karoo shrubland and (C) the broader regional distribution of the Albany Subtropical Thicket and Nama-Karoo shrubland biomes (DEM Takaku et al., 2014; Vegetation Dayaram et al., 2018).
Figure 2

Distribution of CAP model calibration and testing valleys and TWPs in relation to vegetation and elevation

Fig. 2. Digital Elevation Model (DEM; Takaku et al., 2014) of the study region, the occurrence of spekboom dominated thicket (Vlok et al., 2003), calibration and testing valleys, and the locations of each Thicket-Wide Plot (inside and outside CAPs) used in our study. Circles show location of the two calibration valleys. White-filled squares show location of the testing valleys. White-filled triangles show the location of the TWPs that were in CAP-prone areas. Black-filled triangles show the location of the TWPs that were in areas not prone to CAP.
Figure 3

Model calibration valleys in the Zuurberg Mountains

Fig.3. The two frost model-calibration sites (Zuurberg Mountains) in the broader landscape (A) and in demonstrating the thicket-shrubland boundary in both valleys (B: Buffels Nek; C: Klipfontein; source Google, 2019, Maxar Technologies, CNES/Airbus, AfriGIS, Landsat/Copernicus). Red lines indicate the valley diameters used to calculate radii. Grassland and fynbos vegetation is found on hill crests due to a variety of factors. Points indicate the position of temperature loggers in the landscape.
Figure 4

Surface maps of variables used to calculate CAP likelihood

Fig. 4. Maps of (A) elevation., (B) slope, (C) height relative to surroundings, (D) curvature for the Klipfontein valley in the western portion of the Kaboega study site (Takaku et al., 2014).
Figure 5

Results of CAP model at calibration valleys in the Zuurberg Mountains

Fig. 5. The naturally occurring biome boundaries between thicket and Karoo shrubland vegetation closely coincide with predictions of frost occurrence at the two calibration valleys (a: Klipfontein; b: Buffels Nek, source Google, 2020, Landsat/Copernicus, AfriGIS PTY (Ltd) 2019). White lines indicate the position of the boundaries between thicket and karoo vegetation.
Figure 6

Aboveground NPP rates in the frost-exposed and frost-free TWPs

Fig. 6. Differences in plot-level mean aboveground net primary productivity (t.ha\(^{-1}\).yr\(^{-1}\)) of spekboom cuttings in predicted frost-free and frost-prone areas in the 70 plots in the Thicket-Wide Plot (TWP) experiment (see the Supplementary Information for more details). Significant differences (\(\alpha=0.05\)) were determined using Mann-Whitney U-tests.
