ABSTRACT

INTRODUCTION: De Garengeot hernia is a rare type of femoral hernia, defined as a sac containing a veriform appendix. Due to its rare occurrence the information available on diagnosis and management is scarce. We report the use of a recently described technique for femoral hernia repair and appendicectomy.

PRESENTATION OF CASE: A 67 year old female presented to the emergency department with features of incarcerated femoral hernia. CT imaging revealed an incarcerated appendix within a femoral hernia. The patient subsequently underwent surgery, where the femoral hernia was repaired and appendicectomy performed concurrently.

DISCUSSION: Clinical diagnosis is difficult, and there have only been a few documented cases of pre-operative CT diagnoses in the literature. The usual risk factors for developing a hernia would apply to this pathology, and other anatomical and embryological considerations are explored. The King’s College technique for femoral hernia repair involves an incision that allows repair of the hernia and also the ability to enter the peritoneal cavity using the same incision. This approach was used in this case, where the abdominal cavity had to be entered to perform the appendicectomy, before the femoral hernia could be repaired.

CONCLUSION: Pre-operative diagnosis of De Garengeot hernia is difficult, as it may mimic an incarcerated femoral hernia containing other contents. The diagnosis becomes apparent intra-operatively. The clinical significance lies in that intra-abdominal access may be required to safely perform an appendicectomy before the repair of the hernia defect, and this article includes a description of a suitable technique for this particular pathology.

1. Introduction

A femoral hernia is defined as a sac which projects through the femoral canal, and presents clinically as a groin hernia below and lateral to the pubic tubercle, or a finger breadth medial to the femoral artery below the inguinal ligament [1]. Femoral hernias are relatively uncommon, and have a high risk of strangulation [1,2]. This article presents a rare case of appendicitis within a De Garengeot hernia, which is described as an appendix which has migrated within the femoral hernia sac [3]. There has been fewer than 100 cases reported in the literature [2–4]. Pre-operative diagnosis of De Garengeot hernia is very difficult due to its rare occurrence, non-specific history and clinical findings, and a paucity of data on the utility of diagnostic imaging [5].

Due to its rare occurrence and lack of published guidelines on standard management [3], this report attempts to add further insight into the disease entity, and highlights the use of a recently described surgical technique which has not previously been employed for use in repair of this hernia. Also included in this report is a descriptive computed tomography (CT) finding of femoral hernia appendicitis, which is one of very few cases to be reported in the literature with a pre-operative CT diagnosis.

2. Case presentation

A 67 year old female presented to the emergency department with a 1 day history of increasing pain in a pre-existing lump in the right groin. This lump became apparent to the patient 4 days before the onset of pain. She describes having an upper respiratory tract infection for 2 weeks prior, and the persistence of a cough led to the development of this groin lump. There was no history of nausea or vomiting. She had regular bowel motions and was passing flatus. No other significant medical history or surgery in the past. On examination there were no documented fevers, and she was haemodynamically stable. Her abdomen was non-tender, soft and without distention. Below the inguinal ligament, identified by pal-

De Garengeot hernia is defined as a femoral hernia which contains a vermiform appendix. It was first described in 1731 by a Parisian surgeon Rene Jacques Croissant De Garengeot [7]. This entity is extremely rare—reported incidence ranges from 0.8 to 1.0%, with the finding of appendicitis even rarer still, at 0.08–0.5% of all femoral herniae [3]. There has been fewer than 100 cases reported [2–4]. It must be distinguished from Amyand hernia, which is the presence of an appendix within an inguinal hernia, and is reportedly more common than a De Garengeot hernia [3,5].

The importance of femoral hernias lies in the high strangulation risk, which is estimated to be 20% at 3 months and 45% at 21 months. This is in contrast to inguinal hernias, which have a risk of strangulation of 3% at 3 months, with a modest increase to 4.5% at 21 months [1]. This increased risk is thought to be due to the narrow and rigid ring attributed by the nature of the anatomy of the femoral canal [2]. A study examining a national hernia register in Sweden found that an emergency femoral hernia operation was associated with a 10 times increase in risk of mortality, with 63% of cases occurring in women [8].

3.2. Pathophysiology

There is a predisposition for postmenopausal females, being four times more common than males [3,5], reflecting the higher incidence of femoral hernias in females [1]. Contributing factors are thought to be secondary to pregnancy related changes, as well as general factors that increase risk of hernia formation such as increased intra-abdominal pressure, smoking, connective tissue disorders, and older age [3,5]. There have been several theories proposed to the pathogenesis of the migration of appendix into a femoral hernia. One hypothesis is the presence of a large or overriding caecum within the pelvis may push the appendix onto the femoral ring [5,9]. Another thought is that variable anatomic rotation of bowel during development may also play a role [5,10,11], as well as a variably mobile caecum which may also predispose to migration of appendix into the femoral canal [5,9].

Appendicitis may have arisen from intraluminal obstruction caused by the tight neck of the hernia that caused external compression of the appendix, with eventual strangulation and inflammation [12]. This is supported by the fact that the patient had a symptomatic lump for 4 days before the onset of pain. However, not all De Garengeot hernia will have appendicitis [5], and it is unclear whether the true mechanism always occurs from external compression, or can also arise from intraluminal obstruction, as in cases of wider hernia necks [3,13].

3.3. Clinical features and diagnosis

The pre-operative diagnosis of De Garengeot hernia is very difficult, due to non-specific clinical findings and lack of comprehensive published data on diagnostic imaging. A recent article reviewing the literature found that most patients had a non-specific painful lump
that was tender to palpation with or without sepsis. The clinical picture is generally indistinguishable from that of an incarcerated femoral or inguinal hernia, and features of bowel obstruction have also been reported [3,5,10]. The nature of the anatomy of the femoral canal limits the spread of intra-peritoneal infection, and patients are more likely to present with local signs of tenderness and erythema rather than general intra-abdominal signs of peritonitis [13,14]. Documentation of acute appendicitis within a femoral hernia by CT is also extremely rare. There has only been 4 other reported cases of CT detected appendicitis within a femoral hernia [2,5]. In this case, the patient’s primary care physician had organised a CT to further investigate the lump, which revealed the presence of a tubular structure within the femoral hernia sac in continuity with a low-lying caecum, associated with fat-stranding surrounding the portion of appendix within the hernia. Ultrasound scans have also been utilised in several cases, however there has only been one documented case of a positive ultrasound diagnosis, found as a tubular blind-ending structure adjacent to the femoral vein [5,15].

Complications of untreated symptomatic De Garengoet hernia may lead to necrosis of hernia contents with perforation and sepsis or abscess formation [13], development of bowel obstruction [10], and even necrotising fasciitis [5,16]. In the case of a misdiagnosed De Garengoet hernia as an abscess and subsequent surgical drainage, an appendico-cutaneous fistula formation has been reported in the literature, which after persisting for a further 2 years eventually required a definitive excision of fistula tract, appendicectomy and femoral hernia repair [13]. These complications highlight the perils of misdiagnosis leading to inappropriate or delayed management. Surgical repair of the femoral hernia and appendicectomy has been the mainstay of management in the reported literature. There is no standardised method of surgical management of this rare condition, with various approaches being described [5]. It has been recommended by some authors that surgical approach should be based on clinical judgement and the condition of the patient [17].

3.4. Surgical management

Surgery is the mainstay of treatment of an acutely presenting femoral hernia. Lockwood’s infra-inguinal, Lotheissen’s trans-inguinal, and McEvedy’s high incisions are the classically taught surgical approaches [6]. Sorelli et al. proposed a technique which utilises a single skin incision to allow all the previously described approaches to the hernia sac, as well as gain entry into peritoneum [6]. As they have described, in this case the author made the incision 1 cm above the medial half of the ligament. Dissection was carried down to the external oblique aponeurosis and creation of superior and inferior flaps made possible adequate views to differentiate between inguinal and femoral hernia. A femoral hernia sac was identified, and within it contained a strangulated and inflamed appendix. The base of the appendix could not be accessed safely through the hernia orifice, so peritoneal entry was gained by creating a plane just superficial to the external oblique. The linea semilunaris is then divided lateral to the rectus, 4 cm above the inguinal ligament in order to allow preservation of the inguinal canal. This allowed exposure of the rectus muscle, which is retracted medially, and the transversalis fascia and peritoneum incised to gain entry into the peritoneum. Appendicectomy was performed in routine fashion, and the hernia orifice closed with 2–0 prolene sutures.

The advantage of the King’s College approach is that both femoral and inguinal hernias can be repaired, and the abdominal cavity also accessed all via the same single incision. Access to peritoneal cavity is of particular importance in cases of strangulated small bowel, and in this case, an incarcerated appendix which appendicectomy had not been possible without entering the abdominal cavity. Previously described case reports had similar problems with inaccessible base of appendix, and some authors have opted to make a second Lanz incision to perform the appendicectomy [3] or laparotomy [14]. In a previous review, most surgeons opted for the inguinal approach, some converted from laparoscopic to standard oblique inguinal, and another case describes repair by the McEvedy approach [5].

The proponents of the King’s College method report that their technique will minimise the pre-operative debate on choosing the best approach to femoral hernias in general and hope to achieve a standard [6]. Indeed this case is the first report to the Author’s knowledge to describe a successful repair of an incarcerated femoral hernia containing an appendix, gaining access into the peritoneum and performing an appendicectomy at the same time using this particular surgical approach.

4. Conclusion

De Garengoet hernia is a rare type of femoral hernia. Misdiagnosis leading to inappropriate or delayed treatment has resulted in some serious complications. This type of hernia typically presents in post-menopausal females. There have been various methods of repair described, however there is no standard recommended surgical repair for this condition. Pre-operative diagnosis is extremely difficult, and the cause usually becomes apparent intra-operatively. Given the rarity of this condition, De Garengoet hernia may not be readily suspected as a pre-operative diagnosis in a patient presenting with a tender groin lump. The clinical significance lies in that intra-abdominal access may be required to safely perform an appendicectomy before the repair of the hernia defect. This article aims to highlight the presentation of a patient with a femoral hernia appendicitis, to improve awareness of this entity, and to describe one method of repair should one encounter this pathology.
